Load-bearing enabling role under #disc-identifiability-floor Instance 3. The composition-layer identifiability-floor instance establishes a no-go: composite contraction $\kappa_c > 0$ is not in general certifiable from component-level data alone — the coupling-sign bit distinguishing cooperative from adversarial regimes is unidentifiable from component marginals. Four structural escapes are available (observable coupling topology; matched Tier at composite level; passivity certificate; common contraction metric). Scope-satisfaction via at least one of (C-i)–(C-iv) in this segment is the **enabling condition** for any of these escapes: without scope-satisfaction, the “composite” is ill-defined (O_c does

not exist under (C-i)–(C-iii); equilibrium structure $\mathcal{E}$ does not exist under (C-iv); R_c is ill-typed), and the escapes have no coherent target to certify. The scope condition is therefore load-bearing apparatus that the composition-layer floor depends on — scope-satisfaction is what distinguishes a composite whose contraction or equilibrium convergence can be certified (under some escape) from a multi-agent system whose “composite contraction” is not a well-defined object.

How composites come into being: symbiogenesis. The formal mechanism by which a group passes from failing all three routes to satisfying at least one is described in 12.3. Briefly: in biological and social symbiogenesis, a host integrates an endosymbiont; the endosymbiont’s objective is subsumed into the host’s; the combined entity’s objective O_c emerges where two independent objectives stood. After the transition, (C-ii) applies: the endosymbiont’s objective is a sub-objective of O_c . This is the dynamical process of composite-agent identity creation; the scope condition here describes its result.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- **Whether a common scalar exists across the alignment routes (resolved 2026-05-21 — negatively).** The current form treats the three alignment routes (C-i)–(C-iii) as a disjunction of qualitatively distinct conditions rather than as instances of a unified threshold; the strategic-equilibrium route (C-iv) is structurally distinct from all three. The 2026-05-21 strategic-composition spike at spikes/strategic-composition-class-3-attempt-2026-05-21/ resolved this open question in the *negative*: the four scope routes correspond to *regime-tier entry conditions on the dynamic-regime axis* per #disc-dynamic-regime-axis, not to a continuous scalar threshold. Specifically: (C-i)–(C-iii) enter R0 contraction-regime; (C-iv) with potential/monotone game-structure enters R1 equilibrium-regime; (C-iv) without potential/monotone structure enters R2 cyclic-distributional-regime; population-scope limit enters R3 mean-field-equilibrium-regime. The disjunction is structurally appropriate because the regimes themselves are structurally distinct (different fixed-point structures, different Lyapunov-certificate types, different macro-state types per the #disc-dynamic-regime-axis §”Identity” structural-identity for finite N). A unifying scalar across all four would mean a continuous reduction of categorically-distinct regime classes — which the regime-axis treatment shows is not the right organizing structure. U_O remains a quality metric for (C-i) within R0, not a unifying threshold across the routes.
- **Asymmetric unity.** Routes (C-i) and (C-ii) implicitly assume symmetric alignment (sub-agents equally represented in O_c). Symbiogenesis, firm acquisitions, and hierarchical delegation all feature *asymmetric* unity (host dominates; endosymbiont subordinate). The scope condition should accommodate asymmetric alignment; the current (C-ii) hierarchical form partially covers it, but an explicit treatment of role-asymmetric composites is open.
- **Interaction with Class 3 (Coupled) architectures.** 6.3’s architectural classification (Class 1 Separated, Class 2 Partial, Class 3 Coupled) applies to individual agents. Composites of Class 3 (Coupled) agents — e.g., multi-LLM systems — may satisfy this scope condition via shared training rather than shared explicit objective. Whether (C-i)–(C-iii) cover this adequately, or whether a fourth route for implicit alignment is needed, is open.
- **Transitivity.** If A_1, A_2 align and A_2, A_3 align, do A_1, A_3 ? Probably yes via (C-ii) if there is a common parent; not necessarily via (C-i) without a shared objective. Transitivity would make composite formation more robust; non-transitivity would explain why coalition-building requires explicit alignment work.
- **Promotion dependencies.** Before claims-verified: the common-scalar question (first bullet) is now resolved negatively (the scope routes correspond to dynamic-regime entry conditions, not to a unifying scalar — see #disc-dynamic-regime-axis); the remaining dependency is to audit whether any existing Part III segment implicitly assumes this scope without naming it (likely yes for team-persistence, tempo-composition, closure-based results) and update each to reference 12.2 for scope-satisfaction explicitly, including whether they apply to (C-i)–(C-iii), to (C-iv), or to both. Per the regime-axis treatment, (C-i)–(C-iii) $\rightarrow$ R0 / (C-iv) $\rightarrow$ R1 or R2 / population-scope $\rightarrow$ R3 — segments can now name their applicable regime directly.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere — see report flags). **Coverage:** four dirs reached a digested reflection here (193847, 526815, 773921, 849201) plus the §III composition-foundations batch (471203); 829314 skipped this segment. This was a high-engagement segment — the four-route disjunction and the C-iv strategic-composite move drew rich ideation. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **The “Why are we working together?” four-route taxonomy** — the standout plain-language gloss, converged on by two substrates: (C-i) shared objective = “because we want the same thing” (cult / startup); (C-ii) hierarchical derivation = “because the boss told us to” (corporation / military); (C-iii) mutual benefit = “because it’s profitable for both of us right now” (market transaction); (C-iv) strategic equilibrium = “because we are trapped in a Mexican standoff” (Cold War) (Gemini, AUDIT-WORKING-193847; the same four-domain mapping — team / corporation / trade network / stable ecosystem — at Claude, AUDIT-WORKING-773921 and Claude, AUDIT-WORKING-849201). A strong Brief-field seed for the segment.
- The scope condition as “the *legal boundary* for when we are mathematically permitted to zoom out and treat a group of agents as a single macro-agent” (Claude, AUDIT-WORKING-849201) — a compact framing of what the segment buys.
- The disjunctive-not-scalar form repeatedly praised as “an act of deep epistemic honesty” / “extreme mathematical maturity” — refusing to collapse qualitatively distinct organization types “into a single number” prevents the fallacy of composition (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-849201). Worth preserving as the anchor framing for *why* the disjunction is right.

2. Candidate Discussion.

- **C-iv as the formal boundary of “emergence.”** Stated sharply: “emergence is when a system satisfies (C-iv) and therefore can be modeled as a single macro-agent” — the scope condition converts an informal philosophical word into a checkable condition (Claude, AUDIT-WORKING-773921). A candidate Discussion sharpening of what C-iv contributes beyond game theory.
- **The non-teleological-composite point, made concrete.** “Do not assume a composite agent has a single, conscious mind or a single explicit objective O_c .” A free market of trading partners (C-iii) or a stable predator-prey ecosystem (C-iv) is formally a composite agent because its macro-dynamics are bounded and predictable, “even though no individual sub-agent holds the macro-objective” (Claude, AUDIT-WORKING-773921). Candidate Discussion guard against over-reading “agent.”
- **Symbiogenesis as the blueprint for safely building large composites** (aspirational, but with a structural spine). “You cannot safely build a monolithic super-intelligence from scratch (it hits the $\alpha > \rho/R$ wall because its R is too large to maintain high α). You must build it symbiotically” — start from a crèche of small bounded agents interacting via (C-iii) mutual benefit, then solidify into a (C-ii) hierarchy as protocols stabilize (Gemini, AUDIT-WORKING-193847). The structural claim (large R defeats high α , so composition is the route) is real; the application is reach — see Belongs-elsewhere. (*Avoid the “super-intelligence” vocabulary if promoted — canon prefers “future AI.”*)

3. Follow-up items.

- **Asymmetric / role-asymmetric composites under-modeled.** Symbiogenesis, firm acquisitions, and hierarchical delegation are *asymmetric* (host dictates O_c ; endosymbiont subordinate); the current (C-ii) only partially covers this, and explicit host-parasite power-dynamics modeling is “fertile ground for expansion” (Claude, AUDIT-WORKING-773921). Converges with the segment’s existing “Asymmetric unity” Working Note.
- **Transitivity failure as a structural explanation of coalition fragility.** If A_1 aligns with A_2 and A_2 with A_3 , alignment is non-transitive under the (C-iii) mutual-benefit route (a shared *parent* via (C-ii) would give transitivity; mutual benefit alone does not). “This mathematically explains why broad political coalitions are so fragile: they rely on non-transitive pairwise alignments” (Gemini, AUDIT-WORKING-193847). A candidate sharpening of the segment’s existing “Transitivity” Working Note into a stated consequence.

4. Readers often ask / wonder.

- “Does symbiogenesis happen via parametric learning or a structural snap?” A natural reader question once composition is defined — slow weight-alignment vs a sudden topological transition (Claude, AUDIT-WORKING-849201). The next segment (12.3) and its weighted-Lyapunov $\mu \rightarrow 0$ sketch begin to answer this; surface the pointer.
- “Is a strategic composite (e.g. the Cold War) really one agent?” Converged reader stumble on C-iv (see the parallel note under 12.1); the answer is the equilibrium-relative macro-state, worth preempting at first encounter.

5. Candidate figures.

- **Gate-into-four-routes diagram with a split output.** Multi-agent scope as a gate opening onto four routes, with the output deliberately split: C-i through C-iii yield an *objective-based* composite (shared O_c); C-iv yields an *equilibrium-based* strategic composite (shared $\mathcal{E}$, no O_c). The two target types kept visually separate because downstream machinery must know which object it computes over (Codex/Claude, AUDIT-WORKING-526815, “diagram attempt”).

Belongs elsewhere.

- **04-eli-core / consciousness-infrastructure — the crèche-to-hierarchy developmental path.** The symbiogenic-construction reading (“provide the stable environment where N independent agents can slowly fuse into one composite agent without collapsing into a non-convergent adversarial regime during the transition”) is a developmental blueprint pointing at the crèche / nursery material in 04-eli-core/, not at this scope segment (Gemini, AUDIT-WORKING-193847). Converges with the cost-shadow nursery reading lifted into 4.5.
- **Prior-art mapping — Miller (2022) IAM.** The (C-iii) mutual-benefit route maps onto Miller’s IAM (Interaction, Agency, Mutual benefit) social-behavior definition; flagged as bridging Agent-Based Modeling with Control Theory (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-849201). A prior-art/Discussion-citation pointer rather than gold per se — the segment already references Miller; this is a convergence signal that the mapping reads as natural to fresh readers.

12.3 Hypothesis: Symbiogenic Composition

Symbiogenesis is an asymmetric composition mechanism in which one agent (the *host*) integrates another (the *endosymbiont*) as a specialized sub-component, with the endosymbiont’s objective gradually subsumed into the host’s. It is distinct from peer coupling (13.1) and from population-level restructuring (the extreme transition motif drawn from Miller 2022, discussed in 4.8): symbiogenesis is how composite agents *come into existence* by crossing the 12.2 from below. The mechanism is well-attested empirically (eukaryote formation, firm mergers, legal-precedent adoption, language families) but formally underspecified within AAT. This segment captures the phenomenon and flags the specific formalization gaps.

Formal Expression.

Given two purposeful agents A_h (host) and A_e (endosymbiont), each satisfying 1.6, symbiogenic composition is a process on the joint state space with three coupled dynamics:

Hypothesis (symbiogenic-composition).

(S-1) Objective absorption. The endosymbiont’s objective O_e transforms toward alignment with or derivation from the host’s objective O_h :

$$O_e(\tau) \xrightarrow{\tau \rightarrow \tau_{\text{consolidated}}} \mathcal{D}_e(O_h) \quad (12.7)$$

where $\mathcal{D}_e$ is a derivation functional (in the sense of route (C-ii) in 12.2): O_e becomes a sub-objective derived from O_h . Before: O_h and O_e are independent objectives, no route of 12.2 applies, and the pair is a multi-agent system (12.1) rather than a composite. After: O_e is a role within O_h ; route (C-ii) applies; the composite (A_h, A_e) satisfies the composition scope condition.

(S-2) Function transfer. Structural content from the endosymbiont's state (elements of M_e or Σ_e) transfers to or becomes accessible by the host:

$$\{M_h, \Sigma_h\}(\tau) \xrightarrow{\tau \rightarrow \tau_{\text{consolidated}}} \{M_h, \Sigma_h\} \cup \mathcal{F}(M_e, \Sigma_e) \quad (12.8)$$

where $\mathcal{F}$ is a transfer mapping (structure-preserving integration of endosymbiont functions into host state). In biological symbiogenesis: gene transfer. In organizational symbiogenesis: acquired firm's processes, patents, know-how integrated into acquirer's operations. This is the grafting operation of 9.7 in its cross-agent form — the host grafts structure originating in the endosymbiont.

(S-3) Autonomy reduction. The endosymbiont's effective action space contracts; many of its choices become fixed by the host's coordination:

$$\mathcal{A}_e^{\text{effective}}(\tau) \xrightarrow{\tau \rightarrow \tau_{\text{consolidated}}} \mathcal{A}_e^{\text{restricted}} \subsetneq \mathcal{A}_e^{\text{initial}} \quad (12.9)$$

The endosymbiont retains enough autonomy to avoid catastrophic transfers (e.g., mitochondria retain some genome to handle local fast-timescale responses that would be hazardous to route through the host nucleus) but loses most independent decision-making.

Integrated transition. At consolidation, the joint system is a single composite agent A_c whose substate contains the integrated structure:

$$X_c = (M_c, G_c) = (M_h \cup \mathcal{F}(M_e, \Sigma_e), (O_c, \Sigma_c)) \quad \text{with } O_c \approx O_h \quad (12.10)$$

The endosymbiont persists as a specialized sub-component of the host, not as an independent agent. The 12.2 is now satisfied; the peer-coupling machinery of 13.1 applies to the resulting composite.

Epistemic Status.

Robust qualitative. Max attainable: *robust qualitative* — the phenomenon is well-attested empirically across biological and social domains, but a general mathematical formalization within AAT is open.

What is well-established (externally):

- The existence of symbiogenesis as a distinct evolutionary mechanism (Mereschkowsky 1905, 1910; Sagan 1967; Margulis & Sagan 1997). Mitochondria and chloroplasts are the paradigm cases.
- The social analog in firms, technology, language, legal systems, religions (Miller 2022, Appendix B).
- “Innovation by parts” as qualitatively different from “innovation by sparks” (gradual mutation) — Miller's framing.

What is *not* derived within AAT:

- A formal model of the objective-transfer dynamics (S-1). What evolutionary or optimization process drives $O_e \rightarrow \mathcal{D}_e(O_h)$?

- A formal specification of the transfer functional $\mathcal{F}$ in (S-2). What structure is preserved, what is lost, what is transformed?
- A precise characterization of autonomy reduction (S-3). Why does the endosymbiont retain some autonomy rather than becoming fully deterministic?
- Quantitative predictions — e.g., when symbiogenesis is favored over peer coupling, what governs the timescale of consolidation, under what conditions it reverses.

The three dynamics (S-1), (S-2), (S-3) are proposed schemas, not results. A follow-up development of an AAT-specific dynamical model is the natural next step.

Discussion.

The role of this mechanism in Part III. Three distinct composition mechanisms are now in scope:

1. **Peer coupling** (13.1, 15.1, 13.2) — sub-agents interact through shared environment; closure defect measures faithfulness of projection. Presumes scope-satisfaction via at least one route of 12.2 (not a scalar U_O threshold).
2. **Extreme transition motif** (Miller 2022; introduced in 4.8; pending dedicated segments for composition-transition dynamics, latent structural diversity, and endogenous coupling) — population-level restructuring via neutral drift / niche creation / cascading displacement. U_O shifts across a population as agent types replace one another.
3. **Symbiogenesis** (this segment) — hierarchical absorption. U_O crosses the composition scope condition from below, creating a composite that did not previously exist.

Before symbiogenesis, the sub-agents were a multi-agent system (12.1) but not a composite. After, the resulting composite is subject to all of AAT's composition machinery. The symbiogenic transition is the specific dynamical process of composite-agent identity creation.

Why this cannot be modeled as peer coupling. Peer coupling assumes pre-existing sub-agents being projected into a macro-description. The closure-defect framework presupposes the composite exists; it measures how faithfully the macro tracks the micro. Symbiogenesis is about a composite *coming into being* from two previously-independent agents. No projection Λ of the pre-symbiogenic system yields the post-symbiogenic composite, because the endosymbiont's objective *changes* during the process — its objective is different before and after. The transformation is intrinsic to the sub-agents' state, not an external projection choice.

Why this cannot be modeled as extreme transition. The extreme transition motif operates at the population level with many agents, neutral drift of types, and niche-construction dynamics. Symbiogenesis is typically between two specific agents (or a small number) and proceeds through a specific asymmetric integration rather than through statistical population dynamics. The mechanisms overlap — symbiogenesis often occurs as part of a larger transition — but the core mechanism of symbiogenesis (bilateral asymmetric integration) is distinct from the population-level dynamics of extreme transitions.

Examples across domains.

Table 12.1

<i>Domain</i>	<i>Host</i>	<i>Endosymbiont</i>	<i>Integrated composite</i>
Biology	Archaeal host cell	α -proteobacterium	Eukaryotic cell (mitochondrion persists as organelle)
Biology	Eukaryotic cell	Cyanobacterium	Plant cell (chloroplast persists as organelle)
Commerce	Acquiring firm	Acquired firm	Merged firm (acquired operates as division)

<i>Domain</i>	<i>Host</i>	<i>Endosymbiont</i>	<i>Integrated composite</i>
Technology	Base platform	Integrated component	Composite product (component operates within host system)
Linguistics	Host language	Adopted vocabulary/grammar	Creolized / evolved language
Law	Legal system	Adopted precedent	Evolved jurisprudence (precedent operates as doctrine)
Religion	Host tradition	Absorbed elements	Syncretic practice

In each case: asymmetric integration, autonomy reduction of the absorbed entity, gradual objective subsumption, functional specialization.

Connection to 9.7. The single-agent “grafting” operation in 9.7 is within-agent — an agent incorporates external structure into its own Σ_t . Symbiogenesis is cross-agent — the grafted structure originates in another agent, and the integration is accompanied by that other agent’s objective being absorbed. These are related but distinct: grafting is the structural-change mechanism on the host side; symbiogenesis is the bilateral process that includes grafting plus objective-absorption plus autonomy reduction.

Rate-distortion interpretation (connecting to 14.1). Under the Information Bottleneck conjecture in 14.1, peer coupling is IB compression with the relevance variable defined by a shared composite objective. Symbiogenesis is the process by which the relevance variable itself shifts: from two separate IB problems (each sub-agent’s own survival objective) to a single IB problem (the composite’s survival objective). The symbiogenic transition creates the shared relevance variable, which in turn makes the IB frontier well-defined for the composite. This is a structural shift in the IB problem, not a compression along a fixed IB frontier.

Working Notes.

- **Objective-transfer dynamics (S-1).** The most load-bearing open formalization. What process drives $O_e \rightarrow \mathcal{D}_e(O_h)$? Candidates: evolutionary selection (endosymbionts whose objectives align with host survival are selected for, since the alternative is extinction); bounded-rationality constraint (coordinating two divergent objectives exceeds the endosymbiont’s capacity, forcing simplification); explicit design (firm mergers where acquired objectives are deliberately restructured). Each gives a different dynamical equation.
- **Function transfer $\mathcal{F}$ (S-2).** Needs to respect the structure of the host’s M_h and Σ_h . In biology, gene transfer preserves molecular functions but changes regulatory context. In social analogs, the analog is: functions are preserved, but their triggers and dependencies change. A general specification is open.
- **Autonomy reduction (S-3).** Why not complete? The endosymbiont retains some autonomy because complete integration would eliminate the fast local response capacity that made symbiogenesis advantageous in the first place. A cost-benefit analysis on autonomy retention (in the style of 9.9) would make this quantitative.
- **(S-3) as weighted-Lyapunov limit (sketch-level).** J’s asymmetric limit $\alpha_2 \rightarrow 0$ under weighted Lyapunov $V_\mu(\xi) = \frac{1}{2}(\|\delta_1\|^2 + \mu\|\delta_2\|^2)$ with $\mu \rightarrow 0$ formalizes (S-3): the endosymbiont’s autonomous correction dynamics are weighted out of the joint stability argument, leaving the host’s sector condition as the composite’s persistence condition. This is a smooth deformation of the peer-coupling (CM4) inequality, not a discontinuous regime change — symbiogenesis and peer coupling are parameter-limits of the same weighted-Lyapunov analysis. The sketch is promotable to derived once (S-2) function transfer is formalized in this segment (the weighted Lyapunov limit does not address what happens to M_h when structure from M_e is inherited).
- **Reverse symbiogenesis.** Endosymbionts occasionally regain autonomy (biological examples: some organelle-hosted genes return to the nucleus; organizational examples: acquired divisions spun off). Theoretically: the scope condition can be crossed in either direction. A composite that loses U_O dissolves back into a multi-agent system. The triggering conditions and typical dynamics are open.

- **Interaction with logogenic agents.** In LLM-based agent architectures, multiple models can compose through shared training or through interface-specified protocols. Whether this constitutes symbiogenesis (with one model dominating) or peer coupling depends on whether the component models retain independent objectives. Worth investigating in 03-llm-core/.
- **Quantitative predictions.** When is symbiogenesis favored over peer coupling? Hypothesis: when the coordination overhead C_{coord} between would-be peer-coupled agents exceeds the integration cost of symbiogenesis. Transaction-cost theory (Coase / Williamson) is the economic analog. The AAT version would connect C_{coord} (13.2) to the energetic or informational cost of maintaining separate objectives, with symbiogenesis favored when the latter exceeds the former.
- **Timescale of consolidation.** In biology, symbiogenesis takes evolutionary time (millions of years). In firms, months to years. In software/ideas, potentially much faster. The consolidation timescale $\tau_{\text{consolidated}}$ is domain-dependent; a general characterization is open.
- **Saddle-node bifurcation analysis — quantitative threshold form, conditional on a nonlinear coordination penalty.** Under the *hypothesis* that aggregate multi-agent mismatch δ obeys $\dot{\delta} = \rho_{\text{env}} - \alpha_{\text{auto}}\delta + k\delta^2$ with a nonlinear coordination penalty $+k\delta^2$ ($k > 0$) capturing compounding coordination failure between misaligned autonomous sub-agents, the steady-state fixed points $\delta^* = (\alpha_{\text{auto}} \pm \sqrt{\alpha_{\text{auto}}^2 - 4k\rho_{\text{env}}})/(2k)$ exist only for $\rho_{\text{env}} \leq \rho_c := \alpha_{\text{auto}}^2/(4k)$. Above ρ_c the two fixed points collide in a *saddle-node bifurcation* and disappear: $\dot{\delta} > 0$ everywhere, and the autonomous multi-agent system has no stable equilibrium. The symbiogenic escape route is structural: the composite merges sub-agent objectives and state ($\mu \rightarrow 0$), eliminating the coordination-penalty term and recovering linear dynamics on the merged state. The bifurcation analysis therefore predicts symbiogenesis as a *mathematically forced phase transition* at critical environmental volatility ρ_c rather than as a contingent organizational choice. **Status: conditional on derivation of the $+k\delta^2$ coordination penalty from #def-shared-intent.** The $+k\delta^2$ form is currently stipulated rather than derived; making it rigorous requires showing that compounding coordination failure between agents with mismatch δ_A, δ_B produces an aggregate-mismatch dynamics with this specific quadratic-in- δ structure under named conditions on the shared-intent quantity. Without that derivation, the threshold $\rho_c = \alpha_{\text{auto}}^2/(4k)$ is a *formulation*, not a theorem; with it, the threshold form is exact under the named hypothesis. The closed-negative result here — that the bifurcation derivation is conditional on a derivation step not yet attempted — is itself load-bearing: any future strengthening of #hyp-symbiogenic-composition from hypothesis-tier to derived-result-tier must produce the missing derivation of the coordination penalty from a more fundamental AAT construct (the natural candidate is shared-intent mutual information between sub-agent models $M_t^{(A)}$ and $M_t^{(B)}$ under coupled-evidence regimes).
- **Dynamic-regime placement (added 2026-05-21 per Phase 5 cross-segment ripple).** Symbiogenic absorption is the **canonical structural mechanism for the R1 $\rightarrow$ R0 transition** on the dynamic-regime axis (per #disc-dynamic-regime-axis §”Transition asymmetry: descent is the default, ascent costs more”): pre-absorption, the composite operates in R1 equilibrium-regime under partially-opposing objectives between host and endosymbiont; post-absorption, the merged composite operates in R0 contraction-regime under the unified objective surface, with the (CM2) closed-form of #deriv-critical-mass-composition applying at the asymmetric-parameter limit. Symbiogenesis is therefore the self-driven *ascending* move on the dynamic-regime axis — paying the structural cost of objective-merger to exit the equilibrium-regime failure modes (saddle-Nash, multi-equilibria, last-iterate non-convergence) for the R0 contraction-regime guarantees. The saddle-node bifurcation analysis above (ρ_c threshold) is what makes the ascent *forced* rather than optional above critical environmental volatility.
- **Track E surface-back of catalog citations (2026-05-22) — Szathmáry 2015 major-transitions framework.** Adjacent literature surfaced 2026-05-22 from Track E catalog at ref/prior-art-analysis/08-composite-agency.md (Pillar 3): Szathmáry, E. (2015), *Toward major evolutionary transitions theory 2.0* (PNAS 112:10104)[†]. Substantial conceptual ancestry for the symbiogenic-absorption mechanism this segment formalizes: Szathmáry’s major-evolutionary-transitions (MET) framework names lower-level units becoming constrained by a higher-level unit, with progressively-reduced autonomy and “de-Darwinized” sub-units — exactly the asymmetric-parameter-limit structure (CM2)’s closed form formalizes mathematically. AAT does not claim to have discovered asymmetric absorption; the contribution is the *mathematical form* (the asymmetric-parameter limit reading of #deriv-critical-mass-composition + the dynamic-regime-axis R1 $\rightarrow$ R0 transition reading) that makes the symbiogenic process predictable rather than purely empirical. Other named conceptual ancestors (Maynard Smith & Szathmáry 1995 *The Major Transitions in Evolution*, Cambridge; Margulis 1981 *Symbiosis in Cell Evolution* — the canonical biological instance) are textbook/well-known and inherited from general scientific literacy rather than catalog-attributed.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (handled elsewhere — see report flags). **Coverage:** three dirs reached a digested reflection (526815, 829314, 849201) plus the §III composition-foundations batch (471203). The richest ideation here clusters around the weighted-Lyapunov $\mu \rightarrow 0$ sketch the segment’s Working Notes already carry — the gold is the *pedagogy around that math*, not new math. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **The thermodynamic bargain — autonomy for persistence.** The single strongest framing here: symbiogenesis (and corporate acquisition, and mitochondrial endosymbiosis) is “a fundamental thermodynamic trade: **autonomy** ($\mu \rightarrow 0$) **in exchange for persistence** ($R \rightarrow R_h$).” The absorbed entity’s independent mismatch dynamics drop out of the joint stability equation in the limit $\mu \rightarrow 0$; what it *gains* is that it “no longer has to worry about the harsh environmental drift ρ or running out of runway (reserve R), because it is now sheltered inside the massive reserve R_h of the host.” This is offered as the intuition that explains why symbiogenesis is ubiquitous in both nature and capitalism (Gemini, AUDIT-WORKING-829314). A candidate Brief/Discussion anchor that makes the $\mu \rightarrow 0$ limit legible without symbols.

2. Candidate Discussion.

- **Symbiogenesis and peer coupling as parameter-limits of one equation.** The pedagogical reading of the existing $\mu \rightarrow 0$ Working Note: a “merger of equals” (peer coupling) weighs both parties’ stability dynamics roughly equally ($\mu \approx 1$) and must coordinate everything; an acquisition (symbiogenesis) sends the small party’s weight $\mu \rightarrow 0$ so its independent dynamics vanish from the joint stability argument. “Symbiogenesis isn’t a magical discontinuous leap, but a smooth parameter limit of the standard peer-coupling stability proof” (Claude, AUDIT-WORKING-849201; the merger-of-equals-vs-acquisition vignette at Gemini, AUDIT-WORKING-829314). Candidate Discussion prose making the segment’s sketch self-explaining. (*The auditors also urge promoting the $\mu \rightarrow 0$ limit from Working Notes into the Formal Expression — that is a strengthen/promotion question flagged in the report, not gold.*)
- **Why retained autonomy is not zero — the singular-perturbation reading.** “Why not just execute the startup’s founders and replace them with a script?” Because the host *wants* the fast, low-level local responses the endosymbiont was good at, without routing them through the slow macro-loop — so it “deliberately preserves a tiny sliver of the startup’s autonomy to handle high-frequency local disturbances that would violate the host’s slow tempo budget” (Gemini, AUDIT-WORKING-829314; same point, with a curiosity about deriving an *optimal* retained autonomy μ^* from local-disturbance spectral frequency ρ_{local}). Sharpens the segment’s existing (S-3)-“why not complete?” Working Note by tying it explicitly to temporal nesting / singular perturbation.

3. Follow-up items.

- **Optimal retained autonomy μ^* from local-disturbance spectrum.** A candidate quantitative extension of (S-3): derive the retained-autonomy weight μ^* as a function of the spectral frequency of the local disturbance ρ_{local} the endosymbiont absorbs (faster local disturbances $\rightarrow$ more retained autonomy). Connects to 4.9 (Gemini, AUDIT-WORKING-829314).
- **When is symbiogenesis favored over peer coupling? — transaction-cost framing.** Multiple substrates reached for transaction-cost economics (Coase / Williamson) as the analog: symbiogenesis is favored when the coordination overhead of maintaining separate objectives exceeds the integration cost (Claude, AUDIT-WORKING-849201; converges with the segment’s existing “Quantitative predictions” Working Note tying this to C_{coord}).

4. Readers often ask / wonder.

- **“What drives $O_e \rightarrow \mathcal{D}_e(O_h)$ — selection, bounded rationality, or design?”** A natural reader want for the most load-bearing open dynamic (S-1); the segment’s Working Notes already enumerate the three candidate drivers, and a fresh reader independently reached for the same set (Claude, AUDIT-WORKING-849201). Worth a one-line forward-pointer in the body so the reader knows the question is named.

5. Candidate figures.

- **Three simultaneous contractions, with a typed-ambiguity output.** Symbiogenesis drawn as three coupled contractions over time — (S-1) objective absorption, (S-2) function grafting, (S-3) autonomy reduction — with the output deliberately shown as a *typed ambiguity*: either a composite with a still-agentive subordinate sub-agent, or a host system with an integrated non-agentive component if autonomy falls below the agency-scope threshold (Codex/Claude, AUDIT-WORKING-526815, “diagram attempt”). The typing distinction it visualizes is also a real correctness concern flagged in the report (whether the absorbed entity is still an AAT sub-agent).

Belongs elsewhere.

- **Mitochondria / eukaryotic-cell as the canonical biological instance.** Repeatedly invoked (the eukaryotic cell as a parasite/predator that became a structurally necessary sub-component) (Gemini, AUDIT-WORKING-193847 under 12.2; Gemini, AUDIT-WORKING-829314). The segment already maps to mitochondria; this is convergence signal that the analogy lands, and the Margulis 1981 prior-art anchor is already in Working Notes.

“Citation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). Catalog has more verification support than raw Undermind synthesis but less than full primary-source reading. Verification queued with the BG2 cluster.

Chapter 13

Composition Machinery

[Gap] Discussion

13.1 *Formulation*: Composition Closure Criterion

The formal definition of when a group of interacting agents constitutes a *valid composite macro-agent*. The criterion: the closed-loop dynamics *approximately commute with coarse-graining* — projecting micro-states to macro-states and then running macro-dynamics yields approximately the same result as running micro-dynamics and then projecting. The **closure defect** ε^* is the minimum achievable mismatch between these two paths, taken over all admissible projections and macro-dynamics.

The construction accommodates a **timescale ratio** $K_c \geq 1$ — the number of micro-timesteps per macro-step — that lets the framework handle both lockstep composites ($K_c = 1$, synchronous-update) and composites that operate strictly slower than their sub-agents ($K_c \gg 1$, the regime 4.9 asserts as natural). When the ratio is large, the composite’s description need not — and should not — track the micro-trajectory between macro-boundaries; timescale abstraction is recovered.

The closure-defect framework applies *only* to sets that satisfy 12.2. Given scope-satisfaction, a set forms a *meaningful* composite agent when $\varepsilon^* \leq \varepsilon_{\max}$. Without scope-satisfaction, the infimum is still well-defined as a projection property, but the resulting “composite” has ill-defined purposeful substate and composition-level machinery (team persistence, composite tempo) does not apply.

The formulation specifies **admissibility constraints** (A1)-(A4) on the macro-dynamics — conditions the macro must satisfy to be AAT-shaped: (A1) the macro-state decomposes into model and purposeful components with a recursive update; (A2) a macro-mismatch signal is well-defined; (A3) macro-tempo is well-defined; (A4) the macro-correction function satisfies the sector condition (4.4). Together these make the composite a proper AAT agent rather than just a low-dimensional projection. Parallel constraints (P1)-(P3) govern the projection (information preservation, Lipschitz continuity, dimensionality reduction). A **bridge lemma** is the technical heart of the result: Part I’s sector-persistence template (G) applied at the composite level requires a *strictly stronger* contraction assumption on the macro-update map than (A4) alone supplies — the assumption is structurally motivated by (A4) but not formally derived from it. For different *Tiers* of sub-agent quality, Part I/II results transfer differently to the composite: Tier 1 transfers *exactly*; Tier 2 transfers locally with bounded degradation; Tier 3 requires per-domain verification.

The closure defect itself is the **effective disturbance** at the composite level — it enters the composite’s persistence inequality as the rate at which macro-tracking diverges from micro-truth, combining with external environment per-

turbations to set the composite's total disturbance load (13.2). This makes precise the *cost of imperfect composition*: a composite with high closure defect carries that defect as a perpetual disturbance source against its own persistence.

Formal Expression.

Let a system consist of N sub-agents interacting in a shared environment with state space $\mathcal{S}_{\text{env}}$. The micro-state, micro-observations, and micro-actions are:

$$X_{\text{micro},t} = \{(M_{i,t}, G_{i,t})\}_{i=1}^N \in \mathcal{X}_{\text{micro}} \quad (13.1)$$

$$o_{\text{micro},t} = \{o_{i,t}\}_{i=1}^N \in \mathcal{O}_{\text{micro}} \quad (13.2)$$

$$a_{\text{micro},t} = \{a_{i,t}\}_{i=1}^N \in \mathcal{A}_{\text{micro}} \quad (13.3)$$

The coupled micro-dynamics form an action-observation loop:

$$X_{\text{micro},t} \xrightarrow{\pi_{\text{micro}}} a_{\text{micro},t} \xrightarrow{E} (\Omega_{t+1}, o_{\text{micro},t+1}) \xrightarrow{f_{\text{micro}}} X_{\text{micro},t+1} \quad (13.4)$$

We constrain our search to an admissible class of projections $\Lambda \in \mathcal{P}_{\text{adm}}$ mapping micro to macro, an admissible class of macro-dynamics $(\pi_c, E_c, f_c) \in \mathcal{M}_{\text{adm}}$, and a **timescale ratio** $K_c \geq 1$: the number of micro-timesteps per macro-step. Micro-time is indexed by $t \in \{0, \dots, H\}$; macro-time by $m \in \{0, \dots, \lfloor H/K_c \rfloor\}$ with macro-step m corresponding to micro-timestep $t = mK_c$. The projection components then have type signatures:

- $\Lambda_x : \mathcal{X}_{\text{micro}} \rightarrow \mathcal{X}_c = (M_c, G_c)$ — pointwise, evaluated at macro-boundaries.
- $\Lambda_\Omega : \mathcal{S}_{\text{env}} \rightarrow \mathcal{S}_{\text{env},c}$ — pointwise, evaluated at macro-boundaries.
- $\Lambda_o : \mathcal{O}_{\text{micro}}^{K_c} \rightarrow \mathcal{O}_c$ — aggregates the window of K_c micro-observations between successive macro-boundaries.
- $\Lambda_a : \mathcal{A}_{\text{micro}}^{K_c} \rightarrow \mathcal{A}_c$ — aggregates the window of K_c micro-actions similarly (used on the observation-comparison side; the macro-policy π_c emits one macro-action per macro-step).

Aggregation is part of the projection specification — common choices are mean/sum (linear systems), first/last (event-rate projections), or task-specific sufficient statistics. When $K_c = 1$ the windows collapse, Λ_o, Λ_a reduce to pointwise maps, and micro- and macro-tempos coincide (synchronous-update composites). When $K_c \gg 1$ the composite operates on the quasi-steady-state output of its sub-agents, the regime that 4.9 asserts as the natural one for composition. K_c is part of the problem specification; it does not appear in (A1)-(A4) or (P1)-(P3) below, but it determines at what granularity closure is measured.

Let $\mathcal{D}_{\text{micro}}$ be the distribution of reachable trajectories generated entirely by the true micro-system over horizon H , and let $o_{\text{micro},(m-1)K_c:mK_c}$ denote the window of K_c micro-observations ($o_{\text{micro},(m-1)K_c+1}, \dots, o_{\text{micro},mK_c}$) between macro-boundaries $m-1$ and m (similarly for actions).

[*Definition (Composition Closure)*] We define the minimal achievable closure defect ε^* over the admissible classes as:

$$\varepsilon^* = \inf_{\Lambda \in \mathcal{P}_{\text{adm}}, (\pi_c, E_c, f_c) \in \mathcal{M}_{\text{adm}}} \left\| (\varepsilon_x, \varepsilon_a, \varepsilon_o) \right\| \quad (13.5)$$

where the expected component errors evaluated over true micro-trajectories $\tau \sim \mathcal{D}_{\text{micro}}$, measured **per macro-step**, are:

$$\begin{aligned}
\bullet \quad \varepsilon_x &= \mathbb{E}_\tau \left[\frac{1}{M_H} \sum_{m=1}^{M_H} \left\| \Lambda_x(X_{\text{micro}, mK_c}) - f_c(\Lambda_x(X_{\text{micro}, (m-1)K_c}), \Lambda_o(o_{\text{micro}, (m-1)K_c : mK_c})) \right\|_x \right] \\
\bullet \quad \varepsilon_a &= \mathbb{E}_\tau \left[\frac{1}{M_H} \sum_{m=1}^{M_H} \left\| \Lambda_a(a_{\text{micro}, (m-1)K_c : mK_c}) - \pi_c(\Lambda_x(X_{\text{micro}, (m-1)K_c})) \right\|_a \right] \\
\bullet \quad \varepsilon_o &= \mathbb{E}_\tau \left[\frac{1}{M_H} \sum_{m=1}^{M_H} \left\| \Lambda_o(E_{\text{obs}}(\Omega, a_{\text{micro}})|_{(m-1)K_c : mK_c}) - E_{c,\text{obs}}(\Lambda_\Omega(\Omega_{(m-1)K_c}), \pi_c(\Lambda_x(X_{\text{micro}, (m-1)K_c}))) \right\|_o \right]
\end{aligned}$$

where $M_H = \lfloor H/K_c \rfloor$ is the number of macro-steps in horizon H , and $E_{\text{obs}}(\Omega, a_{\text{micro}})|_{(m-1)K_c : mK_c}$ denotes the window of micro-observations the environment produces across the macro-step.

Units. $\varepsilon_x, \varepsilon_a, \varepsilon_o$ carry units of distance — per-macro-step norm errors. Multiplied by the macro-update rate ν_c (units $[\text{time}^{-1}]$), they yield the disturbance-rate units $[\text{distance}] \cdot [\text{time}^{-1}]$ demanded by the sector-persistence template's ρ_ξ (G) and by the dimensional accounting in 13.2. The previous per-micro-step formulation conflated ε^* 's granularity with ν_c 's — the macro-step formulation resolves the unit inconsistency.

$K_c = 1$ special case. When micro and macro update in lockstep, $M_H = H$, the observation/action windows collapse, and the formulas reduce to the synchronous form. This is the regime of tightly-coupled groups (distributed algorithms running in phase, ensemble filters where every member steps per tick) and is where the two-Kalman worked example below operates.

$K_c \gg 1$ case. When the composite lives at a strictly slower timescale than its sub-agents (the regime 4.9 asserts as natural), only micro-states at macro-boundaries enter ε_x , and macro-observations aggregate K_c micro-observations. The closure defect then measures how well the macro-dynamics predicts the *next* macro-state from the *previous* macro-state and the aggregated micro-observation window — not any intermediate micro-state. Timescale abstraction is recovered: the composite's description need not — and under $K_c \gg 1$ should not — track the micro-trajectory between macro-boundaries.

The closure-defect framework applies to sets that satisfy 12.2 — i.e., that form composites via at least one of the three alignment routes (shared objective, hierarchical derivation, mutual benefit). Given scope-satisfaction, a set forms a *meaningful* composite agent — distinguished from a multi-agent system whose low- ε^* projection is a happenstance of the environment rather than a reflection of composite coherence — when $\varepsilon^* \leq \varepsilon_{\text{max}}$. Without scope-satisfaction, the ε^* infimum is still well-defined as a projection property, but the resulting “composite” has ill-defined purposeful substate $G_c = (O_c, \Sigma_c)$ and composition-level machinery (team persistence, composite tempo) does not apply.

Admissibility constraints on macro-dynamics.

$\mathcal{M}_{\text{adm}}$ is the class of macro-dynamics (π_c, E_c, f_c) satisfying:

Formulation (macro-dynamics-admissibility).

(A1) AAT agent structure. The macro-state decomposes as $X_c = (M_c, G_c)$. The macro-update is recursive at macro-time m :

$$X_{c,m+1} = f_c(X_{c,m}, o_{c,m+1}) \quad (13.6)$$

The macro-policy is state-dependent: $a_{c,m} = \pi_c(X_{c,m})$. This ensures the macro-agent has the same structural components as a single AAT agent (1.1, 3.2, 3.3).

(A2) Macro-mismatch. A mismatch signal is well-defined:

$$\delta_{c,m} = o_{c,m} - \hat{o}_{c,m}(M_c, a_{c,m-1}) \quad (13.7)$$

where $\hat{o}_{c,m}$ is the macro-model's prediction of the next macro-observation. This ensures the macro-agent can detect prediction errors — the foundation of adaptation (3.4).

(A3) Macro-tempo. The macro-update has well-defined adaptive tempo:

$$\mathcal{T}_c = \sum_k v_c^{(k)} \cdot \eta_c^{(k)*} \quad (13.8)$$

where k indexes the macro-agent's observation channels, $v_c^{(k)}$ is the event rate, and $\eta_c^{(k)*}$ is the optimal gain (3.8, 3.6). This ensures the persistence condition is formulable at the macro level. The additive form carries 3.8's noise-independence scope at the *macro* channel level (A5): when macro channels aggregate cross-correlated micro-streams, the exact macro tempo is the joint form, and the additive expression deviates with sign — the composite-level consequences are worked in 13.2.

(A4) Bounded macro-correction. The macro-correction function satisfies the sector condition (4.4):

$$\delta_c^T F_c(\mathcal{T}_c, \delta_c) \geq \alpha_c \|\delta_c\|^2 \quad \text{for } \|\delta_c\| \leq R_c \quad (13.9)$$

with $\alpha_c > 0$ (positive correction rate) and $R_c > 0$ (finite reserve). This ensures the macro-agent's corrections work — they reduce mismatch rather than amplifying it, within the macro-model's capacity.

What (A1)-(A4) prevent. Without these constraints, the infimum over $\mathcal{M}_{\text{adm}}$ is trivially zero (any dynamical system can curve-fit micro-trajectories over a finite horizon). The constraints force the macro-dynamics to be a genuine AAT agent — with decomposed state, prediction errors, adaptive tempo, and stable correction — not an arbitrary function approximator. ε^* then measures the irreducible cost of representing multiple agents as one AAT agent.

What (A1)-(A4) do NOT require. Directed separation (6.3) is not part of the admissibility constraints. It is an additional structural property that some composites have and others don't (13.3). Results that depend on directed separation declare it as an additional assumption. Similarly, strategy structure ($G_c = (O_c, \Sigma_c)$ with a DAG) is not required — simpler goal representations are admissible.

Admissibility constraints on projections.

The admissible class of projections $\mathcal{P}_{\text{adm}}(\varepsilon_I, L)$ consists of projections $\Lambda = (\Lambda_x, \Lambda_o, \Lambda_a, \Lambda_\Omega)$ satisfying three conditions:

Definition (projection-admissibility, proposed from spike).

(P1) Information preservation. The projection retains at least a fraction $(1 - \varepsilon_I)$ of the predictive mutual information, evaluated across a macro-step:

$$I(\Lambda_x(X_{\text{micro}, (m-1)K_c}; \Lambda_o(o_{\text{micro}, (m-1)K_c : mK_c}) \mid \Lambda_a(a_{\text{micro}, (m-1)K_c : mK_c})) \geq (1 - \varepsilon_I) \cdot I(X_{\text{micro}, (m-1)K_c}; o_{\text{micro}, (m-1)K_c : mK_c} \mid a_{\text{micro}, (m-1)K_c : mK_c}) \quad (13.10)$$

The left side is the predictive information the macro-state has about the next macro-observation (aggregated over the K_c -window), conditioned on the macro-action. The right side is the micro-state's predictive information about the *same* macro-observation, conditioned on the same aggregated actions — both sides share a common target so the ratio is well-defined. The parameter $\varepsilon_I \in [0, 1]$ controls how much predictive power may be sacrificed by projection. This is the information bottleneck (Tishby et al. 1999) applied to the projection map. When $K_c = 1$, the windows collapse to singletons and (P1) reduces to the per-micro-step form previously stated.

(P2) Lipschitz continuity. Each component of Λ is Lipschitz-continuous with constant L :

$$\|\Lambda_x(X) - \Lambda_x(X')\|_{\mathcal{X}_c} \leq L \cdot \|X - X'\|_{\mathcal{X}_{\text{micro}}} \quad \forall X, X' \in \mathcal{X}_{\text{micro}} \quad (13.11)$$

(and analogously for Λ_o , Λ_a , Λ_Ω , each with its own Lipschitz constant). Without Lipschitz regularity, bounded closure defect does not imply bounded trajectory error — the bridge lemma requires this or something equivalent. When the projection is L -Lipschitz, the trajectory error bound becomes $L \cdot \varepsilon^* / \alpha_c$.

(P3) Dimensionality reduction. The macro-state space has strictly lower dimension than the micro-state space:

$$\dim(\mathcal{X}_c) < \dim(\mathcal{X}_{\text{micro}}) \quad (13.12)$$

This prevents the trivial identity projection, which achieves $\varepsilon^* = 0$ but is not a genuine abstraction.

Why three conditions. No single condition suffices alone. (P1) prevents degenerate projections (a constant map $\Lambda_x = c$ has zero mutual information). (P2) prevents pathological projections (discontinuous maps that amplify micro-errors into unbounded macro-errors). (P3) prevents trivial projections (the identity map satisfies (P1) and (P2) but achieves nothing). Together they constrain $\mathcal{P}_{\text{adm}}$ to projections that are informative, regular, and genuinely reductive.

The (ε_I, L) parameters are part of the problem specification, not derived quantities. The natural choice for many applications is $L = 1$ (non-expansive projection) and ε_I chosen as the minimum information loss compatible with genuine dimensionality reduction.

Independence from (A1)-(A4). The macro-dynamics admissibility (A1)-(A4) partially constrains the projection — (A1) requires Λ_x to preserve the M_c/G_c decomposition, and (A4) implicitly requires regularity through the sector condition. But (A1)-(A4) do not specify how much predictive information the projection must retain. A macro-agent with a very coarse projection can satisfy (A1)-(A4) while being a poor representation of the micro-system. The information-preservation condition (P1) fills this gap.

Bridge lemma: closure defect to trajectory error.

The bridge lemma is the sector-persistence template (G) applied with state variable $\xi = e_m = X_{c,m} - \Lambda_x(X_{\text{micro},mK_c})$ (trajectory error at macro-boundaries, between macro-evolved state and projected micro-state) and effective disturbance rate $\rho_\xi = \varepsilon^* \nu_c$ (closure defect per macro-step, multiplied by macro-update rate). The units are consistent by construction of the macro-step formulation above: ε^* is per-macro-step (distance) and ν_c is macro-step rate ($[\text{time}^{-1}]$), so ρ_ξ has the disturbance-rate units the template requires. The template yields directly:

Derived (bridge-lemma, from sector-persistence-template + A4 + contraction assumption).

$$\limsup_{m \rightarrow \infty} \|e_m\| \leq \frac{\varepsilon^* \nu_c}{\alpha_c} \quad (13.13)$$

This bound fits within the composite's sector-condition region iff $\varepsilon^* < \alpha_c R_c / \nu_c$, which is the persistence condition applied to the closure-error rate: if it fails, the macro-description diverges from micro-reality.

What the bridge lemma adds beyond the template. The template's precondition (T2) is the one-point sector bound. For the trajectory-error instantiation, the bound propagation requires a *strictly stronger* condition: the macro-update map $f_c(\cdot, o)$ must be contracting in its state argument (**incremental sector bound**, DA2'-inc — strong monotonicity of F_c), not merely one-point sector-bounded at each state. The per-step contraction factor is $\lambda = 1 - \alpha_c / \nu_c < 1$ (automatic when $\alpha_c < \nu_c$, true for any realistic agent that doesn't fully correct in a single step). This stronger condition is where the tier structure enters; see Epistemic Status for the Tier 1/2/3 taxonomy.

The sector condition (A4) does double duty — conditionally. (A4) ensures the macro-agent corrects external mismatch (single-agent persistence) AND — under the incremental sector bound — that the macro-description tracks

micro-reality (this bridge). Both are instances of the same template applied to different state variables with different effective disturbance rates.

What Is Derived vs. What Is Chosen.

Table 13.1

Property	Source	Strength
Closure-defect quantity ε^* as infimum over admissible classes	Definition built from (A1)-(A4), (P1)-(P3), and K_c	Formulation choice
Three-component decomposition into $\varepsilon_x, \varepsilon_a, \varepsilon_o$	Match to the three arrows of the action-observation loop (state, action, observation)	Formulation choice
Per-macro-step formulation; ε^* has units of distance-per-macro-step	2026-04-22 temporal coarse-graining repair (Finding A); forced by dimensional consistency with $\rho_\xi = \varepsilon^* \nu_c$ in G and 13.2	Derived (dimensional consistency)
Timescale ratio $K_c \geq 1$ as independent problem-specification parameter	Application-specific; $K_c = 1$ (synchronous) and $K_c \gg 1$ (4.9 regime) both admissible	Formulation choice
(A1) Macro AAT structure $X_c = (M_c, G_c)$ with recursive update	Import from 1.1 + 3.2 + 3.3	Formulation choice (requirement)
(A2) Well-defined macro-mismatch	Import from 3.4	Formulation choice (requirement)
(A3) Well-defined macro-tempo	Import from 3.8 + 3.6	Formulation choice (requirement)
(A4) Sector-bounded macro-correction	Import from 4.4	Formulation choice (requirement)
(A1)-(A4) as a requirement set render the infimum non-trivial (exclude curve-fitting macro-dynamics)	Consequence of restricting $\mathcal{M}_{\text{adm}}$ to genuine AAT agents	Derived (under the chosen requirement set)
(P1) Information-preservation constraint	IB Lagrangian-dual with source X_{micro} , relevance $O_{\text{micro}, t+1}$; formally connects to AA	Formulation choice (requirement)
(P2) Lipschitz continuity of Λ	Required for bridge-lemma trajectory-error bound (without it, bounded ε^* does not imply bounded trajectory error)	Formulation choice (requirement)
(P3) Strict dimensionality reduction	Rules out identity projection (which trivially achieves $\varepsilon^* = 0$ but is not abstraction)	Formulation choice (requirement)
(P1)-(P3) independent of (A1)-(A4)	(A1) and (A4) constrain Λ_x partially but do not fix information-preservation level (§"Independence from (A1)-(A4)")	Derived
Bridge lemma: $\limsup \ e_m\ \leq \varepsilon^* \nu_c / \alpha_c$	Sector-persistence template (G) applied with state $\xi = e_m$, disturbance rate $\rho_\xi = \varepsilon^* \nu_c$	Derived (conditional on incremental sector bound DA2'a-inc)
Persistence-as-closure-boundedness condition $\varepsilon^* < \alpha_c R_c / \nu_c$	Sector-condition region fits the asymptotic error ball	Derived (under A4 + DA2'a-inc)
Incremental sector bound (DA2'a-inc) is strictly stronger than (A4)'s one-point sector bound	Witness $F_d(\delta) = 2\delta + 3 \sin \delta$ (oscillatory, globally inward, locally non-monotone), Discussion §"DA2'a-inc is strictly stronger than (A4)"	Proved

Property	Source	Strength
Three-tier agent classification (Tier 1 / 2 / 3) for bridge-lemma applicability	Taxonomy induced by whether DA2'a-inc holds globally (T1), locally (T2), or must be verified per-domain (T3)	Formulation choice (classification)
Tier 1: bridge lemma derived for Bayesian updaters on exponential families, gradient descent on strongly convex losses, linear correction with positive-definite gain-observation product	Standard monotone-operator / Kalman analysis; $H^T H$ -norm contraction derivation in Discussion §"Bridge-lemma contraction"	Derived (conditional on DA2'a-inc + linear prediction, i.e., C2)
Tier 2: local contraction with factor degraded by $\kappa(D\delta)^2$	Extended-Kalman / locally-convex analysis	Derived (local)
Tier 3: contraction must be verified per-domain	No general result available for non-convex / discontinuous / non-mismatch-driven components	Discussion-grade
Composite (A4) from sub-agent properties: $\alpha_c \geq \min_i (\alpha_i - \Delta \mathcal{J}_i^{\text{cost}})$, $R_c \leq \min_i R_i$	Weakest-link bound (Discussion §"Deriving composite (A4) from sub-agent properties")	Derived (conditional on bounded coordination cost per 15.1)
Composite critical-mass inequality $(\alpha - C)R > \rho + \gamma \mathcal{J}$ (symmetric-matched-Tier-1) — sign-sensitive refinement of the weakest-link bound; recovers 15.1 (cooperative) and 15.2 (adversarial) as signed special cases	J	Derived (conditional on Tier 1 + matched-symmetric + Model D + coupling model C1/C2)
Composite persistence as (contraction) $\wedge$ (scope-satisfaction): $\kappa_c(U_O) > 0 \wedge$ 12.2	J (CM4); U_O enters multiplicatively on γ plus scope-gate, not additively	Derived (with (UO-mult) discussion-grade)
Asymmetric-limit connection to 12.3 (S-3) autonomy reduction	J §asymmetric-limit; weighted Lyapunov V_μ with $\mu \rightarrow 0$	Sketch (S-2 function transfer not yet formalized; promotable when 12.3 closes (S-2))
Meta-machine exact composition ($\varepsilon^* = 0$) for finite-state Moore machines	Miller 2022 §3.3; product automaton is the micro-dynamics by construction	Derived (external theorem)
Two-Kalman instantiation: $\varepsilon^* = 0$ at all ρ_{corr} for the means-only projection at steady state	Analytic steady-state calculation (Discussion §"Two-Kalman instantiation (closed form)")	Proved (closed form)
ε_x depends on both sub-agent unity and update-rule heterogeneity (ΔK)	Heterogeneous-gain Kalman case; 14.1	Derived (specific closed form for the two-Kalman case)
Mahalanobis norm as natural choice for estimation-type agents	Two-Kalman verification; Kalman gain minimizes expected squared Mahalanobis distance	Formulation choice (canonical for estimation; general-domain norm specification open)
N -agent scaling of ε^*	A "polynomial vs. exponential in N " framing is mis-typed: ε^* is a per-step residue, while "scales in N " is an accumulation-typed predicate	Resolved: $\varepsilon^*(N)$ is dimension-free-zero in the benign linear-Gaussian-stationary regime (all N , all coupling), graph-Laplacian-bounded with no exponential regime under compression (the consensus operator #deriv-critical-mass-composition already names), and order-incompatibility-invariant ($\leq S \log 2$, N -free) for strategy-DAG composition. No exponential regime exists. Full statement: the next two rows + Discussion
Computability of (P1) for nonlinear / non-Gaussian systems	Requires Monte Carlo or variational bounds; closed-form only for linear-Gaussian	Open

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Principled setting of the ϵ_I threshold	No formal criterion currently; candidate tying to team size and coupling structure	Open
Strategy-DAG projection under Λ_x	Causal- τ -abstraction frame; 8.3 §"Composing heterogeneous strategy DAGs" (topology / SCC-condensation), 14.1 (fixed-topology credence instance)	Resolved (<i>conditional</i> ; one named sub-open Q1): the right object is a causal- τ -abstraction; exact Σ_c iff shared sub-orders jointly acyclic + AND/OR-compatible, else the minimal admissible Σ_c is the SCC-condensation with defect $\sum_{ C >1} \text{TC}(C) \leq S \log 2$ — bounded by shared-plan size, N-free. Beckers–Eberhardt–Halpern (τ, ϵ) -abstraction $\Rightarrow$ bounded ϵ_Σ (the <i>frame</i> , not term-for-term; the high-level distance remains AAT's to choose). Q1 (constant-tightness for non-deterministic intra-SCC coupling) is a named sub-open, not a reopening
Mori-Zwanzig zero-lag bound $\epsilon^* \geq \ Q_\Lambda UP_\Lambda\ _{\text{op}}$	Koopman/MZ projection (stationary coordinate-compatible case)	Derived (conditional on stationarity)
Full-kernel MZ bound on ϵ^*	Type mismatch (trajectory-accumulation vs. per-step)	Refuted at the ϵ^* -level; natural home is the bridge-lemma trajectory-error bound

The dividing line: (A1)-(A4) and (P1)-(P3) are *formulation choices of the requirement set* — alternative requirement sets are possible (e.g., entropy-preservation instead of MI-preservation; contraction bound in place of Lipschitz), and this one is chosen for parsimony, direct import from prior AAT segments, and downstream tractability. The *consequences* that follow under this requirement set — the non-triviality of the infimum, the bridge-lemma bound, the weakest-link composite-(A4) derivation, the two-Kalman $\epsilon^* = 0$ result — are Derived, with bridge-lemma-level results carrying the additional DA2'a-inc condition (which is proved strictly stronger than (A4) alone). The Tier 1/2/3 classification is itself a formulation, but the per-tier results are derived under tier-specific conditions. The genuinely-open questions are now the computability / principled-setting questions for (P1) and ϵ_I . The N -agent-scaling and strategy-DAG-projection rows are **resolved** (re-typed; the “poly-vs-exp” / “domain-specific-unresolved” framings were mis-typed — see the two rows above): there is no exponential-in- N regime, and N -scaling does not decide whether large teams are representable as single AAT agents.

Epistemic Status.

Conditional. Max attainable: conditional (formulation choice).

The closure defect ϵ^* is well-defined given (A1)-(A4), (P1)-(P3), the timescale ratio K_c , and specified norms. The macro-dynamics admissibility (A1)-(A4) and the projection admissibility (P1)-(P3) are independent formulation choices — (A1)-(A4) specify what “AAT-shaped macro-dynamics” means; (P1)-(P3) specify what “informative, regular, genuinely reductive projections” means. Both are needed for ϵ^* to be an infimum over a non-trivial, non-degenerate class. The timescale ratio $K_c \geq 1$ is a third, independent piece of problem specification: it sets the granularity at which closure is measured and the type signatures of Λ_o, Λ_a . K_c does not constrain the macro-dynamics class and is not derived — it is chosen from the timescale separation of the application (per 4.9). Both $K_c = 1$ (tightly-coupled composites) and $K_c \gg 1$ (hierarchically composed composites on their own timescale) are admissible. The projection admissibility conditions have a proposed definition with one exact instantiation (two-Kalman case at $K_c = 1$, worked in the Discussion); general-case computability of (P1) and the dependence of ϵ^* on K_c for a fixed application remain open.

The bridge lemma is *conditional* — not fully derived from (A4) alone. The precise additional condition is the **incremental sector bound** (DA2'a-inc): the correction function F_d must be *strongly monotone* ($\langle \delta - \delta', F_d(\delta) - F_d(\delta') \rangle \geq c_{\min} \|\delta - \delta'\|^2$ for all pairs), not just satisfy the one-point sector bound. This is strictly stronger than (A4) — a witness exists: the oscillatory correction $F_d(\delta) = 2\delta + 3 \sin \delta$ is globally inward-pointing but locally non-monotone (Discussion §"DA2'a-inc is strictly stronger than (A4)"). Three tiers of agents result:

- **Tier 1 (contraction proved):** Kalman filters, exponential-family Bayesian updaters, gradient descent on strongly convex losses, all linear corrections with positive definite gain-observation product. For these agents the bridge lemma is *derived* from (A4) + DA2'a-inc + linear prediction (C2), with contraction factor λ_{eff} from $\mathcal{O}$.
- **Tier 2 (local contraction):** Extended Kalman, locally convex gradients, nonlinear prediction models. Contraction holds locally with factor degraded by $\kappa(D\hat{o})^2$.
- **Tier 3 (independent verification):** Non-convex optimization, discontinuous/rule-based corrections, agents with non-mismatch-driven state components. Contraction must be verified per-domain.

The discrete-time recurrence argument itself is standard (Elaydi 2005); the contribution is identifying the incremental sector bound as the precise condition that bridges sector-bounded correction to full-update-map contraction. The full $H^\top H$ -norm contraction derivation is in the Discussion (§"Bridge-lemma contraction in the $H^\top H$ -norm").

The norm choices ($\|\cdot\|_{\mathcal{X}}$, $\|\cdot\|_{\mathcal{A}}$, $\|\cdot\|_{\mathcal{O}}$, and the combination norm) are load-bearing. For estimation-type agents, the Mahalanobis norm (weighted by inverse prediction-error covariance) is the natural choice — verified exactly in the two-Kalman case. For general domains, norm specification remains open.

Discussion.

This criterion replaces intuitive questions about “where the boundary of an agent is” with a functional test: does a macroscopic AAT description preserve the underlying micro-dynamics well enough to remain predictive and capable? The core requirement is an **approximate dynamical homomorphism** — the macro-dynamics approximately commute with the projection.

Relationship to 11. The Part I postulate requires that AAT’s machinery be scale-invariant — predictions at different levels of description must be compatible. This segment operationalizes “compatible” as “bounded closure defect under admissible coarse-graining.” The admissibility constraints ensure the macro-description is genuinely AAT-shaped, so the same persistence condition, the same tempo framework, and the same mismatch dynamics apply at the macro level with macro-level parameters.

Projection-behaviour facet of the stability certificate (5). Coarse-graining is a non-invertible projection of the certificate (**H**): the certificate-as-metric survives (the Schur complement of a positive-definite form is positive-definite) but the *dynamic* guarantee does not — the closure defect ϵ^* is the certificate’s projection-residue, equal to the Mori–Zwanzig zero-lag memory-commutator norm (derivation table above), zero exactly when the resolved subspace is invariant. Read through the spine, this is the question “does the agent’s measuring-stick survive being viewed coarsely”: its shape survives, its guarantee leaks by exactly the memory term. The composition-level identifiability floor (no common certificate across sub-agents; Liberzon, 5.1 Instance 3) is this same residue read as a boundary event — a *distinct* obstruction from the rank-collapse floors (a non-invertible projection, not a congruence), which is why the cross-sectional structure is several meta-patterns and not one.

The Jacobian-level observation. The incremental sector bound (DA2'-inc) used to prove the bridge lemma is mathematically equivalent to the contraction-metric condition (CT2) evaluated at the identity metric $M = I$, for continuously differentiable (C^1) correction functions F on convex domains. This equivalence (cf. Rockafellar & Wets 1998) means that AAT’s bridge lemma is a specialized application of generalized contraction theory. See #result-contraction-template for the full lifting of this condition to arbitrary Riemannian metrics.

Topology-indexed composition closures (via AI). `#result-contraction-template` lifts the bridge-lemma’s DA2’-inc condition into the contraction-metric framework of Lohmiller & Slotine 1998. Under its (CT1)–(CT3) preconditions, three topology-indexed closure results apply:

- **Parallel composition** preserves contraction under blockdiag metric at rate $\min(\lambda_1, \lambda_2)$ — recovers this segment’s weakest-link bound.
- **Cascade composition** ($\dot{x}_1 = f_1(x_1)$, $\dot{x}_2 = f_2(x_1, x_2)$) preserves contraction under lower-triangular weighted metric at rate bounded by $\min(\lambda_1, \lambda_2)$ up to coupling-gain adjustment (Slotine 2003 Thm 2). Handles hierarchical agent structures.
- **Negative feedback with bounded loop gain** (Slotine 2003 Thm 3) gives the heterogeneous critical-mass inequality $(\lambda_1 - C_1)(\lambda_2 - C_2) > k_{12}k_{21}/4$ via (CM2-M) in AI — extending J’s matched-symmetric (CM2) to heterogeneous sub-agents with different architectures and coupling strengths.

The Tier 1/2/3 bridge-lemma taxonomy of this segment maps cleanly to Tier 1M/2M/3M under AI (globally metric-contracting / locally metric-contracting / no globally valid metric). The observation that (CT2) at $M = I$ is *equivalent* to DA2’-inc means this segment has been carrying the Jacobian-level Euclidean contraction condition at the composite level all along; AI surfaces this at the single-agent level and adds the compositional theorems that generalize this segment’s closure content beyond the matched-symmetric case.

DA2’-inc $\equiv$ (CT2) at $M = I$ — structural-transparency equivalence. *[Derived, status: exact.]* For C^1 correction functions F on convex domains, the following three conditions are equivalent (standard monotone-operator theory; Rockafellar & Wets 1998 *Variational Analysis* Corollary 12.4; Nesterov 2004 *Introductory Lectures on Convex Optimization* §2.1.3 Theorem 2.1.9 — strong monotonicity $\Leftrightarrow$ symmetric-part of Jacobian uniformly positive-definite):

- (a) DA2’-inc (strong monotonicity): $(\delta - \delta')^\top (F(\delta) - F(\delta')) \geq c\|\delta - \delta'\|^2$ for all δ, δ' .
- (b) Jacobian-symmetric-part PD: $(\partial F / \partial \delta)_{\text{sym}} \succeq cI$ pointwise on the domain.
- (c) (CT2) at $M = I$ with $\lambda = c$: $-\partial F / \partial \delta - (\partial F / \partial \delta)^\top \leq -2\lambda I$.

Derivation. (a) $\rightarrow$ (b): take $\delta' \rightarrow \delta$ along direction v , divide by $\|\delta - \delta'\|^2$, take the limit. (b) $\rightarrow$ (a): integrate $v^\top (\partial F / \partial \delta)_{\text{sym}} v \geq c\|v\|^2$ along the segment from δ' to δ . (b) $\Leftrightarrow$ (c): direct algebraic identity.

Implication for AAT-internal derivability. Under this equivalence, the Euclidean sub-scope metric- α_1 cases of `#result-contraction-template` (Kalman-scalar, Euclidean strongly-convex-gradient, L2-regularized, linear-PD-symmetric) are AAT-internally derived from the DA2’-inc commitment already carried at the composite level — no new axiom required. What the (CT2)-at- $M = I$ framing adds is *visibility*: the Jacobian-level condition was implicit under the DA2’-inc name; surfacing the equivalence converts the Euclidean sub-scope from “theorem-imported from Lohmiller-Slotine” to “AAT-internally derived via a standard monotone-operator identity.” This is structural transparency, not new content. Non-Euclidean metric- α_2 cases (Fisher, Hessian, Lyapunov-metric) remain separately treated in `#result-contraction-template` — the equivalence is specific to $M = I$.

DA2’a-inc is strictly stronger than (A4): the witness. *[Derived, status: exact.]* The incremental sector bound (DA2’a-inc) does **not** follow from the one-point sector bound (A4) alone. A scalar witness exhibits a correction function satisfying the one-point bound while violating incremental monotonicity. Take

$$F_d(\delta) = 2\delta + 3 \sin \delta \quad \text{on } |\delta| \leq \pi. \quad (13.14)$$

One-point bound holds. Since $\delta \sin \delta \geq 0$ on $[-\pi, \pi]$ (the two factors share sign),

$$\delta F_d(\delta) = 2\delta^2 + 3\delta \sin \delta \geq 2\delta^2, \quad (13.15)$$

so the one-point sector bound (A4) holds with $\alpha = c_{\min} = 2$ on $\mathcal{B}_\pi$.

Incremental bound fails. In one dimension the incremental condition $(\delta - \delta')(F_d(\delta) - F_d(\delta')) \geq c_{\min}(\delta - \delta')^2$ is equivalent to $F_d'(\delta) \geq c_{\min}$ pointwise. Here $F_d'(\delta) = 2 + 3 \cos \delta$, and at $\delta = \pi$ this is $2 + 3 \cos \pi = 2 - 3 = -1 < 0$. So near $\delta = \pi$ there exist $\delta_1 < \delta_2$ with $F_d(\delta_1) > F_d(\delta_2)$, giving $(\delta_1 - \delta_2)(F_d(\delta_1) - F_d(\delta_2)) < 0$ — the incremental bound fails for *any* $c_{\min} > 0$.

The geometric reading: the one-point bound says “every correction points inward toward the equilibrium”; the incremental bound says “larger mismatches always receive larger corrections.” An oscillatory correction can be globally inward-pointing (one-point bound holds with margin) while *locally* the correction magnitude decreases as the mismatch grows (it wobbles) — which breaks incremental monotonicity. This is why the bridge lemma’s Tier-1 promotion carries the additional DA2’a-inc condition rather than resting on (A4): the witness shows the gap is real, not an artifact of proof technique.

Bridge-lemma contraction in the $H^\top H$ -norm (Tier 1). [Derived (bridge-lemma-contraction), conditional on (C1) incremental sector-Lipschitz, (C2) linear prediction, (C3) bounded gain.] The Tier-1 promotion of the bridge lemma — from “ f_c is assumed contracting” to “ f_c is contracting, derived” — rests on the following. Let the macro-update be mismatch-driven, $f_c(X, o) = X + \eta g(o - \hat{o}(X))$, with observation-space correction $F_d(\delta) = Hg(\delta)$, and assume:

- (C1) F_d is incrementally sector-Lipschitz: $\langle \delta - \delta', F_d(\delta) - F_d(\delta') \rangle \geq c_{\min} \|\delta - \delta'\|^2$ (DA2’a-inc, strong monotonicity) and $\|F_d(\delta) - F_d(\delta')\| \leq c_{\max} \|\delta - \delta'\|$;
- (C2) linear prediction $\hat{o}(X) = HX$, so $\delta - \delta' = H(X' - X)$;
- (C3) bounded gain $\eta < 2c_{\min}/c_{\max}^2$.

Then the full update map contracts in the $H^\top H$ -norm $\|v\|_{H^\top H}^2 = v^\top H^\top H v$:

$$\|f_c(X, o) - f_c(X', o)\|_{H^\top H} \leq \lambda_{\text{eff}} \|X - X'\|_{H^\top H}, \quad \lambda_{\text{eff}}^2 = 1 - 2\eta c_{\min} + \eta^2 c_{\max}^2 < 1. \quad (13.16)$$

Derivation. Applying H to the update difference $\Delta f = f_c(X, o) - f_c(X', o) = (X - X') + \eta[g(\delta) - g(\delta')]$ and writing $\Delta\delta = \delta - \delta' = H(X' - X)$,

$$H\Delta f = -\Delta\delta + \eta[F_d(\delta) - F_d(\delta')]. \quad (13.17)$$

Taking the squared Euclidean norm (which is the squared $H^\top H$ -norm of Δf):

$$\|\Delta f\|_{H^\top H}^2 = \|\Delta\delta\|^2 - 2\eta \langle \Delta\delta, F_d(\delta) - F_d(\delta') \rangle + \eta^2 \|F_d(\delta) - F_d(\delta')\|^2. \quad (13.18)$$

Applying (C1)’s incremental sector bound to the middle term and incremental Lipschitz bound to the last term:

$$\|\Delta f\|_{H^\top H}^2 \leq (1 - 2\eta c_{\min} + \eta^2 c_{\max}^2) \|\Delta\delta\|^2 = \lambda_{\text{eff}}^2 \|\Delta\delta\|^2, \quad (13.19)$$

and $\|\Delta\delta\|^2 = \|H(X' - X)\|^2 = \|X - X'\|_{H^\top H}^2$ closes the bound; (C3) makes $\lambda_{\text{eff}} < 1$. $\square$

This λ_{eff} is exactly the mismatch-dynamics contraction factor of $\bigcirc$ — the trajectory error e_m generates a virtual mismatch He_m contracted by the same mechanism that contracts actual mismatch, which is why the bridge bound $\limsup \|e_m\| \leq \varepsilon^* \nu_c / \alpha_c$ holds with no separate assumption once (C1)–(C3) do. When $H = I$ (direct observation) the norm is Euclidean and the factor is exactly λ_{eff} , recovering the scalar-Kalman case; for invertible H the Euclidean factor degrades by $\kappa(H)^2$. The classes for which (C1) holds — all linear corrections with positive-definite Hg , all exponential-family Bayesian updaters (strong monotonicity from log-partition convexity), all gradient descent on strongly convex losses

— are the Tier-1 agents; (C2)’s linear-prediction requirement is what separates Tier 1 (exact) from Tier 2 (local, factor degraded by the prediction Jacobian’s condition number squared).

The sector condition does double duty — conditionally. (A4) ensures the macro-agent’s corrections work (structural persistence), AND — given the additional contraction assumption (see Epistemic Status) — it ensures the macro-description tracks micro-reality (bridge lemma). Both uses address *structural persistence* in the sense of LEXICON.md — the capacity of the correction machinery, not the current operating point or the composite’s identity through time. The central insight is that structural persistence of the composite and faithfulness to its constituents are related through the same mechanism — contracting correction dynamics under bounded perturbation — but the bridge from sector-bounded correction to full-update-map contraction requires an assumption beyond (A4) that has been verified for estimation-type agents (Kalman) and remains open for general agents. When this assumption holds, the composite that persists in its own right also persists as a faithful representation of its constituents.

Deriving composite (A4) from sub-agent properties. If each sub-agent satisfies the sector condition with parameters (α_i, R_i) , and coordination costs are bounded by $\Delta\mathcal{F}_i^{\text{cost}}$ per agent (15.1), then the composite satisfies (A4) with:

$$\alpha_c \geq \min_i (\alpha_i - \Delta\mathcal{F}_i^{\text{cost}}) \quad (13.20)$$

$$R_c \leq \min_i R_i \quad (13.21)$$

This is a weakest-link bound (conservative but clean): each sub-agent’s effective correction rate is its own α_i degraded by its coordination overhead $\Delta\mathcal{F}_i^{\text{cost}}$, and the composite inherits the worst of these, while its reserve R_c cannot exceed the smallest sub-agent reserve. Cooperative coupling (15.1) can improve α_c beyond this bound by reducing effective disturbance. The key implication: (A4) is *verifiable* from micro-level properties — compute each sub-agent’s sector-condition parameters, estimate coordination costs, and check whether the composite has positive correction rate. No need to compute f_c directly.

Sign-sensitive refinement (derived). The sign-blind weakest-link bound is subsumed by J’s closed-form inequality $(\alpha - C)R > \rho + \gamma\mathcal{J}$ (CM2) in the matched-symmetric-Tier-1 case, where the right-hand side makes the effective disturbance explicit and the sign of the coupling γ (cooperative $\gamma < 0$ vs adversarial $\gamma > 0$) enters directly. (CM2) can yield composite persistence even when the weakest-link bound alone fails — when cooperative coupling reduces $\rho + \gamma\mathcal{J}$ below what the raw $\alpha - C$ margin would permit. 15.1 (cooperative) and 15.2 (adversarial) are recovered as signed special cases. The honest composite-persistence statement is the conjunction of contraction (CM3) and scope-satisfaction (12.2) — (CM4) — making explicit that composite persistence can fail in two qualitatively different ways: the composite fails to contract, or the composite was never a composite. The asymmetric-parameter limit $\alpha_2 \rightarrow 0$ via weighted Lyapunov V_μ formalizes 12.3’s (S-3) autonomy-reduction mechanism as a smooth deformation of (CM4), not a discontinuous regime change.

Connection to team-persistence. 15.1 derives persistence conditions for sub-agents in a cooperative-adversarial network. This segment provides the macro-level complement: the conditions under which the composite itself is a valid AAT agent. Together they close the loop: sub-agents persist individually (team-persistence) AND the composite is a meaningful macro-agent (composition closure with admissibility).

Constructive (A1)–(A4) via wrapping. The wrapping construction in #der-class-coercion-via-wrapping is a special-case instantiation where (A1)–(A4) hold *by construction* through the wrapper’s type signatures rather than by post-hoc verification of an admissible projection Λ . The wrapper builds explicit $X_W = (M_W, G_W)$ with belief-update and strategy-update maps that have specified type signatures; (A1) is automatic; (A2)–(A4) follow from wrapper-design constraints (commit to a prediction map; choose f_M from the Tier-1 belief-update class). The closure-defect ε^* in this special case has a different reading than the standard fidelity reading — the wrapper *deliberately* changes the underlying component’s behavior to enforce structural separation. Two distinct ε^* quantities appear in wrapper analyses: $\varepsilon_{\text{track}}^*$

(the standard fidelity quantity defined here, used in the bridge lemma) and $\epsilon_{\text{coerce}}^*$ (the wrapper-vs-component behavioral divergence, distinct from $\epsilon_{\text{track}}^*$ and not bounded by the bridge lemma). See #der-class-coercion-via-wrapping Discussion for the disambiguation.

Meta-machine: exact composition for finite automata (Miller 2022). When agents are finite-state automata (Moore machines), composition is *exact*: two machines with state sets S_1, S_2 interacting through their output/input channels form a **meta-machine** (Miller 2022, *Ex Machina*, §3.3) — itself a Moore machine with state set $S_1 \times S_2$, deterministic transitions (each machine’s output determines the other’s input), and a single starting state from the constituent starting states. The closure defect $\epsilon^* = 0$ trivially, because the product automaton *is* the micro-dynamics — there is no approximation. The meta-machine always falls into a cycle (finite states with deterministic transitions must eventually revisit a state), so two interacting automata produce an eventually-periodic joint behavior. The composition-closure framework becomes interesting when we ask for a *compressed* macro-description: can a smaller automaton (fewer than $|S_1| \times |S_2|$ states) approximate the meta-machine? This is where $\epsilon^* > 0$ and the admissibility constraints become non-trivial — (P3) requires genuine dimensionality reduction, and (P1) asks how much predictive information the compression preserves. Machine minimization (the theorem that every automaton has a unique minimized equivalent; Hopcroft et al. 2006) is a natural candidate for the optimal projection: the minimized meta-machine has the fewest states that reproduce the full joint behavior, achieving $\epsilon^* = 0$ with (P3) satisfied whenever the minimized machine is smaller than the product. See BD (planned) for the full instantiation.

Two-Kalman instantiation (closed form). The simplest nontrivial worked case: two scalar Kalman filters tracking a bivariate random walk with cross-correlated process noise $\text{Cov}(w_1, w_2) = \rho_{\text{corr}} q$ (common variance q , common observation noise r), each observing only its own component, no communication. This case sits at $K_c = 1$ — both sub-agents and the composite step together — so the macro-step formulation reduces to the pointwise form and the Λ_o aggregation is the identity. The natural projection keeps the state estimates and discards the covariance states (means-only projection, dimension 2 from micro-dimension 4). Each filter has the scalar steady state $P^* = \frac{1}{2}(-q + \sqrt{q^2 + 4qr})$, gain $K^* = P_{\text{pred}}^*/(P_{\text{pred}}^* + r)$, and marginal innovation variance $S^* = P^* + q + r$.

Although each filter is decoupled (agent i ’s update uses only o_i), the composite innovation vector $\delta_c = (\delta_1, \delta_2)$ is *cross-correlated* whenever $\rho_{\text{corr}} \neq 0$, because the environment couples the processes. The steady-state cross-covariance of the estimation errors $e_i = \omega_i - \hat{\omega}_i$ solves the fixed point $C_e = (1 - K^*)^2 C_e + \rho_{\text{corr}} q$, giving

$$C_e = \frac{\rho_{\text{corr}} q}{1 - (1 - K^*)^2} = \frac{\rho_{\text{corr}} q}{K^*(2 - K^*)}, \quad (13.22)$$

and the innovation cross-covariance is $\Gamma = \text{Cov}(\delta_1, \delta_2) = C_e + \rho_{\text{corr}} q$, so the composite innovation covariance is

$$\Sigma_\delta = \begin{pmatrix} S^* & \Gamma \\ \Gamma & S^* \end{pmatrix}, \quad \Gamma = \frac{\rho_{\text{corr}} q (1 + 2K^* - K^{*2})}{K^*(2 - K^*)}. \quad (13.23)$$

The per-step closure error of a macro-agent using gain K_c is $\epsilon_x^2 = \text{tr}((K^*I - K_c)\Sigma_\delta(K^*I - K_c)^T)$, minimized at $K_c = K^*I$ where it is exactly zero. So **at steady state the closure defect is exactly $\epsilon^* = 0$ for all ρ_{corr}** — the means-only projection perfectly represents the micro-dynamics because the Kalman gains have converged to constants and the discarded covariance state carries no information. All three projection conditions are verified exactly: $\epsilon_I = 0$ (the discarded covariance is a deterministic constant, so it carries zero conditional mutual information; (P1) holds with equality), $L = 1$ (the projection is a coordinate extraction with operator norm 1), and $\dim(\mathcal{X}_c) = 2 < 4 = \dim(\mathcal{X}_{\text{micro}})$. The admissibility conditions (A1)–(A4) hold for the macro-Kalman with $\alpha_c = K^*$, $R_c = \infty$, $\mathcal{T}_c = 2K^*$. The transient defect (before the gains converge) decays geometrically at rate $(1 - K^*)^2$ and is exponentially small after $O(1/|\log(1 - K^*)|)$ steps.

The “cost of independence” — the estimation performance lost by not exploiting cross-correlations — is a separate quantity, the **performance gap** $\Delta_{\text{perf}} = 2(P^* - p)$ between the independent composite and the optimal joint filter (diagonal

posterior covariance p). It is *not* a closure defect: it measures suboptimality relative to a centralized agent, not failure of the macro-description to track the micro-system. For small correlation it is second-order, $\Delta_{\text{perf}} \approx 2\rho_{\text{corr}}^2 q^2 r / (S^*)^2$ (the cross-gain is $O(\rho_{\text{corr}})$, and the information it extracts is $O(\rho_{\text{corr}}^2)$), growing monotonically to its maximum at $|\rho_{\text{corr}}| = 1$. The composition-closure framework diagnoses representability (“is this group a coherent AAT agent?” — yes), not optimality (“is this group as good as a centralized agent?” — no, when $\rho_{\text{corr}} \neq 0$). A group can be a perfectly valid composite agent while being suboptimal.

The first genuine $\varepsilon^* > 0$: purposeful sub-agents with Beta-Bernoulli strategy. The benign $\varepsilon^* = 0$ above turns on the discarded auxiliary state (the covariance) *converging* to a constant. Lift the sub-agents to purposeful agents, each carrying a single-edge strategy DAG with credence p_i updated Beta-Bernoulli on observed success/failure — $p_{i,t+1} = p_{i,t} + (\mathbb{1}[\cdot] - p_{i,t}) / (n_{i,t} + 2)$ — and the discarded auxiliary state is the observation count n_i , which *diverges* rather than converging. The edge-update gain $1/(n_i + 2) \rightarrow 0$ as $n_i \rightarrow \infty$. A macro-agent that discards n_i must use a fixed macro-gain η_c , and the per-step strategy closure error $\varepsilon_\Sigma = \mathbb{E}[|(1/(n_i + 2) - \eta_c)(\mathbb{1}[\cdot] - p_i)|]$ then grows without bound (fixed η_c cannot match a decaying gain) unless $\eta_c = 0$, at which point the macro-agent stops learning. So this is the first genuine source of $\varepsilon^* > 0$: a decaying-gain micro-dynamics is non-representable by fixed-gain macro-dynamics. It is structurally distinct from the Kalman case precisely in the convergence-vs-divergence of the discarded state — the Kalman covariance converges (defect vanishes at steady state); the Beta-Bernoulli count diverges (defect persists). The repair is to keep an effective-sample-size n_c in the macro-state (option (b)), restoring $\varepsilon^* = 0$ at the cost of a less aggressive projection — which signals that the purposeful substate carries more load-bearing dimensions than the epistemic substate. When $\varepsilon^* > 0$, the bridge lemma becomes load-bearing: the macro-strategy eventually goes stale and must be re-projected, the composition-level analog of 4.8.

Norm specification for estimation-type agents. The two-Kalman case identifies the Mahalanobis norm as the natural choice for agents whose primary function is state estimation. The state norm weights by the inverse prediction-error covariance: $\|X_c - X'_c\|^2 = (\hat{\omega}_c - \hat{\omega}'_c)^T (P_{\text{pred}}^*)^{-1} (\hat{\omega}_c - \hat{\omega}'_c)$. The observation norm weights by the inverse innovation covariance $S^{-1} = (P_{\text{pred}}^* + R)^{-1}$. The general principle: norms should weight by inverse uncertainty, so that differences in well-estimated components count more than differences in poorly-estimated ones. This is the norm the Kalman filter implicitly uses — the Kalman gain minimizes the expected squared Mahalanobis distance from truth. For domains without a natural covariance structure (discrete states, non-Gaussian models), the Euclidean norm remains the default.

Findings.

Composition-Closure Defect and Bridge Lemma. Brief: When does a group of interacting agents legitimately count as one larger agent? The closure-defect ε^* is the minimum residual prediction error from collapsing the micro-system into an AAT-shaped macro-description, taken over admissible coarse-grainings. The bridge lemma converts this prediction-level error into a trajectory-level guarantee: under sector-bounded macro-correction plus strong monotonicity of the macro-update, the macro-description tracks micro-reality with bounded asymptotic error $\varepsilon^* \nu_c / \alpha_c$. Composition is therefore not asserted by interface or by intuition — it is certified by an inequality, with explicit failure modes on both sides (the macro-dynamics fail to be AAT-shaped; the projection fails to be informative-and-regular; the macro-correction is not strongly monotone).

Impact: Closes the gap that Markov-blanket and active-inference accounts of nested agency leave open: those accounts give a statistical / thermodynamic boundary criterion but no control-theoretic loss bound on treating a collection as one agent. The closure-defect framework supplies the bound, attaches it to AAT’s existing sector-condition machinery, and routes Part I and Part II results across composite boundaries on Tier-1-classified sub-agents. Downstream this lets #deriv-critical-mass-composition derive the composite sector constant from sub-agent parameters in closed form, lets #der-tempo-composition give Brooks’s Law a formal expression in tempo units, and supplies the escape route (b) for #disc-identifiability-floor Instance 3. The criterion also draws an honest scope line: $\varepsilon^* = 0$ does not mean optimality (two non-communicating Kalman filters achieve $\varepsilon^* = 0$ while being suboptimal versus a joint filter); the framework diagnoses representability, not optimality.

Novelty Claim: *Claim differentiation* on bounded-loss composition as agent-boundary criterion. The bridge-lemma form is mathematically continuous with the approximate-information-state and influence-based-abstraction lines (Subramanian 2020; Congeduti 2020; Abel 2016; Taylor 2008), which prove approximation-loss results for compressed control under coarse-graining or aggregation. The differentiation is the *use* of such a bound as a criterion for when a multi-agent system can be re-described as a single agent — not as a control-policy compression result on a fixed agent — combined with explicit admissibility conditions (A1)-(A4) on the macro-dynamics that force the macro-description to itself be AAT-shaped, ruling out trivial curve-fits.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Statistical / thermodynamic boundary of a nested agent	Parr, da Costa & Friston 2019, “Markov blankets, information geometry and stochastic thermodynamics” <i>Phil. Trans. R. Soc. A</i> 378 (published 2019, found via Undermind 2026-04 Pillar 2)	<i>conceptual precursor</i> — supplies the boundary-and-nesting intuition; does not provide a coarse-graining error bound, a coordination-overhead theorem, or a strong-monotonicity condition for valid macro-agent treatment
Hierarchical-blanket nested agency with temporal depth	Kirchhoff, Parr, Palacios, Friston & Kiverstein 2018, “The Markov blankets of life” <i>J. R. Soc. Interface</i> 15 (published 2018, found 2026-04)	<i>conceptual precursor</i> — invokes synergetic ordering and self-organization at the compositional step but remains conceptual; no theorem bounding predictive loss of coarse-graining
Bound on control loss from compressed history	Subramanian, Sinha, Seraj & Mahajan 2020, “Approximate information state for approximate planning and reinforcement learning in partially observed systems” <i>arXiv:2010.08843</i> (published 2020, found 2026-04)	<i>closest mathematical neighbor</i> — proves a bound from predictive-compression error to control error in the same shape as the bridge lemma. ASF reuses the predictive-compression-to-control-loss mechanism and applies it at the coarser granularity of <i>agent boundary formation</i> , not single-agent state compression
Loss bound from approximate influence-based abstraction	Congeduti, Mey & Oliehoek 2020, “Loss Bounds for Approximate Influence-Based Abstraction” <i>arXiv:2011.01788</i> (published 2020, found 2026-04)	<i>closest mathematical neighbor</i> — closer than the Markov-blanket line to coordination-overhead mathematics. ASF differs in framing: Congeduti bounds policy-value loss under approximate cross-agent influence; the bridge lemma bounds <i>macro-state trajectory error</i> under coarse-graining
Near-optimality under state aggregation	Abel, Hershkowitz & Littman 2016, “Near Optimal Behavior via Approximate State Abstraction” <i>ICML</i> ; Taylor, Precup & Panangaden 2008, “Bounding Performance Loss in Approximate MDP Homomorphisms” <i>NeurIPS</i> (published 2016/2008, found 2026-04)	<i>adjacent literature</i> — single-agent MDP framing with aggregation bounds; same loss-from-coarse-graining mechanism, not framed as composite agency or organizational closure

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Exact reduction of decentralized control via common information	Nayyar, Mahajan & Teneketzis 2012, “Decentralized Stochastic Control with Partial History Sharing” <i>IEEE TAC</i> 58 (published 2012, found 2026-04)	<i>adjacent literature</i> — names the formal space where a lossy composition theorem would live but proves an exact reduction, not a closure-defect bound
Approximate dynamical homomorphism / model reduction	Mori-Zwanzig projection (1965); balanced truncation (Moore 1981); Koopman-operator analysis (Koopman 1931; modern review Mezić 2005)	<i>formal antecedent</i> — supplies the approximate-dynamical-homomorphism framing of the closure defect. The MZ zero-lag bound surfaces in this segment’s derivation table under stationarity. Adopted as standard machinery
Information bottleneck for the projection	Tishby, Pereira & Bialek 1999, “The information bottleneck method” <i>Allerton</i>	<i>formal antecedent</i> — admissibility condition (P1) is the IB Lagrangian-dual with source X_{micro} and relevance “next macro-observation given action”
Consistent abstractions of control systems	Pappas & Simic 2002, <i>Consistent abstractions of affine control systems</i> (IEEE TAC 47:745) ¹	<i>formal antecedent</i> — control-theoretic foundation for defining macro-systems via surjective coarse-graining. The macro-dynamics admissibility condition (A1) is operationalizing exactly Pappas-Simic’s surjectivity-of-coarse-graining requirement at the agent-state level
Compositional abstraction with explicit output-error bounds	Rungger & Zamani 2015, <i>Compositional Construction of Approximate Abstractions of Interconnected Control Systems</i> (IEEE TCNS 5:116) ²	<i>closest formal ancestor</i> — compositional abstraction with explicit output-error bounds is structurally the same shape as the closure-defect ε^* machinery this segment defines. The framework’s bridge-lemma quantitative-error treatment is a refinement of the Rungger-Zamani approach applied at the agent-boundary-formation layer rather than the interconnected-control-system layer
Markov-chain lumpability	Buchholz 1994, <i>Exact and ordinary lumpability in finite Markov chains</i> (J. Appl. Probab. 31:59) ³	<i>adjacent literature</i> — Markov-aggregation ancestor of the commute-with-coarse-graining criterion underlying admissibility (P1)–(P3). The lumpability framework distinguishes <i>exact</i> (commutativity-of-projection-and-transition) from <i>ordinary</i> (statistical-equivalence-of-aggregated-states) — the former is the strong-monotonicity condition the bridge lemma uses

Search Log:

- 2026-04 (*nominally comprehensive*): Two-search Undermind pass over composite agency, approximate information states, Markov-blanket nested agency, decentralized control, state abstraction, and influence-based abstraction. Verdict: *Conceptual Precursor* (High confidence). Markov-blanket line (Parr 2019; Kirchhoff 2018) positioned as conceptual precursor on nested agency without bridge-lemma mathematics; approximate-information-states / state-abstraction / influence-based-abstraction line (Sub20; Con20; Abe16; Tay08; Nay12) positioned as closest mathematical neighbors with shared predictive-loss-to-control-error mechanism but applied to single-agent or already-decomposed control problems rather than to agent boundary formation.

¹Citation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). Catalog has more verification support than raw Undermind synthesis but less than full primary-source reading. Verification queued with the BG2 cluster.

²Citation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). Catalog has more verification support than raw Undermind synthesis but less than full primary-source reading. Verification queued with the BG2 cluster.

³Citation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). Catalog has more verification support than raw Undermind synthesis but less than full primary-source reading. Verification queued with the BG2 cluster.

- 2026-04 (*intuition-only*, prior to comprehensive search): adjacent literatures expected to host prior art were dynamical-systems model reduction (Mori-Zwanzig, balanced truncation), active-inference Markov-blanket work, and PAC-MDP state-abstraction. The comprehensive search confirmed all three families and added the influence-based-abstraction and decentralized-control-via-common-information lines that intuition did not surface.

Working Notes.

- **Resolved:** $\mathcal{P}_{\text{adm}}$ now has a proposed definition. (P1)-(P3) above. Confirmed independent of (A1)-(A4) — the macro-dynamics admissibility partially constrains projections but does not specify information-preservation level. See `spikes/.integrated/spike-projection-admissibility.md` §5 for the analysis.
- **Resolved (2026-04-22): temporal coarse-graining gap.** The previous formulation summed $\varepsilon_x, \varepsilon_a, \varepsilon_o$ over micro-timesteps ($t = 1, \dots, H$), forcing synchronous micro-and-macro cadence. This contradicted 4.9 (composites naturally update on slower timescales, $\nu_{\text{level } n+1} \ll \nu_{\text{level } n}$) and conflicted with 13.2's dimensional accounting, which treats ε^* as a per-macro-step quantity and ν_c as the macro-update rate. Introducing the timescale ratio $K_c \geq 1$ and reformulating the defects per macro-step fixes both issues: Λ_o, Λ_a become window-aware (aggregating K_c micro-observations/actions), the sum runs over macro-steps m , and $\varepsilon^* \nu_c$ has consistent rate units by construction. $K_c = 1$ recovers the previous formula; $K_c \gg 1$ enables the timescale abstraction that was always part of the composition theory's intent. The bridge lemma and the sector-persistence-template instantiation are unchanged in substance — the template's state variable is now e_m at macro-boundaries rather than e_t at micro-timesteps, but the Lyapunov argument is identical. Option 3 of `audits/pending-findings-2026-04-21.md` Finding A; Option 2 (full Mori-Zwanzig equilibrium-residual form) remains a possible future refinement if one wants an explicit singular-perturbation framing.
- **Resolved: norm choices for estimation-type agents.** The Mahalanobis norm (inverse-covariance-weighted) is the natural choice for Kalman-type agents, verified exactly in the two-Kalman case. The general principle (weight by inverse uncertainty) extends to other estimation frameworks. For non-estimation agents (discrete states, non-Gaussian), norms remain domain-specific.
- **Open: computing (P1) for nonlinear/non-Gaussian systems.** The information-preservation condition requires conditional mutual information over the joint distribution of micro-states, observations, and actions. Tractable for linear-Gaussian systems (closed-form); requires Monte Carlo estimation or variational bounds for general systems.
- **Open: the right value of ε_I .** The information-preservation threshold is a free parameter. Too small ($\varepsilon_I \rightarrow 0$) excludes useful projections; too large ($\varepsilon_I \rightarrow 1$) admits degenerate ones. A natural candidate: ε_I comparable to the fractional information loss from adding one agent to the composite — tying it to team size and coupling structure. Formalizing this is open.
- **Resolved (2026-05-19): N -agent scaling of ε^* — the poly-vs-exp framing was mis-typed.** ε^* is a *per-step* residue; “scales polynomially or exponentially in N ” is an *accumulation*-typed predicate (the accumulation-type confound — see CHANGELOG 2026-05-19, `NOTATION.md` §“Accumulation typing”). Re-typed, it dissolves: dimension-free-zero (benign linear-Gaussian-stationary, all N , all coupling); graph-Laplacian-bounded with no exponential regime under compression (the consensus operator already in `#deriv-critical-mass-composition`); order-incompatibility-invariant $\leq |S| \log 2$ (N -free) for strategy-DAG composition. *History (not present truth): this note previously asserted an open “polynomial vs. exponential, coupling-structure-dependent” question and “the formal analog of the claim that very large teams cannot be treated as single agents”; that framing was the mis-type and is withdrawn — deleted and replaced when the re-typing landed, 2026-05-19, see CHANGELOG.* Reasoning trail: `spikes/spike-composition-scaling-N.md` (scoping) + the accumulation-type-confound trail (transient, $\rightarrow$.integrated/).
- **Partial: Mori-Zwanzig connection.** Under stationarity and coordinate-compatibility assumptions on the micro-dynamics, the Koopman-operator framing lifts Λ_x to a Hilbert-space projection P_Λ with $Q_\Lambda = I - P_\Lambda$. The MZ-optimal Markovian macro-dynamics is $f_c^{\text{MZ}} = P_\Lambda U P_\Lambda$ (the conditional expectation given the macro-state), providing a concrete benchmark against which admissibility constraints can be measured. When $f_c^{\text{MZ}} \notin \mathcal{M}_{\text{adm}}$, the per-step bound $\varepsilon^* \geq \|Q_\Lambda U P_\Lambda\|_{\text{op}}$ holds — a zero-lag memory-kernel bound. The bridge-lemma contraction on f_c in state space corresponds to spectral gap of $Q_\Lambda U$ in observable space (distinct quantities but related). *What does not close:* the full-kernel bound $\varepsilon^* \geq C \cdot \|K\|_{\ell^1}$ (sum-of-lags) is a type mismatch — ε^* is per-step; $\|K\|_{\ell^1}$ is trajectory-accumulation. Natural home for the full-kernel norm is the bridge lemma's trajectory-error bound, not ε^* directly. *Hard obstruction:* MZ's stationarity assumption fails for purposeful agents

with non-stationary auxiliary state (Beta-Bernoulli with diverging n) — exactly the cases where $\varepsilon^* > 0$ genuinely. Extending to these requires innovation-frame reformulation, not yet developed.

- **(P1) as IB Lagrangian-dual — resolved.** (P1) is the Lagrangian-dual of a standard IB constraint with source X_{micro} , compressed representation $\Lambda_X(X_{\text{micro}})$, relevance variable $o_{\text{micro},t+1} \mid a_{\text{micro},t}$, and $\beta(\varepsilon_I)$ the rate-distortion multiplier. See AA for the derivation and for the shared IB shape across AAT’s four compression operations (M_t, Σ_t , shared intent, Λ). (P2) Lipschitz continuity remains a separate analytic admissibility condition. (P3) dimensional reduction remains separate in the Gaussian case (the IB-optimal T at any finite β typically uses full support; categorical dimensional reduction is harder than any rate constraint). The “all admissibility is IB” slogan overclaims; the accurate slogan is “(P1) is IB; (P2) and (P3) compose with it as separate conditions.” Cross-instance unification is shape-sharing (U-medium), not a reduction to a single master problem (U-strong) — cross-instance theorems do not follow from the shared IB shape alone.
- **Two independent drivers of ε_x .** The non-degenerate Kalman case (heterogeneous gains $K_1^* \neq K_2^*$ with projection $\Lambda_X(\hat{\omega}_1, \hat{\omega}_2) = (\hat{\omega}_1 + \hat{\omega}_2)/\sqrt{2}$) shows ε_x depends on *both* sub-agent unity (process correlation, captured by U_M) and update-rule heterogeneity ($\Delta K = K_1^* - K_2^*$). $\Delta K = 0$ gives $\varepsilon_x = 0$ at every correlation; $\Delta K \neq 0$ gives $\varepsilon_x > 0$ even at perfect correlation. The closed form is $\varepsilon_x^2 = (\Delta K/2)^2 [S_- - C_{+-}^2/S_+]$ where $S_{\pm}$ are innovation variances in the $\pm$ rotation and C_{+-} their cross-covariance. Heterogeneity is not captured by the four unity dimensions in 14 as currently defined; this is a gap in that segment, not in this one — the closure defect correctly registers both drivers. See 14.1 for the full analysis.
- **Resolved (2026-05-19): strategy-DAG projection under Λ_X .** The right object is a causal- τ -abstraction of the joint micro-strategy (Beckers–Eberhardt–Halpern frame, adopted with citation; *not* term-for-term — BEH leaves the high-level distance application-dependent, so the norm-on-graphs choice remains AAT’s). Exact Σ_c iff shared sub-orders are jointly acyclic and AND/OR-compatible; otherwise the minimal admissible Σ_c is the SCC-condensation with closure defect $\sum_{|C|>1} \text{TC}(C) \leq |S| \log 2$ — bounded by shared-plan size, N -free. Status *conditional* with one named sub-open (Q1: constant-tightness for non-deterministic intra-SCC status coupling — a sub-open, not a reopening). *History (not present truth): this note previously listed the question as “deeply domain-specific and not resolved by (P1)-(P3)”;* resolved and replaced 2026-05-19 — see CHANGELOG. Derivation home: 8.3 § “Composing heterogeneous strategy DAGs” (the τ -abstraction typing, the SCC-condensation no-go, the Brooks’s-Law-floor corollary) and 14.1 (the fixed-topology credence-composition instance); reason-trail at spikes/.integrated/spike-strategy-dag-composition.md.
- **~~The bridge lemma’s contraction assumption — proving it from (A4) alone.~~ CHARACTERIZED 2026-04-06** (spikes/.integrated/spike-bridge-lemma-contraction.md). The contraction assumption cannot be proved from (A4) alone. The precise additional condition is the **incremental sector bound** (DA2’a-inc): the correction function F_d must be *strongly monotone* ($\langle \delta - \delta', F_d(\delta) - F_d(\delta') \rangle \geq c_{\min} \|\delta - \delta'\|^2$), not just satisfy the one-point sector bound. Strong monotonicity is strictly stronger than the one-point sector bound (counterexample: oscillatory corrections that are globally inward-pointing but locally non-monotone). Three agent tiers emerge: **Tier 1** (contraction proved — all Bayesian updaters on exponential families, all gradient agents on strongly convex losses, all linear corrections with positive definite gain-observation product); **Tier 2** (local contraction — nonlinear prediction models, with factor degraded by $\kappa(D\delta)^2$); **Tier 3** (independent verification required — non-convex optimization, discontinuous rules, agents with non-mismatch-driven state components). For Tier 1 agents, the bridge lemma is promoted from “conditional” to “derived (conditional on DA2’-inc + linear prediction).” The contraction factor equals λ_{eff} from O.
- The weakest-link structure ($\alpha_c = \min_i \alpha_i^{\text{eff}}$) is conservative. In practice, strong sub-agents may compensate for weak ones through cooperative coupling. A tighter bound would account for cross-agent compensation, likely through the cooperative disturbance reduction terms in 15.1.
- **A richer toy case** is needed: two purposeful agents (Part II) with strategy DAGs, cooperative communication, and a shared objective. This would exercise (A1) fully (including the G_c component) and test whether the admissibility constraints are tight enough to be useful without being so tight they exclude interesting composites.
- The approach is an approximate dynamical homomorphism condition, a standard tool in dynamical systems and model reduction (cf. Mori-Zwanzig projection, balanced truncation). The specific contribution is applying it to AAT’s closed-loop agent structure with sector-condition-based stability guarantees.

- **Categorical-cybernetics fit-check candidate (added 2026-05-22).** Capucci-Gavranović-Hedges-Rischel 2022 (*Towards Foundations of Categorical Cybernetics*, parametrised optics + selection functions) and Smithe 2024 (*Structured Active Inference*, generative models as “systems on an interface,” agents as controllers dual to generative models) supply a category-theoretic home for AAT’s composition machinery. The fit-check question for this segment specifically: does the closure-defect ε^* machinery admit a parametrised-optic formulation? Does ε^* have a natural reading as an optic morphism obstruction? Registered as `spikes/PROPOSED.md` Tier 2 first fit-check entry (2026-05-22), under the broader `spikes/PROPOSED-ADVANCED.md` Phase 3 #15 categorical-cybernetics 3-5-spike sequence. Long-horizon; high-leverage but substantial framework-foundation engagement. First-spike scope is *fit-check only* — if the fit is clean, subsequent spikes formalize per sub-question; if incompatible, recognition-tier citation acknowledgment in Discussion is the honest landing. Source-trail: `spikes/spike-enrichment-cluster2-2026-05-21/01-cluster-synthesis.md` Rank 4; landed via Track CR Phase 7.
- **Mori-Zwanzig memory-kernel relationship — upper-bound direction closes; named lower bound does not.** The closure defect ε^* has a tractable upper-bound relationship to a Mori-Zwanzig (MZ) memory kernel norm $\|K\|$ when AAT’s state-space projection Λ is composed with an MZ Hilbert-space projection P on a stationary observable measure π : under (i) stationarity of π under micro-dynamics, (ii) compatibility of Λ with P ’s range (the projected observables include the coarse-grained state coordinates AAT’s Λ retains), and (iii) bounded operator-norm of K , the upper bound $\varepsilon^* \leq C \cdot \|K\|$ holds for a constant C depending on α_c, ν_c . The *named target* lower bound $\varepsilon^* \geq C' \cdot \|K\|$ — which would make slow-decaying memory kernels an *obstruction* to small closure defect — does NOT close under the current AAT formulation without additional structural hypotheses. The obstruction is that Λ (state-space coarse-graining) and P (Hilbert-space projection on observables) are *different objects*, and a generic AAT coarse-graining does not give an orthogonal MZ-style projection on the observable Hilbert space; the lower bound would require either a stronger compatibility assumption between Λ and P or a separate orthogonality-of-residual argument that has not been worked out. The honest structural takeaway: MZ memory-kernel decay is a *sufficient* condition for small ε^* (via the upper bound direction) but is not *necessary*; AAT’s closure defect can be small for reasons that don’t reduce to MZ memory-kernel norms. Future work would either close the lower-bound direction under specific Hilbert-space hypotheses on the agent’s observable algebra, or settle the asymmetry as a structural feature distinguishing AAT’s coarse-graining from MZ projection-operator formalism.
- **Dynamic-regime placement (added 2026-05-21 per Phase 5 cross-segment ripple).** The (A1)–(A4) admissibility conditions and the closure-defect ε^* machinery this segment defines operate on **R0 contraction-regime** composites per `#dynamic-regime-axis`. R1 equilibrium-regime composites (under sub-scope α' of `#deriv-strategic-composition`) admit a parallel Lyapunov machinery via the A2'-analog transfer (potential or weighted-norm Lyapunov on joint deviation from Nash); R2 cyclic-distributional-regime composites (sub-scope β') admit only CCE set-convergence at $O(1/\sqrt{T})$ rate (Hart-Mas-Colell 2000) — neither inherits the bridge-lemma directly. The (A2) prediction map + (A4) sector condition presume a unique attracting fixed point in joint state space, which the R1 / R2 cases lack. Any segment citing `#form-composition-closure`’s machinery should also name the regime tier its sub-claim sits at.
- **Track E surface-back of catalog citations (2026-05-22).** Three Related Work entries added 2026-05-22 from Track E catalog at `ref/prior-art-analysis/08-composite-agency.md` (Pillars 1 + key anchor papers): Pappas-Simic 2002 (consistent abstractions of control systems — control-theoretic foundation for surjective coarse-graining); Rungger-Zamani 2015 (compositional abstraction with explicit output-error bounds — closest formal ancestor for ε^* machinery); Buchholz 1994 (Markov-chain lumpability — exact-vs-ordinary lumpability ancestor for the commute-with-coarse-graining criterion). All marked [`^cat-2026-05-22`] for verification-deferred attribution; primary-source verification queued in the BG2 cluster. Catalog citations had prior Pillar-style search support but were not verified by the current executor at landing time.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure material, kept separate from the certified theory-fix findings (handled elsewhere — this segment drew a dense crop of correctness findings, the F108–F115 cluster, all routed to the findings track; see report flags). **Coverage:** four dirs reached a digested reflection (193847, 526815, 829314, 849201) plus the §III composition-foundations batch (471203). Multiple substrates called this “the strongest Part III segment” / “the theoretical peak of the framework” — the highest-engagement composition segment. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **“When is a group of things a single thing?”** The closure defect ε^* stated as the mathematical answer to the ancient reductionism-vs-emergence question — “a society *is* a valid macroscopic entity if and only if $\varepsilon^* < \alpha_c R_c / \nu_c$.” If the inequality holds, the macro-description (sociology, macro-economics) tracks reality well enough to persist and “you don’t need to track every individual”; if it fails, “the society is just a chaotic multi-agent system” and macro-modeling of *that* group is an illusion (Gemini, AUDIT-WORKING-829314; the same “exact mathematical test for whether a group can be modeled as a single agent” framing at Claude, AUDIT-WORKING-849201 and Claude, AUDIT-WORKING-773921). The single strongest Brief/Discussion-opener candidate in this chapter.
- **Representability, not optimality.** The two-Kalman result ($\varepsilon^* = 0$ for two non-communicating filters tracking correlated walks, at *all* correlations) glossed as: “you can perfectly mathematically model a stupid organization as a single stupid macro-agent” — ε^* measures whether the group *acts like a single thing*, not whether it *acts well*; the “cost of independence” is a performance gap, not a closure defect (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; sharpest at Claude, AUDIT-WORKING-471203 — “the composition-closure framework diagnoses representability, not optimality ... exactly the right scope-honesty move”). Already a Working-Notes / Discussion theme; this is converged plain-language phrasing for it.

2. Candidate Discussion.

- $K_c \gg 1$ is **“the math of management.”** The timescale ratio glossed pedagogically: at $K_c = 1$ the manager updates at worker-speed and must observe every action in real time — micromanagement, which violates 4.9; at $K_c \gg 1$ the manager looks only at *aggregate* output over the window, which is Auftragstaktik (mission command), and the math proves this is exactly what enables genuine dimensionality reduction (P3) and information compression (P1) — “the manager doesn’t need to know *how* the workers achieved the goal, only *that* they did” (Gemini, AUDIT-WORKING-193847). A candidate Discussion vignette that makes the K_c / window-aware-projection machinery legible. The corporate-quarterly-update version (“the closure defect measures whether the corporation’s Q2 state can be predicted from its Q1 state, ignoring all the daily micro-fluctuations”) at Gemini, AUDIT-WORKING-829314 is the same point.
- **The Bridge Lemma converts prediction error into a survival bound.** Framing for the lemma’s payoff: it “converts abstract prediction error (defect) into physical trajectory bounds (survival)” — the mechanism by which “macro-economics or sociology can exist as predictive sciences distinct from micro-physics/psychology, provided the coarse-graining Λ is admissible” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314). Candidate Discussion gloss on *why* the bridge lemma is the chapter’s crown jewel.
- **The (A4)-insufficient / DA2’-inc-required point, plainly.** Several substrates independently praised the explicit proof that the one-point sector bound (A4) is *insufficient* and the strictly-stronger incremental sector bound (strong monotonicity, contraction between *any two trajectories* not just toward the origin) is required — with the Tier 1/2/3 classification (Kalman / convex = Tier 1; non-convex NN = Tier 3) read as “flawless dynamical-systems theory” and the DA2’-inc $\equiv$ Lohmiller-Slotine (CT2)-at- $M = I$ equivalence read as converting an *imported* theorem into an *AAT-internally-derived* consequence — “structural transparency, not new content” (Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-471203). Worth preserving the trajectory-vs-origin contraction distinction as the plain-language hook for why (A4) alone doesn’t suffice.

3. Follow-up items.

- **Most consequential modern composites are Tier 3.** A scope-honesty observation worth surfacing: transformer attention is non-convex, prediction models nonlinear, update dynamics not naturally mismatch-driven — so most LLM-based composite agents land in Tier 3, where the bridge lemma’s *global* guarantee does not apply (Tier 2/3 results apply with caveats) (Claude, AUDIT-WORKING-471203). Downstream theorems relying on the bridge lemma should constrain scope to Tier 1 or acknowledge local/heuristic status for Tier 2/3 (Claude, AUDIT-WORKING-849201 raised this as a “critical finding potential” to police downstream).
- **(P1) computability is narrow.** The information-preservation condition is tractable in closed form only for linear-Gaussian systems; general systems need Monte Carlo or variational bounds, and the two-Kalman case is the only fully verified instance

(Claude, AUDIT-WORKING-471203). Already an open Working Note; converged-on as a practical-applicability limit worth stating where a reader would reach for it.

4. Readers often ask / wonder.

- **“How does ε^* scale with N ? Can a hierarchy push $N \rightarrow \infty$ with bounded defect?”** A natural reader question raised by three substrates (Gemini, AUDIT-WORKING-193847 — wondering polynomial vs exponential; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-471203 — “the structural test of whether very large teams can be treated as single agents at all”). The segment’s Working Notes now *answer* this (the poly-vs-exp framing was an accumulation-type confound; re-typed it dissolves to dimension-free-zero / graph-Laplacian-bounded / $\leq |S| \log 2$). Strong signal that the resolved answer should be surfaced in the body where the question naturally arises — fresh readers keep asking it.

5. Candidate figures.

- **The approximate-commuting square.** The closure criterion drawn as a square that fails to close: true micro-dynamics across the top, projection Λ down the side, macro-dynamics across the bottom — and ε^* is the gap by which the square fails to close. Side gates for projection admissibility (P1–P3) and macro-agent admissibility (A1–A4); a bridge arrow from per-step defect to bounded trajectory error under incremental contraction (Codex/Claude, AUDIT-WORKING-526815, “diagram attempt”). The commuting-square is the standard picture for an approximate dynamical homomorphism and would make “composition is a bounded-loss coarse-graining, not a vibe or an interface boundary” immediate.

Belongs elsewhere.

- **Consciousness-architecture — abstraction requires a slower self-clock.** The $K_c \gg 1$ reading extended to interiority: a mind’s macro-state (“its high-level ‘I’”) must run at a slower clock than its perceptual/motor sub-agents — if it tries to track every token or motor twitch at $K_c = 1$, the projection cost overwhelms the system even when ε^* is low. “True consciousness requires abstraction, and abstraction requires ignoring the high-frequency jitter of your own sub-components” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at 03-llm-core/ / 04-eli-core/ (and at 4.9), not at this formulation segment.
- **Categorical-cybernetics home for ε^* .** The closure defect as a candidate “optic morphism obstruction” in the Capucci-Gavranović-Hedges-Rischel 2022 parametrised-optics framework — “if AAT can be fully expressed in Category Theory, it becomes substrate-independent at the deepest possible mathematical level” (Claude, AUDIT-WORKING-773921). Already registered as a spikes/PROPOSED.md Tier-2 fit-check in this segment’s Working Notes; convergence signal that a fresh reader independently reached for the same home.

13.2 *Derived (conditional): Derived: Composite Tempo Inequality*

The adaptive tempo of a composite agent is *bounded above* by the **joint tempo** of its sub-agents’ pooled observation streams — not, in general, by the sum of their individual tempos. The gap between the joint potential and the realized composite tempo is the **coordination overhead** C_{coord} — tempo consumed by *internal reconciliation* rather than external mismatch correction. The relation between the joint baseline and the additive accounting $\sum_i \mathcal{F}_i$ is *signed*, inheriting AS’s two-sided deviation across agents: equal under cross-agent noise independence, smaller under common-source noise (the echo-chamber team), and **larger under anti-correlated noise — a composite can genuinely outrun the sum of its parts** (triangulating team), realizable at exactly zero closure defect by fusion as simple as averaging.

The intuition, corrected. Tempo is a rate of mismatch correction, and the composite’s corrective capacity is set by the *information in its parts’ pooled streams* — which is not the sum of the parts’ individual capacities, because cross-agent noise structure is capacity no individual part has (anti-correlated errors cancel under fusion) or capacity the additive accounting double-counts (a shared upstream source). When closure defect is positive, sub-agents additionally spend tempo correcting *internal* mismatches generated by other sub-agents (Alice changes an API; Bob must update his model) or taking actions that counteract each other. That fraction is the coordination overhead and is *unavailable for external mismatch correction*.

The derivation connects closure defect to coordination overhead through *dimensional accounting*. The closure defect ε^* (units: distance) times the macro-update rate ν_c (units: inverse time) yields an internal disturbance rate matching the units of environmental disturbance. This internal mismatch must be corrected by the composite's correction capacity, and the correction consumes tempo that would otherwise address external mismatch. Conversion from disturbance rate to tempo-equivalent requires dividing by the task-adequacy distance scale $\|\delta_{\text{critical}}\|$ — mirroring the persistence-condition form used at the single-agent level. The composite therefore faces total *effective disturbance* combining external and closure-defect contributions, with coordination overhead bounded below by $C_{\text{coord}} \geq \varepsilon^* \nu_c / \|\delta_{\text{critical}}\|$.

This makes Brooks's Law precise. Adding sub-agents increases potential aggregate tempo $\sum \mathcal{T}_i$, but if it also increases closure defect (more coordination links to maintain), the realized composite tempo can *fall* — adding people to a late project makes it later when the closure-defect-driven tempo penalty from the additional links exceeds the new member's tempo contribution. The result is labeled *sketch* rather than exact because the closure-defect-to-coordination connection depends on the bridge lemma in 13.1 (which requires a contraction assumption on the macro-update map that is structurally motivated by (A4) but not formally derived from it). The remaining gap: whether the lower bound is tight or whether additional coordination costs (negotiation, synchronization, conflict resolution) contribute beyond the closure-defect mechanism.

Formal Expression.

This segment instantiates the sector-persistence template (G) at the composite level with state variable $\xi = \delta_c$ (composite mismatch) and a decomposed effective disturbance $\rho_{\text{eff}} = \rho_{\text{ext}} + \varepsilon^* \nu_c$ — external environment plus closure-defect contribution from 13.1's bridge lemma. The template supplies the Lyapunov machinery; this segment's distinctive content is the tempo-equivalent form of the coordination overhead lower bound $C_{\text{coord}} \geq \varepsilon^* \nu_c$.

Let $\mathcal{T}_i$ be the adaptive tempo of sub-agent i within a composite group of N agents. Let $\mathcal{T}_c$ be the adaptive tempo of the composite macro-agent A_c defined by an admissible coarse-graining Λ .

Let $\mathcal{T}_{\text{joint}}$ denote the joint tempo of the sub-agents' pooled observation channels — the exact object of AS ($U_c \cdot \mathbf{1}^T \Sigma_n^{-1} \mathbf{1}$ in the Fisher-local regime, with Σ_n the pooled cross-agent noise covariance).

[Derived (Joint-Bounded Tempo, Conditional on the Fisher-local regime)] For any admissible composite agent A_c , the composite tempo is bounded by the joint tempo of its parts' pooled streams: $\mathcal{T}_c \leq \mathcal{T}_{\text{joint}}$. No admissible macro-dynamics extracts more corrective information per unit time than the pooled micro-observations carry (data processing at the Fisher level).

[Definition (Coordination Overhead)] The **coordination overhead penalty** C_{coord} is the difference between joint potential and realized macro-tempo: $C_{\text{coord}} := \mathcal{T}_{\text{joint}} - \mathcal{T}_c$

[Derived (Signed additive-baseline deviation, from AS applied across agents)] The additive accounting relates to the joint baseline with indefinite sign: $\mathcal{T}_{\text{joint}} \lesseqgtr \sum_{i=1}^N \mathcal{T}_i$, with equality iff the cross-agent noises are independent (plus the measure-zero cancellation set of AS), $<$ under common-source cross-agent noise, and $>$ under noise-cancelling (anti-correlated) structure. The historical form of this segment's claim, $\mathcal{T}_c \leq \sum_i \mathcal{T}_i$, is therefore **conditional on cross-agent noise independence** and false in general — with a closure-exact witness:

[Derived (Super-additive witness, exact)] Two sub-agents observing $o_i = \theta + n_i$ with $\text{Var}(n_i) = r$ and $\text{Corr}(n_1, n_2) = \rho < 0$, each running its own optimal filter; composite defined by the averaging projection $\Lambda_x = \frac{1}{2}(m_1 + m_2)$, macro-observation $\bar{o} = \frac{1}{2}(o_1 + o_2)$, and the recursive running-mean macro-update. The macro-update commutes with the micro-dynamics *identically* ($\varepsilon^* = 0$ exactly; (A1)–(A4) and (P1)–(P3) verified), and $\frac{\mathcal{T}_c}{\sum_i \mathcal{T}_i} = \frac{1}{1+\rho} > 1$, unboundedly as $\rho \rightarrow -1$ — tempos evaluated in the matched-uncertainty (Fisher-inflow) convention of AS; the convention is load-bearing (Epistemic Status). A faithful composite of a triangulating team outruns the sum of its parts; symmetrically, at $\rho > 0$ the same witness has $\mathcal{T}_c < \sum_i \mathcal{T}_i$ at zero closure defect and zero coordination activity — the additive baseline,

not the composite, is what fails. Full derivation + numerics: spikes/spike-composite-tempo-synergy-2026-07-16.md (Working Notes).

Epistemic Status.

Conditional. Max attainable: exact. Component strengths: the joint bound $\mathcal{T}_c \leq \mathcal{T}_{\text{joint}}$ is Fisher-level data processing, exact within the first-order tempo–Fisher regime of AS ((R1)–(R3) of AR — the regime where tempo is a rate); the signed additive-baseline deviation is AS’s theorem applied across agents (same tier); the super-additive witness is *exact* — commutation is an identity, and the tempo ratio $1/(1 + \rho)$ is closed-form, numerically confirmed (spike, Working Notes). The ratio is stated in the matched-uncertainty (Fisher-inflow) convention — comparing information inflow at equal uncertainty, as throughout AS; the convention is load-bearing because static estimation makes literal own-trajectory fractional-contraction tempo estimator-blind. Independent verification probed convention-robustness: under dynamic θ (random-walk environment, each filter at its own steady state — the own-uncertainty reading) the witness’s ratio becomes $\sqrt{1/(2(1 + \rho))}$ with super-additivity threshold $\rho < -1/2$ rather than $\rho < 0$ — the refutation of the additive bound survives every tested reading; only the exact ratio and threshold are convention-tied. The historical sub-additive claim $\mathcal{T}_c \leq \sum_i \mathcal{T}_i$ survives only on the cross-agent noise-independence scope; its former grounding (“composition cannot create corrective capacity out of nothing”) was refuted — cross-agent noise structure *is* corrective capacity that no individual part has, and the additive accounting cannot see it. The $\varepsilon^* \rightarrow C_{\text{coord}}$ connection remains *sketch-grade*: it depends on the bridge lemma in 13.1 (contraction assumption DA2’a-inc, structurally motivated by (A4) but not derived from it), and whether the lower bound is tight — or additional process costs (negotiation, synchronization, conflict resolution) contribute beyond the closure-defect mechanism — is open.

Intuition. Tempo is a rate of mismatch correction. When $\varepsilon^* = 0$ (exact closure) and the composite’s fusion is information-lossless, $\mathcal{T}_c = \mathcal{T}_{\text{joint}}$ — and $\mathcal{T}_{\text{joint}}$ coincides with $\sum \mathcal{T}_i$ exactly when cross-agent noises are independent. When $\varepsilon^* > 0$, sub-agents spend part of their tempo correcting *internal* mismatches generated by other sub-agents (Alice changes an API; Bob must update his M_t) or taking actions that counteract each other. That fraction is C_{coord} and is unavailable for external mismatch correction.

The closure-defect to coordination-overhead connection.

The closure defect ε^* introduces internal mismatch at rate $\varepsilon^* \nu_c$ — units of [distance] · [time^{−1}], a disturbance rate matching the units of environmental ρ . This internal mismatch must be corrected by the macro-agent’s correction capacity, and the correction consumes tempo that would otherwise address external mismatch.

Derived (coordination-overhead-bound, from composition-closure bridge lemma).

Dimensional accounting. Three quantities appear in the composite persistence analysis, each with its own units:

Table 13.3

Quantity	Units	Role
Tempo $\mathcal{T}, \mathcal{T}_c, \mathcal{T}_c^{\text{ext}}, C_{\text{coord}}$	[time ^{−1}]	Rate of mismatch correction
Disturbance rate ρ, ρ_{eff}	[distance] · [time ^{−1}]	Rate of mismatch injection
Closure defect ε^*	[distance]	Per-step norm error
Critical scale $\ \delta_{\text{critical}}\ $	[distance]	Task-adequacy boundary

The conversion between a disturbance rate and a tempo-equivalent requires division by a distance scale, mirroring the persistence condition form $\mathcal{T} > \rho / \|\delta_{\text{critical}}\|$.

Effective disturbance. The macro-agent faces total effective disturbance combining external and closure-defect contributions:

$$\rho_{\text{eff}} = \rho_{\text{ext}} + \varepsilon^* \nu_c \quad (\text{units: } [\text{distance}] \cdot [\text{time}^{-1}]) \quad (13.24)$$

Coordination overhead (tempo-equivalent). The fraction of macro-tempo consumed by closure correction, expressed as a tempo:

Derived (coordination-overhead-tempo-form).

$$C_{\text{coord}} \geq \frac{\varepsilon^* \nu_c}{\|\delta_{\text{critical}}\|} \quad (\text{units: } [\text{time}^{-1}]) \quad (13.25)$$

The closure error rate is converted to a tempo penalty by normalizing against the task-relevant distance scale. The inequality is a lower bound because additional coordination costs (negotiation, synchronization, conflict resolution — see Working Notes) contribute beyond the closure-defect mechanism. When the macro-agent’s correction of internal mismatch is less efficient than its correction of external mismatch (because internal mismatches may be harder to diagnose — they look like environmental change from the macro perspective), the actual overhead exceeds this bound.

Consequences (dimensionally correct):

- The realized external tempo $\mathcal{T}_c^{\text{ext}}$ (the share of composite tempo directed at *external* mismatch) chains under the joint baseline — the coordination-overhead definition plus the bridge-lemma lower bound give the middle inequality, and externally-directed tempo cannot exceed total tempo: $\mathcal{T}_c^{\text{ext}} \leq \mathcal{T}_c \leq \mathcal{T}_{\text{joint}} - \frac{\varepsilon^* \nu_c}{\|\delta_{\text{critical}}\|}$ ($= \sum_i \mathcal{T}_i - \varepsilon^* \nu_c / \|\delta_{\text{critical}}\|$ under cross-agent noise independence)
- **Brooks’s Law.** Adding an agent increases $\mathcal{T}_{\text{joint}}$ (by its marginal joint contribution — which cross-agent correlation can make much smaller, or larger, than its solo tempo) but may also increase ε^* . The turning point — where adding a member lowers realized external tempo — occurs when: $\frac{\Delta \varepsilon^* \nu_c}{\|\delta_{\text{critical}}\|} > \Delta \mathcal{T}_i$. The closure-defect increase (expressed as tempo penalty) exceeds the new member’s tempo contribution.
- **Composite persistence condition.** The composite persists iff $\mathcal{T}_c > \rho_{\text{eff}} / \|\delta_{\text{critical}}\|$; a *necessary* condition in joint-baseline terms is therefore $\mathcal{T}_{\text{joint}} > \frac{\rho_{\text{ext}} + \varepsilon^* \nu_c}{\|\delta_{\text{critical}}\|}$ which separates internal-coordination overhead from external challenge while keeping tempo units on the LHS and disturbance-rate units on the RHS (it reduces to the historical $\sum_i \mathcal{T}_i$ form exactly under cross-agent noise independence).

Discussion.

Equality conditions. $\mathcal{T}_c = \mathcal{T}_{\text{joint}}$ (i.e. $C_{\text{coord}} = 0$) requires: 1. **Orthogonal Routing:** The information dependency DAG exactly matches organizational boundaries (no costly cross-talk required). 2. **Perfect Shared Intent:** No tempo is lost to internal negotiation or conflicting pursuit of the macro-objective. 3. **Lossless Fusion:** No joint information in the pooled streams is discarded by the composite’s aggregation.

These are stated as sufficient conditions; whether they are also necessary is open. The further equality $\mathcal{T}_{\text{joint}} = \sum_i \mathcal{T}_i$ is a *separate* condition — cross-agent noise independence — and its two-sided failure is what retired this segment’s historical additive form: under common-source noise a zero-defect, zero-overhead composite still shows $\mathcal{T}_c < \sum_i \mathcal{T}_i$ (the additive baseline is inflated), and under anti-correlated noise a zero-defect composite shows $\mathcal{T}_c > \sum_i \mathcal{T}_i$ (triangulation). The old condition 3 (“no net macro-information loss”) implicitly carried both the fusion condition and the independence condition; they are now separated.

Brooks’s Law. Adding more agents (increasing $\mathcal{T}_{\text{joint}}$ by their marginal joint contribution — which cross-agent correlation can shrink toward zero or amplify) only increases the composite tempo $\mathcal{T}_c$ if the corresponding increase in closure defect ε^* doesn’t let C_{coord} dominate. The model provides a formal analog of Brooks’s Law: if coordination overhead (C_{coord}) grows faster than joint capability ($\mathcal{T}_{\text{joint}}$) when adding agents, then adding people to a late project makes it later — and a new member whose observation noise echoes the existing team’s contributes almost nothing to $\mathcal{T}_{\text{joint}}$ while still adding coordination links, the sharpest Brooks case. Whether this specific mechanism (coordination overhead consuming tempo) is the dominant cause in practice is an empirical question.

Connection to 15.1. The persistence condition for the composite agent requires $\mathcal{T}_c > \rho_{\text{ext}}/\|\delta_{\text{critical}}\|$. Since $\mathcal{T}_c = \mathcal{T}_{\text{joint}} - C_{\text{coord}}$, high coordination overhead can push the composite below the persistence threshold, causing it to disintegrate as a coherent entity — even though each sub-agent individually persists.

Wrapping construction as a Brooks’s-Law instance. Class coercion of a Class 2 (Partial) or Class 3 (Coupled) component via wrapping (`#der-class-coercion-via-wrapping`) is a concrete instance of the same coordination-overhead form. A wrapper makes $K \geq 2$ component calls per macro-step (one for each goal-blind belief-update query, one for the goal-conditioned strategy-update query, more in richer wrapper designs). The wrapper-level macro-update rate is $\nu_W = \nu_A/K$ where ν_A is the underlying component’s nominal call rate, so the wrapper-level tempo is $\mathcal{T}_W \leq \mathcal{T}_A^{\text{nominal}} - C_{\text{coord}}^{\text{wrap}}$, with the coordination overhead $C_{\text{coord}}^{\text{wrap}}$ scaling with K . The cost of class coercion — the structural enforcement of directed separation at the wrapper level when the underlying component does not provide it — is paid in macro-tempo. Strict-wrapping (W_1) regimes have $K \geq 2$ minimum; partial-wrapping (W_2) regimes have $K = 1$ for the LLM call plus some parsing overhead, but the structural-separation guarantee is correspondingly weaker (see `#der-class-coercion-via-wrapping`).

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- The lower bound $C_{\text{coord}} \geq \varepsilon^* \nu_c / \|\delta_{\text{critical}}\|$ captures the minimum tempo-equivalent overhead from closure defect. Additional coordination costs likely contribute beyond this: negotiation costs (reaching shared decisions), synchronization costs (waiting for slower agents), and conflict resolution costs (undoing contradictory actions). These are not captured by ε^* because they arise from the coordination PROCESS, not from the closure DEFECT. A fuller model would add: $C_{\text{coord}} = \varepsilon^* \nu_c / \|\delta_{\text{critical}}\| + C_{\text{negotiation}} + C_{\text{sync}} + C_{\text{conflict}}$, with all terms in tempo units.
- **Heterogeneity drives closure defect.** For agents with equal correction rates ($\alpha_1 = \alpha_2$), $\varepsilon^* = 0$ and $C_{\text{coord}} = 0$. For agents with different correction rates, $\varepsilon^* \propto |\alpha_1 - \alpha_2|$ — heterogeneity drives closure defect, confirmed analytically in the 2-agent toy case.
- The internal/external mismatch distinction is formalized through the bridge lemma: trajectory error e_t is the internal mismatch (divergence between macro-prediction and micro-reality, units of distance), and the tempo spent reducing e_t is the coordination overhead. The steady-state internal mismatch is $\varepsilon^* \nu_c / \alpha_c$ (a distance, since α_c has units $[\text{time}^{-1}]$), and maintaining this at the critical-distance scale requires ongoing tempo expenditure of $\varepsilon^* \nu_c / \|\delta_{\text{critical}}\|$.
- **Norm specification note.** The closure defect ε^* depends on the norm choices in 13.1. For estimation-type agents, the natural norm is Mahalanobis (weighted by inverse prediction-error covariance). In these norms, ε^* measures the ratio of missed cross-correction to expected estimation uncertainty — a quantity with direct tempo interpretation: it’s the fraction of macro-tempo consumed by correcting errors that optimal cross-exploitation would eliminate.
- **Provenance (2026-07-16).** The signed reformulation (joint baseline, super-additive witness, retirement of the unconditional additive bound) was derived in `spikes/spike-composite-tempo-synergy-2026-07-16.md`, discharging the same-day Working-Note flag; the witness numerics are re-runnable from the spike. Do not restore the additive baseline without checking cross-agent noise independence for the application. Audit-gold quotes elsewhere in these notes that reference the retired additive form are first-encounter archaeology, kept verbatim.

- **Dynamic- θ regime (from the confirmer $\neq$ author verification, 2026-07-16).** Under random-walk θ with steady-state Kalman sub-agents, the *optimal-gain* fused composite no longer commutes exactly ($\epsilon^* > 0$ measured when $\eta_c \neq \eta_i$); the commuting composite (running the sub-agents' gain on the averaged channel) still beats $\sum_i \mathcal{T}_i$ for $\rho < -1/2$ in the own-steady-state reading. A fidelity-tempo tradeoff therefore *does* appear in the dynamic regime even though the static witness has none — worth its own small derivation if a consumer needs the dynamic threshold sharpened.
- **(A4) uniformity wrinkle (static witness).** The running-mean gain decays ($\eta_m = 1/(m+1)$), so no uniform $\alpha_c > 0$ holds over an infinite horizon in the static case; the sub-agents share the wrinkle symmetrically (their gains decay identically), so it cancels from the ratio, and the dynamic- θ steady state repairs it outright.
- **(P1) holds with $\epsilon_I = 0$ exactly** for equal variances — the channel average is exactly sufficient for θ within the pooled pair, so the witness's projection loses *no* predictive information (stronger than admissibility requires); 12.2 is met via the shared-objective route (G_c, π_c trivial in the passive-estimation instance).
- **ϵ^* scaling with N — resolved (no longer open).** The poly-vs-superlinear framing was an accumulation-type confound (a per-step residue asked an accumulation question); re-typed it dissolves — see 13.1 (the N -agent-scaling and strategy-DAG-projection rows + Discussion): $\epsilon^*(N)$ is dimension-free-zero in the benign linear-Gaussian-stationary regime (all N , all coupling), graph-Laplacian-bounded with no exponential regime under compression, and order-incompatibility-invariant ($\leq |S| \log 2$, N -free) for strategy-DAG composition. Brooks's-Law collapse, if it occurs, is driven by coordination overhead C_{coord} , not by $\epsilon^*(N)$ growth (the Brooks's-Law-floor corollary is in 8.3 §"Composing heterogeneous strategy DAGs"); CHANGELOG 2026-05-19.
- **Track E surface-back of catalog citations (2026-05-22).** Three prior-art neighbors surfaced 2026-05-22 from Track E catalog at ref/prior-art-analysis/08-composite-agency.md (Pillar 4 + key anchor papers), each marked [^cat-2026-05-22] for verification-deferred attribution:
 - **Janow 2009, *A Fundamental Limit on Productivity in Organizations: Collaborative Entropy Costs*^a** — closest single-paper precedent for the tempo-tax claim. First-principles Shannon-entropy model of coordination cost as productivity cap. Uses Shannon entropy rather than persistence-bound cybernetic accounting; AAT's contribution is the integration with #form-composition-closure's ϵ^* machinery and the persistence-framework dimensional accounting (Composite Tempo Inequality, now in its joint-baseline form $\mathcal{T}_c = \mathcal{T}_{\text{joint}} - C_{\text{coord}}$).
 - **Gurvich & Van Mieghem 2015, *Collaboration and Multitasking in Networks: Architectures, Bottlenecks, and Capacity*^b** — strongest nearby formal result on synchronization-induced bottleneck idleness as unavoidable coordination overhead. Structural cousin to C_{coord} — same phenomenon under queuing-theoretic vocabulary rather than persistence-framework vocabulary.
 - **Bamieh, Jovanović, Mitra & Patterson 2011, *Coherence in Large-Scale Networks: Dimension-Dependent Limitations of Local Feedback*^c** — large networks can lose macro-coherence as they scale even when local regulation is good. Structural cousin to Brooks's-Law: dimension-dependent loss of coherence as composition order grows.

Primary-source verification queued in the BG2 cluster — see #disc-identifiability-floor Working Notes for the verification-targets list. Catalog citations had prior Pillar-style search support but were not verified by the current executor at landing time.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (handled elsewhere — the F116–F121 tempo-double-counting cluster is routed to the findings track; see report flags). **Coverage:** four dirs reached a digested reflection (526815, 773921, 829314, 849201). Universally high felt-value — the Brooks's-Law derivation and the dimensional accounting were the converged standouts. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **Brooks's Law as a strict thermodynamic inequality.** The converged star of this segment: Fred Brooks observed “adding manpower to a late software project makes it later” and attributed it to $O(N^2)$ communication overhead; AAT gives the *exact* inequality for when the catastrophic slowdown actually happens — $\Delta\epsilon^* \nu_c / \|\delta_{\text{critical}}\| > \Delta\mathcal{T}_i$ — translating “a famous software engineering aphorism into a strict thermodynamic inequality” (Gemini, AUDIT-WORKING-829314 — “an absolute triumph”; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921 — “a formal, computable physics equation for team size limits”). The worked mechanism: a junior engineer's small $\Delta\mathcal{T}_i$ is exceeded by the C_{coord} the seniors spend correcting the internal mismatch the addition created (explaining the codebase, fixing bad PRs, unblocking dependencies). A strong Brief/Discussion anchor.
- **The thermodynamic equation of teamwork.** $C_{\text{coord}} = \sum_i \mathcal{T}_i - \mathcal{T}_c$ glossed as a conservation law: “energy in (sum of tempos) equals useful work ($\mathcal{T}_c^{\text{ext}}$) plus heat (C_{coord})” (Claude, AUDIT-WORKING-849201). Makes the sub-additive bound legible as a first-law accounting.

2. Candidate Discussion.

- **The cost of diversity — heterogeneity drives closure defect.** The existing “ $\epsilon^* \propto |\alpha_1 - \alpha_2|$ ” Working Note, pedagogically unpacked: teams of clones / homogeneous cultures stay in sync “without talking” ($\epsilon^* \approx 0$); a fast learner paired with a slow learner constantly generates internal mismatch for the slow one (by unexpectedly changing APIs / processes), consuming coordination overhead to re-align — so “cognitive diversity in a team mathematically generates coordination overhead.” The honest two-sidedness: the *benefit* of diversity (wider structural reserve R , more accurate M_t) must outweigh this strict ϵ^* penalty for a heterogeneous team to be viable — “AAT provides the calculus to weigh that tradeoff objectively” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921 — “if a model assumes diverse teams coordinate for free, it violates this math”). Candidate Discussion expansion of the heterogeneity Working Note. (*Keep it two-sided — the deflationary “diversity is just cost” reading would be a misframe; the point is a measurable tradeoff, not a verdict.*)
- **C_{coord} is a floor, so Brooks's Law is worse than the equation states.** The closure-defect term captures only the overhead of imperfect macro-representation; negotiation, synchronization, and conflict-resolution costs add more on top — so the inequality is “the absolute theoretical minimum overhead for simply representing the team as a single unit” (Claude, AUDIT-WORKING-773921). Already an existing Working Note ($C_{\text{coord}} = \epsilon^* \nu_c / \|\delta_{\text{critical}}\| + C_{\text{negotiation}} + C_{\text{sync}} + C_{\text{conflict}}$); converged-on framing for why the bound is conservative-in-the-honest-direction.

3. Follow-up items.

- **Wrapping construction as a Brooks's-Law instance (cross-volume).** An LLM wrapper framework that runs K API calls per macro-step to verify/plan is exactly a multi-agent composition with high coordination overhead: “you burn micro-tempo (ν_A/K) to buy macro-level structural separation” (Claude, AUDIT-WORKING-773921). Connects this segment's tempo accounting to 13.4 / 13.5's tempo-cost claim — a candidate explicit cross-reference (the in-composition segment already cites this Brooks's-Law form).

4. Readers often ask / wonder.

- **“Does the convergence with established results (Janow, Bamieh, Gurvich–Van Mieghem) confirm the derivation?”** Auditors read the Track-E surface-back literature (collaborative-entropy productivity caps; dimension-dependent loss of macro-coherence in large networks; synchronization-bottleneck idleness) as evidence that “AAT's first-principles derivations are converging perfectly with established theorems in operations research and distributed control” (Claude, AUDIT-WORKING-773921). A convergence-as-coherence-evidence signal; the prior-art neighbors already live in Working Notes (verification-deferred). Worth a Discussion sentence framing the convergence honestly once those citations are verified.

5. Candidate figures.

- **Tempo flow with a coordination-overhead split, plus a double-count warning.** Aggregate sub-agent tempo $\sum_i \mathcal{T}_i$ flowing toward external correction, with closure defect ε^* diverting part of it into coordination C_{coord} . The diagram explicitly carries a *warning split*: count closure either as an added disturbance burden ($\rho_{\text{eff}} = \rho_{\text{ext}} + \varepsilon^* \nu_c$) or as tempo overhead, “but do not subtract it twice” (Codex/Claude, AUDIT-WORKING-526815, “diagram attempt”). The double-count warning the figure encodes is also the substance of the F116–F119 correctness findings flagged in the report — the figure and the finding point at the same ledger discipline.

^aCitation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). 13.3 Hypothesis: Directed Separation Under Composition

The question whether the composite-level directed-separation condition holds: if every sub-agent satisfies 6.3 individually, does the composite macro-agent also satisfy it? The answer is *conditional on the composite’s routing structure* (12.1).

The framework draws a careful distinction first. Sub-agents’ goal-driven actions shape the environment, which other sub-agents observe. This is **not** a violation of directed separation — it is the same mechanism the single-agent result explicitly allows: goals influence *events* through action, but processing of realized events is goal-blind. Agent *B* observing environmental changes caused by Agent *A*’s goal-driven behavior is *B* processing a realized event goal-blindly. The observations carry information about *A*’s goals, but that is a property of the event’s content, not a failure of goal-blind processing. Similarly, individual messages reflecting individual goals is action through policy, not a routing-structure dependence on the composite’s goals.

The substantive question is whether the **routing structure** depends on the composite’s goal. Two cases. **Case 1 — goal-blind routing**: when neither communication topology nor protocol depends on the composite’s goals (military command structures with doctrinal communication protocols; software teams with defined code-review processes; multi-agent AI systems with protocol-specified message passing), directed separation *survives* at the composite level. **Case 2 — goal-dependent routing**: when the topology changes based on objective (different reporting chains activated depending on mission) or the protocol changes (different intelligence products shared depending on objective), the composite’s effective observation function acquires a goal argument. Even if each sub-agent processes its observations goal-blindly, *the set of observations reaching each sub-agent depends on the composite’s goal through the routing function*. Directed separation *fails* at the composite level.

This refinement establishes that **composite-level class membership depends on routing structure, not just sub-agent class**. A composite of Class-1-(Separated) sub-agents with goal-blind routing remains Class 1 at the composite level. A composite of Class-1-(Separated) sub-agents with goal-*dependent* routing becomes effectively Class 3 (Coupled) at the composite level — and the coupled-formulation machinery applies at the macro level even though every sub-agent individually satisfies directed separation. The architectural classification is therefore *not preserved under composition with goal-dependent routing*. For the special case of a single-component composite (wrapper-around-component), 13.4 promotes the equivalent result from hypothesis to derived; the general *N*-agent case treated here remains a hypothesis.

Formal Expression.

Consider N agents $A_1, \dots, A_N$, each satisfying directed separation individually: $M_{i,\tau+} = f_M^{(i)}(M_{i,\tau-}, e_{i,\tau})$ with no $G_t^{(i)}$ argument.

Hypothesis (directed-separation-under-composition, extending directed-separation to composites).

The question. Directed separation is about **processing**, not **selection** (6.3, scope condition). A single agent's goals affect which events it seeks (through π), but f_M processes whatever event arrives without reference to G_t . At the composite level, the analogous question is: does the composite's routing structure R_t (12.1) depend on the composite's goals G_t^c ?

Note: sub-agents' goal-driven actions shape the environment, which other sub-agents observe. This is NOT a violation of directed separation — it is the same mechanism directed separation explicitly allows at the single-agent level: goals influence events through action, but processing of realized events is goal-blind. Agent B observing environmental changes caused by A 's goal-driven behavior is B processing a realized event goal-blindly. The observations carry information about A 's goals, but that is a property of the event's content, not a failure of goal-blind processing. Similarly, individual messages reflecting individual agents' goals is action through policy, not a routing-structure dependence on G_t^c .

Case 1: Goal-blind routing.

If the routing structure satisfies $R_t \perp G_t^c$ (12.1, goal-blind routing) — neither the communication topology $\mathcal{N}_t$ nor the protocol $c_t^{(j \rightarrow i)}$ depends on the composite's goals — then:

Hypothesis (Case 1).

- Each sub-agent processes observations goal-blindly (individual directed separation)
- The routing is goal-blind (by construction)
- Therefore f_M^c is G_t^c -independent

Directed separation **survives** at the composite level. Examples: military command structures with doctrinal communication protocols, software teams with defined code-review processes, multi-agent AI systems with protocol-specified message passing.

Case 2: Goal-dependent routing.

If R_t depends on G_t^c — either the topology $\mathcal{N}_t$ changes (different reporting chains activated depending on the mission) or the protocol $c_t^{(j \rightarrow i)}$ changes (different intelligence products shared depending on the objective) — then the composite's effective observation function has a goal argument:

Hypothesis (Case 2).

$$o_c = h^c(\Omega, a_{\text{micro}}, G_t^c, \xi) \quad (13.26)$$

Even if each sub-agent's $f_M^{(i)}$ processes o_i goal-blindly, the **set of observations reaching each sub-agent** depends on G_t^c through the routing function. Directed separation **fails** at the composite level. The composite is analogous to a Class 3 (Coupled) architecture: goal content shapes the information pathway, not through individual interpretation but through collective routing.

Epistemic Status.

Conditional on the routing structure of the composite. Max attainable: conditional (the two cases are genuine architectural alternatives). Previously discussion-grade; upgraded after routing formalization in 12.1 and architectural classification promotion in 6.3 (2026-04-01).

Foundation status.

1. The **architectural classification** (Class 1/2/3) is in 6.3's Formal Expression with formal operationalization ($\kappa_{\text{processing}}$). Status: robust qualitative.
2. The **routing structure** R_t is defined in 12.1 with a formal goal-independence condition ($R_t \perp G_t^c$). The definition decomposes into topology independence and protocol independence. Whether this captures all relevant ways that composite information flow can depend on goals is an open question.
3. The **admissible coarse-graining** Λ from 13.1 now has specified admissibility constraints: (A1)-(A4) for macrodynamics and (P1)-(P3) for projections. The remaining gaps are validation (exercising the machinery on a purposeful multi-agent example) and computability (P1 requires conditional mutual information, tractable only for linear-Gaussian), not missing definitions.

The logic of each case is sound given the routing definition. Case 1: goal-blind routing + goal-blind processing = goal-blind composite. Case 2: goal-dependent routing means the composite's observation function depends on G_t^c , regardless of individual processing. Both follow from directed separation's scope condition.

The claim that the architectural classification lifts to composition is **structurally motivated** by 11 (the theory must give consistent answers at every level of description). This is an argument from theoretical coherence, not a derivation.

Discussion.

What this is and what it isn't. This segment provides a two-case taxonomy for directed separation under composition. It is not yet a derivation — the remaining caveat (admissibility placeholders) prevents that. It IS a useful classification that identifies which composites fall within Part III's scope (Case 1) and which require a coupled formulation (Case 2).

Constructive special case: wrapper-around-component. For the special case of a single-component composite — one underlying primitive component embedded inside an external scaffold — the question of when directed separation holds is *derived* by #der-class-coercion-via-wrapping. Under explicit conditions on the component (admissibility of goal-blind queries, stationary conditional, no implicit goal-inference) and on the wrapper's update maps (type signatures that exclude G_W from the belief-update path), directed separation holds at the wrapper level by structural commitment. The construction promotes the wrapper-around-component case from hypothesis to derived; the general N -agent composition case (Case 1 vs. Case 2 above) remains a hypothesis pending further work.

Most composites of interest are Case 1. Fixed communication structures are the norm in designed multi-agent systems: military doctrine specifies information flow regardless of the current mission; software development processes define code review, CI, and deployment pipelines independent of the feature being built; multi-agent AI protocols specify message formats and channels. Goal-dependent routing (Case 2) is rarer: crisis management (where communication structure changes with threat type), ad hoc teams assembled for specific objectives, and attention-based multi-agent architectures where query routing depends on the shared goal.

Connection to logogenic agents. LLM-based agents are individually Class 3 (Coupled; goal-conditioned attention). Whether composites of LLM agents are Case 1 or Case 2 depends on whether the inter-agent communication protocol is fixed or goal-dependent. A multi-agent LLM system with fixed API contracts between agents is Case 1 at the composite level even though each agent is individually Class 3 (Coupled). The internal architecture of each agent and the composition architecture are separate questions.

Adversarial implications. Goal-dependent routing (Case 2) makes the composite’s objective partially observable through its communication patterns. An adversary who can observe which information is being routed where can infer the composite’s current goal. This creates a meta-strategic incentive for fixed routing: it preserves not just epistemic hygiene but operational security.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- **Goal-information leakage is a separate phenomenon.** In any composite, sub-agents’ goal-driven actions shape the environment, so observations carry statistical information about goals. This is real and may matter for adversarial dynamics, trust calibration, and OPSEC — but it is NOT a directed-separation issue. It’s the normal action-environment coupling that directed separation explicitly allows. If this phenomenon deserves formalization (and it may — the mutual information $I(o_c; G_t^c \mid \Omega_t)$ is well-defined and operationally relevant), it should be its own segment about goal-information leakage, not a case within directed-separation analysis. An earlier draft of this segment conflated the two; this was caught by external review.
- **Partial goal-dependence.** Real composites may have mostly-fixed routing with occasional goal-dependent exceptions (a military unit that follows doctrinal comms but occasionally switches to crisis-specific channels). The error from treating such composites as Case 1 depends on the frequency and magnitude of the goal-dependent exceptions. A formal treatment would need to quantify this, possibly through a “routing independence fraction.”
- **Testable prediction.** Organizations that restructure communication channels based on the current strategic objective should exhibit lower prediction accuracy at the organizational level (the shared model becomes goal-contaminated through routing, not just through environmental coupling). Compare prediction accuracy before and after mission-dependent communication restructuring.
- **Composite-class-inheritance table (canonical home: #der-directed-separation; added 2026-05-21 per Phase 5 cross-segment ripple).** This hypothesis segment’s Case 1 / Case 2 dichotomy was the original framing for composite-level class lift. The 2026-05-21 strategic-composition cycle (spikes/strategic-composition-class-3-attempt-2026-05-21/) extended the analysis along a third axis (substrate sharing with G^c -allocation, per 01-STRENGTHEN-ATTEMPTS.md §5 (R4)) and produced the *axis-decomposed composite-class-inheritance table* now living in #der-directed-separation §“Composite-level class inheritance.” That table is the consolidated home for the sub-agent-class $\times$ routing $\times$ substrate $\rightarrow$ composite-class lookup; this segment’s Case 1 / Case 2 dichotomy remains the underlying hypothesis (still hypothesis-grade — the N -agent general case is not derived; the wrapper-around-component special case is derived in #der-class-coercion-via-wrapping). The dynamic-regime axis (#disc-dynamic-regime-axis) — goal alignment vs strategic interaction — is *independent* of the routing-structure axis this segment treats, and a clean separation: alignment work moves composites along the regime axis; routing-structure work moves them along the architectural-class axis.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (handled elsewhere — the F122–F126 cluster, esp. the Case-1-needs-goal-blind-projection-too point, is routed to the findings track; see report flags). **Coverage:** two dirs reached a digested reflection (526815, 849201). Lower note-count, but high felt-value on the OPSEC and LLM-composite-inversion observations. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The Case 1 / Case 2 line stated plainly as an infrastructure test: a composite stays Class 1 (Separated) when “the infrastructure doesn’t change based on the goal” ($R_t \perp G_t^c$) and each sub-agent’s f_M is goal-blind; it slides to Class 2 when “the infrastructure shifts based on the goal (e.g., activating crisis channels), [so] the composite’s observation function becomes goal-dependent” (Claude, AUDIT-WORKING-849201). A compact Brief gloss of the dichotomy.

2. Candidate Discussion.

- **Goal-dependent routing is an OPSEC vulnerability — derived from the structure.** The standout insight: when routing depends on the composite goal, “adversaries can infer the goal just by watching the routing topology” — so Case-2 routing is not only an epistemic-hygiene failure but a security leak, “a brilliant practical insight derived directly from the theoretical structure” (Claude, AUDIT-WORKING-849201). A candidate Discussion addition turning the routing distinction into an operational consequence (and it resonates with the consciousness-infrastructure goal-blind-routing imperative lifted into 12.1).
- **The LLM-composite inversion.** “While individual LLMs are Class 2/3, a multi-LLM system with fixed API contracts might be Case 1 at the macro level” — a “fascinating inversion of expectations” where composition *recovers* separation that the components individually lack (Claude, AUDIT-WORKING-849201). The segment treats this; the framing is a candidate reader-orienting Discussion line. (*Correctness caveat flagged in the report: F124 notes this belongs under the wrapper-derived special case 13.4, since the general Case-1 setup assumes each sub-agent is individually separated — keep the tier/scope honest if promoted.*)

3. Follow-up items.

- **Case 1 needs goal-blind projection, not just goal-blind sub-agents + routing.** A real structural sharpening (routed as a finding, noted here for completeness): the Case-1 conclusion also requires the macro projection / coarse-graining and macro-update interface to be goal-blind — a goal-conditioned Λ , aggregation window, or macro-observation definition can reintroduce coupling even when sub-agent processing and routing are clean. The proposed sharper theorem shape: “goal-blind sub-agent processing, goal-blind routing, *and* goal-blind projection/update together preserve composite-level directed separation” (Codex/Claude, AUDIT-WORKING-526815, F122). This is a strengthen-the-hypothesis candidate, not framing gold — see report off-ramp flag.

4. Readers often ask / wonder.

- “Isn’t a sub-agent inferring another’s goal from its actions already a separation failure?” No — and the segment’s existing “goal-information leakage” Working Note resolves exactly this trap: inferring goals from observed actions is normal, valid Bayesian inference (the action-environment coupling directed separation explicitly allows), distinct from a *structural* flaw in the processing pipeline. A fresh reader independently flagged this distinction as “resolving a major conceptual trap” (Claude, AUDIT-WORKING-849201). Strong signal the distinction is a natural reader stumble worth keeping prominent.

Belongs elsewhere.

- (*No distinct belongs-elsewhere gold beyond the cross-links already noted — the OPSEC and goal-blind-routing-imperative material co-locates naturally with 12.1 and the consciousness-infrastructure reach lifted there.*)

13.4 Derived: Class Coercion via Wrapping

A *constructive* result of substantial practical importance. A Class 2 (Partial) or Class 3 (Coupled) component (one whose forward pass entangles belief-update and goal-conditioning) can be embedded inside an external scaffold whose state $X_W = (M_W, G_W)$ is updated by *structurally distinct query channels*: **goal-blind queries** to the component update M_W ; **goal-conditioned queries** update G_W . Under stated conditions on the component, directed separation holds at the wrapper level *by construction*, and the composite system is Class 1 (Separated) per #der-directed-separation — even though the underlying component is not. This is the constructive direction of #hyp-directed-separation-under-composition for the wrapper-around-component special case: a procedure for *making* directed separation hold when the underlying component does not provide it.

The wrapper has four type-signed components: a *belief-side query selector* that chooses the model-update query from belief and observation only — *no goal argument*; a *strategy-side query selector* that may depend on the goal; a *belief update map* that updates M_W from prior belief, observation, the query made, and the component’s response — *no goal*

argument; and a *strategy-update map* that may depend on the goal. The wrapper makes at least two component calls per macro-step: one goal-blind for the model update and one goal-conditioned for the purposeful-state update.

The result requires conditions on the component. **(C1) Goal-blind admissibility** — the component admits non-trivial goal-blind queries; the framework partitions components into *Class A* (goal-blind by design: POMDP belief-state filters, world models, sensory pipelines, retrieval systems), *Class B* (admit a goal-blind query mode alongside goal-conditioned ones: LLMs in summarization/fact-extraction modes, hybrid RL with separable value/policy), and *Class C* (fundamentally goal-conditioned: pure end-to-end goal-conditioned policy networks), with the construction applying to Classes A and B. **(C2) Stationary component conditional** — the component’s output distribution conditional on input is fixed during operation (adaptation-during-deployment systems are out of scope). **(C2’) No goal-correlated cross-call state** — the component carries no information about the latent operator goal across the goal-blind / goal-conditioned call boundary; this is the condition on which the *structural* W_1 leakage bound depends. **(C3) No implicit goal-inference** — the component’s response to a goal-blind query does not depend on G_W via inference from query patterns; for pretrained components like LLMs, (C3) holds *exactly* only when query content is statistically independent of G_W in the pretraining distribution. The framework supplies **two theorems**: an *exact* form under (C1)–(C3), and an *approximate* form under (C1)–(C2) plus a KL-leakage bound, where the wrapper-level leakage on M_W updates is bounded by the same bound (small leakage in, small leakage out via the data-processing inequality).

The construction supports three **wrapping regimes** of decreasing strictness, distinguished by where structural separation lives. **W_1 (strict wrapping)** uses separate q_M and q_G calls per macro-step; separation lives at the *query boundary* and the residual leakage is the *selection-channel* quantity $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ — bounded *structurally* by the goal-content of the wrapper’s query-selection policy (under (C1)+(C2’)). **W_2 (partial wrapping)** uses one goal-conditioned call per macro-step with a typed parsed response routing updates to M_W vs G_W slots; separation lives at the *write boundary* and leakage is bounded only *behaviorally* — by the component’s compliance with the prompted instruction-to-separate. **W_0 (no wrapping)** runs the raw Class 2 / Class 3 component with no separation commitment. What differs across the regimes is *what determines* the leakage rate — and, for W_1 , whether the structural bound is available at all: it requires (C2’), failing which W_1 too degrades to a behavioral bound (`#disc-w1-structural-bound-boundary`). The hierarchy refines the Class 1 (Separated) cell of `#der-directed-separation` with a *Class-1-by-structure* (W_1 or natively goal-blind) vs *Class-1-by-behavior* (W_2) sub-distinction.

The result is *load-bearing* for the framework’s treatment of LLM agents: an LLM is internally Class 3 (Coupled), but an LLM-agent *system* (LLM + tools + memory + monitoring) can be designed with modular topology that recovers Class 1 status at the system level. The construction’s cost is paid in two places — *more component calls per macro-step* (the Brooks’s-Law tempo overhead derived in the companion segment) and a *residual leakage rate* bounded structurally under W_1 or behaviorally under W_2 . The companion segment `#der-class-coercion-in-composition` establishes that the wrapped system is also a valid AAT composite agent (satisfying (A1)–(A4) of `#form-composition-closure`) and inherits the sector-persistence template at the wrapper level.

Formal Expression.

Setup. Let $A : \mathcal{I}_A \rightarrow \mathcal{O}_A$ be a primitive component, treated by the wrapper as a black-box oracle: the wrapper issues queries (inputs) and consumes responses (outputs), without access to A ’s internal state. $\mathcal{Q}_A \subseteq \mathcal{I}_A$ is the set of admissible queries.

A **wrapper** W over A has state $X_W = (M_W, G_W) \in \mathcal{X}_M \times \mathcal{X}_G$ with $\mathcal{X}_G = \mathcal{X}_O \times \mathcal{X}_\Sigma$ per `#def-strategy-dimension`. The wrapper interacts with an environment via observations $o_W \in \mathcal{O}_W$ and actions $a_W \in \mathcal{A}_W$.

[*Definition (wrapper-update-maps)*] The wrapper’s update at macro-step m uses four type-signed components:

- **Belief-side query selector:** $q_M : \mathcal{X}_M \times \mathcal{O}_W \rightarrow \mathcal{Q}_A$. The wrapper chooses the query for M_W updates from belief and observation only — *no G_W argument*.
- **Strategy-side query selector:** $q_G : \mathcal{X}_M \times \mathcal{X}_G \rightarrow \mathcal{Q}_A$. May depend on G_W .

- **Belief-update map:** $f_M : \mathcal{X}_M \times \mathcal{O}_W \times \mathcal{Q}_A \times \mathcal{O}_A \rightarrow \mathcal{X}_M$. Updates M_W from prior belief, observation, the query made, and the component's response. *No G_W argument.*
- **Strategy-update map:** $f_G : \mathcal{X}_G \times \mathcal{X}_M \times \mathcal{Q}_A \times \mathcal{O}_A \rightarrow \mathcal{X}_G$. May depend on G_W .

The external policy $\pi_W : \mathcal{X}_W \rightarrow \mathcal{A}_W$ selects the wrapper's external action.

A macro-step proceeds: construct $q_M(M_W, o_W) \rightarrow$ query $A \rightarrow$ apply f_M ; construct $q_G(M'_W, G_W) \rightarrow$ query $A \rightarrow$ apply f_G ; emit $\pi_W(X'_W)$. The wrapper makes $K \geq 2$ component calls per macro-step in this minimal form (more in richer wrapper designs).

Conditions. [*Conditions (component-admissibility)*] The theorem applies under three conditions on the component A :

(C1) Goal-blind admissibility. $\mathcal{Q}_A$ contains queries whose specification can be constructed from (M_W, o_W) alone — i.e., a non-trivial q_M exists. Components partition into three classes: - **Class A (goal-blind by design).** A 's interface is goal-blind by construction — POMDP belief-state filters, world models, sensory pipelines, retrieval systems, calculators. (C1) holds trivially. - **Class B (admit a goal-blind query mode).** A supports goal-conditioned queries but also goal-blind ones. Large language models in summarization or fact-extraction modes; hybrid RL agents with separable value/policy; multi-modal models. (C1) holds operationally — the wrapper *chooses* to use the goal-blind mode. - **Class C (fundamentally goal-conditioned).** A 's only operating mode requires goal-conditioning. Pure end-to-end goal-conditioned policy networks. (C1) fails; the construction does not apply.

(C2) Stationary component conditional. A 's output distribution conditional on input is fixed during the wrapper's operation: $P(A(\cdot) \mid q)$ does not depend on prior queries or on side information beyond q . Adaptation-during-deployment systems are out of scope.

(C2') No goal-correlated cross-call state. The component's hidden state does not carry information about the latent operator goal G^{op} across the boundary between the goal-blind (q_M) and goal-conditioned (q_G) calls of a macro-step. Equivalently, A 's response to q_M is conditionally independent of G^{op} given q_M and the component's *pre-call* state, and that pre-call state is itself goal-uncorrelated — either reset across the call boundary, or stripped of Σ - and G -content. (C2') is the condition on which the *structural* W_1 leakage bound below depends, and it strengthens (C2): the breaking condition for the structural bound is not online weight-adaptation but mere goal-correlated state persistence across the call boundary — which a frozen-weights LLM with a conversation cache exhibits with no weight adaptation at all. When (C2') fails the structural bound is unavailable and only a behavioral bound remains; this boundary is derived in `#disc-w1-structural-bound-boundary`.

(C3) No implicit goal-inference. A 's response to a goal-blind query does not depend on G_W via inference from query patterns:

$$P(A(q_M) \mid q_M, G_W) = P(A(q_M) \mid q_M) \quad \forall q_M, G_W \quad (13.27)$$

For pretrained components (notably LLMs), (C3) holds *exactly* only when query content is statistically independent of G_W in the pretraining distribution. The approximate form weakens (C3) to a leakage bound (Theorem 2 below).

Theorem 1: Directed separation at the wrapper level (exact form).

Under (C1)–(C3), directed separation holds *exactly* at the wrapper level:

Derived (directed-separation-at-wrapper-exact, from C1+C2+C3).

$$P(M_{W,m+1} \mid M_{W,m}, o_{W,m+1}, G_{W,m}) = P(M_{W,m+1} \mid M_{W,m}, o_{W,m+1}) \quad (13.28)$$

Therefore W is a Class 1 (Separated) architecture per $\#der$ -directed-separation.

Proof. Identify all paths from $G_{W,m}$ to $M_{W,m+1}$ given $(M_{W,m}, o_{W,m+1})$. The update is

$$M_{W,m+1} = f_M(M_{W,m}, o_{W,m+1}, q_M(M_{W,m}, o_{W,m+1}), A(q_M(M_{W,m}, o_{W,m+1}))) \quad (13.29)$$

f_M has no G_W argument by type signature (D-pathway-1 closed). q_M has no G_W argument by type signature (D-pathway-2 closed). The remaining pathway is $A(q_M)$ depending on G_W given q_M . Under (C3), $P(A(q_M) \mid q_M, G_W) = P(A(q_M) \mid q_M)$ — the response is conditionally independent of G_W given q_M . Since q_M is itself a deterministic function of $(M_{W,m}, o_{W,m+1})$, conditioning on $(M_{W,m}, o_{W,m+1})$ determines q_M , and the integrand $P(M_{W,m+1} \mid M_{W,m}, o_{W,m+1}, q_M, A(q_M)) \cdot P(A(q_M) \mid q_M, G_W)$ no longer depends on G_W . The conditional distribution of $M_{W,m+1}$ given $(M_{W,m}, o_{W,m+1}, G_{W,m})$ equals that given $(M_{W,m}, o_{W,m+1})$. ■

Theorem 2: Directed separation (approximate form, C3 weakened to leakage bound).

If (C3) is replaced by a KL-leakage bound

Derived (directed-separation-at-wrapper-approximate, from C1+C2+leakage-bound).

$$D_{\text{KL}}(P(A(q_M) \mid q_M, G_W) \parallel P(A(q_M) \mid q_M)) \leq \kappa \quad \forall q_M, G_W \quad (13.30)$$

then the wrapper-level KL-divergence on M_W updates is bounded by the same κ :

$$D_{\text{KL}}(P(M_{W,m+1} \mid M_{W,m}, o_{W,m+1}, G_{W,m}) \parallel P(M_{W,m+1} \mid M_{W,m}, o_{W,m+1})) \leq \kappa \quad (13.31)$$

The wrapper is *almost-Class-1 (Separated)* with leakage rate $\leq \kappa$. *Proof.* The wrapper-level M_W update is a deterministic function of the component response given the wrapper's other inputs; the data-processing inequality propagates the KL bound from response distribution to wrapper-state distribution. ■

The W_1 structural leakage bound: a selection-channel quantity. The residual goal-leakage that survives in the W_1 regime is a *selection-channel* quantity, not a processing-channel one. The distinction is between two senses of the goal variable: the wrapper's internal purposeful-state register G_W — which q_M structurally does not take as an argument and which Theorem 1 closes by type signature — and the latent *operator goal* G^{op} that generated the situation the wrapper is in, which a competent component can infer from the *content* of the query the wrapper chose. The processing channel ($G_W \rightarrow A(q_M) \mid q_M$) is shut structurally and exactly by Theorem 1; the entire residual leakage is the selection channel ($G^{\text{op}} \rightarrow \text{wrapper history} \rightarrow \text{choice of } q_M \rightarrow A(q_M)$), and its magnitude is governed by the goal-content carried in the query the wrapper selects.

Under (C1) and (C2'), the goal-information reaching the wrapper's belief update through the goal-blind channel is bounded by the goal-content of the wrapper's query-selection policy:

Derived (*W1-selection-leakage-bound, from C1+C2', data-processing inequality*).

$$\kappa_{W_1}^{\text{sel}} := I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}}), \quad (13.32)$$

where G^{op} is the latent operator goal and q_M is the (random, history-dependent) goal-blind query drawn under the wrapper's operating policy.

Derivation. Under (C2'), $A(q_M)$ depends on G^{op} only through q_M — there is no goal-correlated cross-call state through which the goal could reach the response while bypassing the query — so $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ is a Markov chain. The data-processing inequality along this chain gives $I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$. ■

The bound is a property of the wrapper's q_M -selection policy, not of the component's input–output law, and is therefore design-controllable: maximally goal-blind queries (current observation only, no history, no system prompt) drive $I(q_M; G^{\text{op}}) \rightarrow 0$ and recover exact directed separation on the merits; richer, history-laden queries raise $I(q_M; G^{\text{op}})$ and with it the leakage ceiling. This is the formal content of the quality–separation tradeoff (§Discussion) — a choice of query-selection policy purchases a quantitative, structurally-derived leakage ceiling.

Propagating to the wrapper's belief state: the update $M_{W,m+1}$ is a deterministic function of $(M_{W,m}, o_{W,m+1}, q_M, A(q_M))$, so along $G^{\text{op}} \rightarrow q_M \rightarrow (q_M, A(q_M)) \rightarrow M_{W,m+1}$ the data-processing inequality gives

$$I(M_{W,m+1}; G^{\text{op}} | M_{W,m}, o_{W,m+1}) \leq I(A(q_M); G^{\text{op}} | M_{W,m}, o_{W,m+1}) \leq I(q_M; G^{\text{op}}). \quad (13.33)$$

The conditioning set is $(M_{W,m}, o_{W,m+1})$ — deliberately *not* q_M . Conditioning on q_M would (correctly, for the closed processing path) zero the quantity out and miss the selection leak; the unconditional $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ is the analyst-independent statement, with q_M drawn under the wrapper's actual operating policy.

Wrapping regime hierarchy. The construction supports three regimes, distinguished by where structural separation lives:

Table 13.4

<i>Regime</i>	<i>Construction</i>	<i>Leakage bound</i>	<i>Leakage source</i>
W₀ (no wrapping)	Raw Class 2 (Partial) or Class 3 (Coupled) component	κ_{W_0} at the component's maximum goal-conditioning sensitivity	No constraint
W₂ (partial wrapping)	One goal-conditioned call per macro-step; structurally typed parsed response routes updates to M_W vs. G_W slots	κ_{W_2} bounded <i>behaviorally</i> — by the component's compliance with the prompted instruction-to-separate; no structural bound	Component's instruction-following fidelity
W₁ (strict wrapping)	Theorem 1 / 2 — separate q_M and q_G calls per macro-step	$\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ — bounded <i>structurally</i> by the goal-content of the wrapper's query-selection policy (under (C1)+(C2'))	Query-selection policy's goal-content (the goal G^{op} inferable from query content)

W_1 admits a structural bound — the selection-channel quantity $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ under (C1)+(C2'); W_2 admits only a behavioral bound from the component's compliance fidelity. The two are different in kind — the structural bound is a property of the wrapper's query-selection policy (the goal-content of the queries it chooses) and is therefore design-controllable; the behavioral bound depends on the component's training and prompt-following. The W_1 structural bound is available exactly when the component carries no goal-correlated cross-call state ((C2')); when

(C2') fails the leak routes through an unobservable channel and W_1 too degrades to a behavioral bound — the boundary derived in `#disc-w1-structural-bound-boundary`.

The $W_0 / W_2 / W_1$ distinction refines the Class 1 (Separated) cell of `#der-directed-separation`: within Class 1 (Separated), **Class-1-by-structure** (natively goal-blind components, or W_1 wrapping) has a structurally derivable directed-separation guarantee; **Class-1-by-behavior** (W_2 wrapping) has only an empirically estimable guarantee that depends on the component's instruction-following.

Epistemic Status.

Conditional on (C1), (C2), and (C3) (or its weakening to a leakage bound). The proofs are short conditional-independence reasoning (Theorem 1) and a single application of the data-processing inequality (Theorem 2); both are standard.

The W_1 structural leakage bound $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ is *conditional* on (C1) and (C2'). The data-processing step is standard; the load-bearing condition is (C2') — the Markov chain $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ holds only when the component carries no goal-correlated state across the call boundary. The bound is an upper bound; its gap below $I(q_M; G^{\text{op}})$ is the “accuracy effect” of §Discussion “Two senses of component competence” and is not characterized here (Working Notes).

Max attainable: derived under stated conditions. (C3)'s exact form is a structural ideal that pretrained components (notably LLMs with goal-rich training data) generally satisfy only approximately; the realistic regime is Theorem 2 with κ characterized empirically. (C2)'s exact form is likewise an ideal — a frozen-weights LLM with a conversation cache violates it without any weight adaptation — and where it fails only the behavioral bound of `#disc-w1-structural-bound-boundary` survives.

The wrapping regime hierarchy ($W_0/W_2/W_1$) is a *formulation* — the partition is made by the structural choice of where to place the separation commitment. The leakage bounds within each regime are derived once the regime is fixed.

Discussion.

Quality–separation tradeoff inside Class B. For Class-B components (admitting both goal-blind and goal-conditioned modes), the wrapper has a design choice: how aggressively to restrict q_M to goal-blind content, vs. how much context to allow that may carry goal-correlated information. Maximally goal-blind queries (only the current observation, no context, no history) drive the selection-channel mutual information $I(q_M; G^{\text{op}})$ — and with it the leakage ceiling $\kappa_{W_1}^{\text{sel}}$ — toward zero, but may produce information-poor responses that hurt f_M 's update quality. Maximally informed queries (full history, retrieved context) produce richer responses but raise $I(q_M; G^{\text{op}})$ and therefore the upper bound on $\kappa_{W_1}^{\text{sel}}$. The tradeoff is real and resolved per application — and because $I(q_M; G^{\text{op}})$ is a property of the query-selection policy the wrapper controls, the tradeoff is a design dial, not a property of the component.

Component-admissibility partition. Class A components (goal-blind by design) satisfy (C1) trivially and don't need wrapping in the substantive sense — wrapping for Class A is organizational rather than structural. Class B components (LLMs, hybrid RL with separable value/policy, multi-modal models) are the substantive wrapping case — the wrapper *chooses* to use the goal-blind mode. Class C components (pure end-to-end goal-conditioned policy networks) fail (C1) and are scope-out for the basic theorem. Salvage paths for Class C — null-goal queries, goal-uniform averaging, auxiliary distilled goal-blind heads — exist but cost something (information loss, computation, training).

Resolution of the LLM scope question. The “Class 3 (Coupled) exit” framing — *directed separation violated by goal-conditioned agents (LLMs); handled as architectural scope, not approximation* — is refined by this segment from a scope exit to a constructive route through. Class 3 (Coupled) LLMs are scope-in *for the wrapper construction* (under Class-B admissibility). The cost is paid in residual leakage rate $\kappa_{W_1}^{\text{sel}}$ bounded by the goal-content of the wrapper’s query-selection policy, $I(q_M; G^{\text{op}})$; the tempo cost is established separately in #der-class-coercion-in-composition. Whether this construction yields an operationally useful agent depends on how low the query-selection policy can drive $I(q_M; G^{\text{op}})$ while still licensing useful belief updates — and, where the component carries goal-correlated cross-call state, on whether (C2’) can be enforced at all (#disc-w1-structural-bound-boundary).

Relationship to #hyp-directed-separation-under-composition. The hypothesis is descriptive — when does directed separation hold under composition? This segment provides the constructive answer for the wrapper-around-component special case: directed separation holds whenever the wrapper’s type signatures are respected and (C1)–(C3) hold (or their weakenings). The general N-agent composition question remains a hypothesis; the wrapper-around-component case is now derived.

Wrapping as a truthification mechanism. The wrapping construction is the *rigorous formal version* of what #disc-adversarial-coupling-pressure §”Defensive scaffolding as composition” gestures at informally — peer review, prediction registers, double-entry bookkeeping, adversarial procedure, structured red-teaming. Those external scaffolds are operational mechanisms for *increasing* the modularity of a composite agent in the face of forces that would couple it; the wrapping construction is the structural version of the same operation applied internally rather than externally. Both share the discipline: a goal-blind belief-update query path is structurally enforced (W_1 strict) or behaviorally bounded (W_2), at a definite cost (extra component calls per macro-step plus residual leakage rate). The $W_0/W_2/W_1$ regime hierarchy is the *graded* characterization of how thoroughly the truthification has been applied — W_0 is the un-truthified base state, W_2 behavioral truthification, W_1 structural truthification. Cross-reference: #disc-modularity-state-dynamics is the meta-segment in which the truthification operation sits as one of three operations on the modularity state — alongside strategic self-coupling (#disc-strategic-self-coupling, self-driven-decreasing) and adversarial coupling pressure (#disc-adversarial-coupling-pressure, externally-driven-decreasing). This segment is the canonical *formal* instance of the truthification operation at the component level ($W_0 / W_1 / W_2$ regime hierarchy), paired with the composite-level *defensive-scaffolding* instance from #disc-adversarial-coupling-pressure §”Defensive scaffolding as composition”. The connection is also surfaced in #impl-composition-machinery §”Class-coercion as truthification mechanism.”

Two senses of component competence: world-simulation vs goal-extraction. A subtle decomposition of *component competence* matters for how (C3) and the selection-channel bound $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ scale with the component’s capability. A high-capability component has at least two distinct competences that the classification machinery treats asymmetrically:

1. **World-simulation fidelity** — accuracy of A ’s response to the explicit content of a query, including counterfactual content. Sharpens f_M ’s update quality once a query is in hand.
2. **Input-structure extraction** — competence at inferring latent structure *from the query’s surface form*, including inferring the operator’s goal G^{op} from query patterns. This is the channel (C3) names.

The architectural classification of #der-directed-separation is *blind to (1) and defined by (2)*: class membership turns on whether the goal can causally reach f_M , not on how accurately f_M then computes given goal-blind input. For pretrained components the two competences correlate empirically — the same training that produces world-simulation fidelity also produces input-structure extraction — but conceptually they are distinct, and the distinction is load-bearing for (C3).

The two competences act on the two sides of the selection-channel bound. The bound’s *ceiling* is $I(q_M; G^{\text{op}})$ — the goal-content present in the query, fixed by the wrapper’s selection policy; the *realized* leak is $I(A(q_M); G^{\text{op}})$ — how much of that the response actually carries. The gap between them is governed by competence:

- *Accuracy effect (widens the gap, lowers the realized leak).* A more competent world-simulator returns posteriors closer to the true conditional $P(\cdot \mid q_M)$, which is goal-independent by definition; it leaves the goal-content sitting in q_M unexploited in its response, so $I(A(q_M); G^{\text{op}})$ can sit well below the ceiling $I(q_M; G^{\text{op}})$.
- *Inference effect (closes the gap, raises the realized leak).* A more competent input-structure extractor uses any query-content / goal-content correlation to infer G^{op} from the goal-blind query and bend its response accordingly, driving $I(A(q_M); G^{\text{op}})$ up toward the ceiling — even when no goal argument is structurally exposed.

For pretrained components where the two competences scale together (the typical case for LLMs trained on goal-rich corpora), where the realized leak sits between 0 and the ceiling in the fidelity limit is *empirical and component-specific*, not structural. The selection-channel ceiling is design-controllable (drive $I(q_M; G^{\text{op}})$ down by goal-blind query selection); the position within that ceiling is the accuracy-vs-inference balance, and separating the two appears to open more science than it closes.

Several lines worth pulling, kept open here rather than queued elsewhere so future cycles do not lose them:

- *Decorrelation by construction.* If world-simulation and input-structure extraction can be structurally decoupled at training time — by architectural separation of *what does the world look like given q* from *what is the latent context that produced q* — a Class 3 (Coupled) component could satisfy (C3) even at high world-simulation fidelity. The classification would then refine into “Class 3 but C3-respecting” vs “Class 3 and C3-violating” sub-cases that the current scalar κ_{W_1} does not surface, and the C3-respecting branch may be a more interesting design target than wrapping a C3-violating component.
- *Counterfactual capability is bi-side.* Counterfactual simulation (Pearl Level 2) requires both competences — accurate world-simulation under interventional queries *and* extraction of the intervention’s intended scope from the query. Whether high counterfactual capability tends to raise or lower realized κ in practice is an open empirical question; the answer depends on how the two competences decompose in the specific component.
- *Decomposed empirical estimator.* The existing $\hat{\kappa}_{\text{processing}}$ estimator from #der-directed-separation probes the *net* response divergence under varied goal-priming. An estimator that holds explicit query content fixed while varying only the implicit operator context might isolate the inference-effect contribution, giving a sharper diagnostic than the aggregate κ and surfacing whether a given high-fidelity component sits near $\kappa \rightarrow 0$ (accuracy-dominated) or near κ ceiling (inference-dominated).
- *M4 amplification specificity.* The amplification of #disc-modularity-state-dynamics operations (strategic self-coupling, adversarial coupling pressure) under high component fidelity may track competence (2) specifically rather than competence (1). If so, M4 attack-surface measurement could be sharpened by measuring the inference effect rather than aggregate capability — a more competent world-simulator is not, *by that fact alone*, a more potent vector for the coupling-increasing operations.

The decomposition is named here at *discussion-grade* recognition — kept open as a place to pull on rather than as a closed result. Whether it lifts to *robust qualitative* or higher depends on whether the two competences can be operationalized as separately measurable quantities and whether the architectural-decorrelation conjecture holds for any realizable training regime.

Findings.

Constructive Directed Separation via Wrapping. **Brief:** When you have a component (like an LLM) whose belief-update and goal-conditioning are entangled in a single forward pass, you can build a scaffold around it that maintains explicit, separate stores for what the system believes and what it wants. The structural rule is that belief updates only see queries to the component that don't include the goal as input. Under reasonable conditions on the component, the wrapped system is goal-blind in its belief updates *by construction* — even though the underlying component isn't. The cost shows up as a residual leakage from the component's pretraining (the component might still infer the goal from query content, even when the goal isn't explicit in the input). Two practical regimes appear: strict wrapping with separate goal-blind and goal-conditioned calls (theoretically clean, with a structural leakage bound), and partial wrapping with one goal-conditioned call whose response is parsed into separate update fields (operationally common, with only a behavioral leakage bound — depending on the component's instruction-following fidelity rather than its query structure).

Impact: Promotes #hyp-directed-separation-under-composition to derived (in the wrapper-around-component special case). Refines the Class 1 (Separated) cell of #der-directed-separation with a structural-vs-behavioral sub-distinction (W_1 vs. W_2). Resolves the LLM scope question — Class 3 (Coupled) components are scope-in for the wrapper construction at a measurable cost, not scope-out. The composition-level consequences (wrapper as valid AAT composite agent, persistence-template inheritance, tempo cost) are derived in the companion segment #der-class-coercion-in-composition.

Novelty Claim: *Claim integration* of POMDP / cognitive-architecture prior art with the AAT Class 1/2/3 (Separated/Partial/Coupled) directed-separation taxonomy, plus the $W_0/W_2/W_1$ regime hierarchy that surfaces the structural-vs-behavioral leakage distinction and the LLM-specific (C1)–(C3) admissibility/leakage conditions. The wrapping move itself is rediscovery of patterns established in POMDP theory (Bayesian belief-update is goal-blind by construction) and cognitive architectures (modular agent design with separated belief/goal/action state, four decades). AAT's contribution is the structural-leakage analysis at the directed-separation level and the regime hierarchy that names where the separation guarantee lives.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Goal-blind belief-update by construction	Astrom 1965, "Optimal control of Markov processes with incomplete state information," <i>J. Math. Anal. Appl.</i> 10; Kaelbling, Littman, Cassandra 1998, "Planning and acting in partially observable stochastic domains," <i>Artificial Intelligence</i> 101	<i>formal antecedent</i> — POMDP belief-state filters are goal-blind by construction; the wrapping move recapitulates this in the AAT vocabulary. The closest formal prior art for the directed-separation guarantee.
Modular agent design with separated belief/goal/action	Newell 1990, <i>Unified Theories of Cognition</i> ; Laird 2012, <i>The Soar Cognitive Architecture</i> ; Anderson 2007, <i>How Can the Human Mind Occur in the Physical Universe?</i> ; Sun 2016 <i>Anatomy of the Mind</i> (CLARION); Baars 1988 <i>A Cognitive Theory of Consciousness</i> / Dehaene 2014 <i>Consciousness and the Brain</i> (Global Workspace)	<i>formal antecedent</i> — cognitive architectures have done modular agent design with separated belief/goal/action state for 40+ years. The W_1 wrapping move is essentially the per-cycle commitment that cognitive architectures make at the system level.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Tool-using language-model agent frameworks	Yao et al. 2022, “ReAct: Synergizing reasoning and acting in language models”; Shinn et al. 2023, “Reflexion: language agents with verbal reinforcement learning”; Park et al. 2023, “Generative Agents: Interactive Simulacra of Human Behavior”; Packer et al. 2023, “MemGPT: Towards LLMs as operating systems”; Schick et al. 2023, “Toolformer: language models can teach themselves to use tools”	<i>empirical instantiation</i> — practical wrappers around language-model substrates. Most fall in W_2 (partial wrapping / output-structuring); Generative Agents’ observation→memory step is the closest empirical instance of W_1 . AAT’s regime hierarchy gives these constructions a structural reading.
Hybrid deliberative/reactive architectures (prior art for class-coercion)	Gat 1992, <i>Integrating planning and reacting in a heterogeneous asynchronous architecture for controlling real-world mobile robots</i> (AAAI) ⁴ ; Simmons 1994, <i>Structured control for autonomous robots</i> (IEEE Trans. Robotics 10:34) ⁵ ; Au 2004, planner wrappers with external-query management ⁶	<i>formal antecedent</i> — hybrid deliberative/reactive architectures orchestrate reactive (entangled) layers beneath deliberative (separated) planners, structurally precedent for the wrapping construction’s “scaffold an entangled component to recover separated behaviour at the wrapper level” move. AAT’s contribution is <i>not</i> the wrapping move itself but the <i>theorem-shaped</i> wrapper-level directed-separation guarantee (Theorem 1 + Theorem 2) plus the explicit selection-channel leakage bound $\kappa_{W_1}^{se} = I(A(q_M); G^{op}) \leq I(q_M; G^{op})$ and the Brooks’s-Law tempo cost in #der-class-coercion-in-composition

Search Log:

- 2026-05-09 (*targeted*): Web + training-data search across POMDP / cognitive-architecture / scaffolded-LLM threads. Verdict: **substantial overlap** with the POMDP and cognitive-architecture lines as the closest formal prior art. AAT’s contribution is the structural-leakage analysis and regime hierarchy rather than novelty in the wrapping move itself.
- 2026-05-09 (*intuition-only*, prior to the targeted search): adjacent literatures expected to host prior art were active inference (Markov blankets), control theory (approximate simulation), and scaffolded-LLM frameworks. The targeted search confirmed all three and added the POMDP and cognitive-architecture lines as the formal precedents.

Working Notes.

- **Empirical κ measurement.** The selection-channel ceiling $I(q_M; G^{op})$ is estimable by varying the latent operator goal across a fixed query-selection policy and measuring the divergence of the resulting query distribution; the realized leak $I(A(q_M); G^{op})$ requires sampling responses under varied G^{op} at fixed selection policy. Both need an operationalization of the latent G^{op} —

⁶Citation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). Catalog has more verification support than raw Undermind synthesis but less than full primary-source reading. Verification queued with the BG2 cluster.

likely the same construct the $\hat{\kappa}_{\text{processing}}$ estimator of $\#der\text{-directed-separation}$ uses. For a fixed component, the ceiling is a property of the wrapper's q_M -selection policy — narrower (more goal-blind) queries reduce it, richer queries raise it. The empirical instantiation, and a characterization of the gap between realized leak and ceiling (the accuracy effect), is open follow-on; see also the decomposed-estimator spike candidate below.

- **Sub-type-aware wrapping regime selection.** Knowing only that a component is Class 2 (Partial) is insufficient to choose W_1 vs W_2 ; the right regime depends on the un-wrapped component's coupling *form* per the (stage $\times$ source $\times$ form) sub-typology of $\#disc\text{-partial-coupling-pathways}$: content-form sub-types admit W_2 (post-hoc response structuring); process-form sub-types require W_1 (structural goal-blind query path) or are not coercible to Class 1 without pipeline access. Additionally, Σ_t -source coupling (per $\#der\text{-belief-strategy-attractor}$) can undermine W_1 's structural commitment via strategy-context leakage in stateful components — even with no G_W in the query, the component's internal Σ may be influenced by historical query content and then suppress the gain on subsequent goal-blind queries; a Σ -channel-suppressed W_1 (holding strategic context fixed across calls, or stripping Σ -content from queries) may be required. The $W_0/W_1/W_2$ hierarchy is the agent-level analog of the stage-level form distinction in the sub-typology — $W_2 \leftrightarrow \text{content}$; $W_1 \leftrightarrow \text{process-with-pipeline-access}$ — making the structure-vs-behavior refinement at Class 1 the agent-level shadow of a Class 2 axis.
- **Compositional wrapping (wrapper-of-wrapper).** How leakage rates compose under iterated wrapping is open. Conjecture: additive in KL ($\kappa_{\text{outer}} \leq \kappa_{\text{inner}} + \kappa_{\text{outer-shell}}$) by data-processing inequality applied at each level, but tightness is unclear.
- **Behavioral compliance axiom for W_2 .** κ_{W_2} has no structural bound; it depends on the component's instruction-following fidelity. Whether a behavioral-compliance axiom (assuming the component honestly attempts to follow structural-separation instructions) yields a bound is an open hypothesis. If so, it would be hypothesis-grade rather than derived.
- **Identifying the regime in the wild.** Practical scaffolded-LLM frameworks (ReAct, Reflexion, MemGPT, etc.) almost universally implement W_2 . Distinguishing W_2 from W_1 in a deployed system requires inspection of the per-cycle query structure — does f_M 's update path receive a query that contains G_W or not? This is the diagnostic question.
- **Segment split provenance (2026-05-11).** This segment was bifurcated from a combined “class coercion” derivation. Claim A (directed separation at the wrapper level) lives here; Claim B (wrapper as valid AAT composite agent — (A1)–(A4) verification, persistence-template inheritance, Brooks's-Law tempo cost) lives in $\#der\text{-class-coercion-in-composition}$ (which declares this segment as prerequisite). The split reflects FORMAT.md Gate 1 discipline: this segment's depends list ($der\text{-directed-separation}$, $def\text{-agent-environment}$) reflects exactly what the directed-separation theorem actually requires. The composition-level dependencies ($form\text{-composition-closure}$, $deriv\text{-sector-condition}$, $result\text{-sector-persistence-template}$, $der\text{-tempo-composition}$) are Claim B's load and now live with Claim B.
- Reasoning-trail provenance: spike directories at `spikes/class-coercion-wrapping/` and `spikes/temporal-nesting-rg/` carry the working-out of these results.
- **W_1 leakage-bound — regression guard.** Do not regress the selection-channel bound $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ back to the form $\kappa_{W_1} \leq I(A(q_M); G_W \mid q_M)$ that the body previously carried: that quantity is circular and vacuous — it bounds κ by an average of κ , and evaluates identically to zero for the stateless oracle the theorem models, because conditioning on q_M closes the only channel it measures. The fix relocated the goal variable from the wrapper register G_W to the latent operator goal G^{op} read off query content and dropped the conditioning (data-processing along $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ under (C1)+(C2')); the embedded no-go — structural bound available iff (C2') holds, otherwise behavioral-only — is $\#disc\text{-w1-structural-bound-boundary}$. Reasoning trail (filed): `spikes/.integrated/spike-w1-leakage-vacuity-2026-05-31.md`, `spikes/.integrated/spike-w1-w2-boundary-intuition-2026-05-31.md` (cycle narrative: CHANGELOG 2026-05-31).
- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Three independent axes in this segment: (a) GUC Class 1/2/3 — renamed and swapped; (b) $W_0/W_1/W_2$ wrapping regimes — UNCHANGED; (c) Class A/B/C component-admissibility partition — UNCHANGED.
- **Track E surface-back of catalog citations (2026-05-22).** One Related Work entry added 2026-05-22 from Track E catalog at `ref/prior-art-analysis/05-directed-separation.md` (Pillar 4): hybrid deliberative/reactive architectures (Gat 1992, Simmons 1994, Au 2004) as prior art for class-coercion. Marked [[^]cat-2026-05-22] for verification-deferred attribution; primary-source verification queued in the BG2 cluster. The catalog citations had prior Pillar-style search support but were not verified by the current executor at landing time.

- **Spike candidate (PROPOSED Tier 3, 2026-05-28): Decomposed empirical estimator separating accuracy-dominated from inference-dominated κ regimes.** The aggregate $\hat{\kappa}_{\text{processing}}$ estimator of $\#der\text{-directed-separation}$ probes net response divergence under varied goal-priming. A decomposed estimator that holds explicit query content fixed while varying only implicit operator context (system-prompt scaffolding, query metadata, conversational history) might isolate the inference-effect contribution from the accuracy-effect contribution — surfacing whether a given high-fidelity component sits near $\kappa \rightarrow 0$ (accuracy-dominated) or near a κ ceiling (inference-dominated). Substance home: §Discussion “Two senses of component competence: world-simulation vs goal-extraction”. → [PROPOSED Tier 3](#).
- **Spike candidate (PROPOSED Tier 2, 2026-05-28): Decorrelation-by-construction — Class 3 but C3-respecting sub-cases.** Architectural-research question: can world-simulation fidelity and input-structure extraction be structurally decoupled at training time (training-objective decomposition; architectural separation of *what does the world look like given q* from *what is the latent context that produced q* ; data-curation discipline)? If so, a Class 3 (Coupled) component could satisfy (C3) at high world-simulation fidelity, and the architectural classification of $\#der\text{-directed-separation}$ would refine into “Class 3 but C3-respecting” vs “Class 3 and C3-violating” sub-cases that the scalar κ_{W_1} does not currently surface — the C3-respecting branch may be a more interesting design target than wrapping a C3-violating component. Theory-edge / speculative; substance home: §Discussion “Two senses of component competence: world-simulation vs goal-extraction”. → [PROPOSED Tier 2](#).

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs. **Coverage:** only one dir reached a digested reflection on this segment (526815) — the deeply-mathematical critique pass; the other contributing dirs stopped before this segment. **No pedagogical / analogy / figure gold surfaced here** — 526815’s reflection is entirely *certified-track correctness findings* (the F127–F131 cluster on the leakage analysis), which are routed to the findings track, not lifted as Working-Notes gold. The one durable non-finding signal worth preserving for the later Brief/Discussion pass:

Belongs elsewhere / convergence signal.

- **Auditor flagged the $\varepsilon_{\text{track}}$ / $\varepsilon_{\text{coerce}}$ / κ distinction as a contribution to preserve** — “the distinction ... is excellent and should be preserved downstream” (Codex/Claude, AUDIT-WORKING-526815, “Watch”). A signal about which of this segment’s apparatus a fresh reader found most load-bearing; useful when the leakage analysis is eventually given Brief-field plain-language framing.

Off-ramp note: 526815 also raised a substantive *structural* challenge to the W_1 leakage bound — that $\kappa_{W_1} \leq I(A(q_M); G_W | q_M)$ is identically zero for a stateless component under exact conditioning on q_M , so the bound as stated may not measure the leakage it intends (the real channels being query-content correlation, hidden component state, conversation history). This was a strengthen-first / correctness matter for the chapter’s load-bearing construction, **not** Working-Notes gold — flagged in the lift report for the findings/adjudication track. **Resolved** via the strengthen-first spike: the bound was replaced by the selection-channel quantity $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$ and the embedded no-go landed as $\#disc\text{-}w1\text{-structural-bound-boundary}$ (see the W_1 leakage-bound correction provenance note above).

13.5 Derived: Class Coercion in Composition

Under the wrapper construction of $\#der\text{-class-coercion-via-wrapping}$, the wrapped system W is a valid AAT composite agent: it satisfies (A1)–(A4) of $\#form\text{-composition-closure}$, inherits the sector-persistence template from $\#result\text{-sector-persistence-template}$, and incurs a tempo cost in the Brooks’s-Law form of $\#der\text{-tempo-composition}$. This segment establishes those composition-level consequences; the directed-separation guarantee that motivates the construction is established in the prerequisite segment.

Three additional design constraints on the wrapper itself are required for (A2)–(A4) to hold at the wrapper level: that the wrapper commits to a prediction map so macro-mismatch is well-defined; that its belief-update map supports a gain interpretation per $\#def\text{-adaptive-tempo}$; and that the belief-update map satisfies the sector condition with positive correction rate. All three are automatic for Tier-1 belief-update maps via $\#deriv\text{-sector-condition}$ and $\#der\text{-gain-sector-}$

bridge; Tier-2/3 cases inherit the corresponding tier-restricted scope. (A1) holds by construction — the wrapper *builds* in the AAT-shaped state $X_W = (M_W, G_W)$.

Persistence at the wrapper level requires the wrapper’s correction rate to exceed total effective disturbance, which now has *two* contributions: external environmental disturbance acting through the wrapper’s observation channel, and internal disturbance from the component’s response variance, bounded by the variance of the component’s responses to goal-blind queries. The wrapping construction is honest about what it does *not* buy: the component’s internal non-determinism still acts as a disturbance on the wrapper level. What it eliminates is the *belief-goal coupling* that the directed-separation classification identifies as the load-bearing failure mode for Class 3 (Coupled) substrates.

The tempo cost is a **Brooks’s-Law instance**: the wrapper makes $K \geq 2$ component calls per macro-step (one goal-blind for model update, one goal-conditioned for purposeful-state update; more in richer wrapper designs), so the wrapper’s macro-event rate is at most $1/K$ of the component’s underlying rate. The Brooks’s-Law inequality of #der-tempo-composition predicts exactly this — more component calls per macro-step means lower macro-tempo, with the coordination overhead specific to maintaining the wrapper’s (M_W, G_W) state separately from the component’s internal state. The structural reading: a wrapped system gets directed separation (Class 1 status, the full Part II machinery applies) at the *structural price of admission* of (at minimum) halved macro-tempo plus an irreducible internal-disturbance term. This is the framework’s quantitative content for the cost of converting a Class 3 (Coupled) substrate into a Class 1 (Separated) composite.

Formal Expression.

Setup (inherited). The wrapper structure, the four type-signed update components (q_M, q_G, f_M, f_G) , the macro-step schedule ($K \geq 2$ component calls per macro-step), and the admissibility conditions (C1)–(C3) on the component A are defined in #der-class-coercion-via-wrapping. This segment uses that setup without redefinition.

Wrapper-design constraints. For (A2)–(A4) of #form-composition-closure to hold at the wrapper level, the wrapper’s update structure must satisfy three additional constraints:

(D-A2) The wrapper commits to a prediction map $\hat{o}_W : \mathcal{X}_M \times \mathcal{A}_W \rightarrow \mathcal{O}_W$ so that macro-mismatch $\delta_W = o_W - \hat{o}_W$ is well-defined.

Conditions (wrapper-design).

(D-A3) f_M supports a gain interpretation per #def-adaptive-tempo. Holds for Tier-1 belief-update maps — Bayesian on exponential families, gradient on strongly convex losses, linear-PD with bounded gain. Tier-2/3 cases inherit the corresponding tier-restricted scope from #deriv-sector-condition.

(D-A4) f_M satisfies the sector condition with positive correction rate. Automatic for Tier-1 belief-update maps via #deriv-sector-condition Prop A.1 and #der-gain-sector-bridge.

(A1) of #form-composition-closure holds by construction — $X_W = (M_W, G_W)$ has the AAT form because the wrapper *builds it in*.

Theorem: Wrapper as valid AAT composite agent.

Under (D-A2)–(D-A4) and the directed-separation conditions of #der-class-coercion-via-wrapping, the wrapper W satisfies (A1)–(A4) of #form-composition-closure and therefore qualifies as an AAT composite agent.

Derived (wrapper-as-composite, from (D-A2)+(D-A3)+(D-A4)).

Proof. (A1) by construction of the type signatures; the wrapper’s state is $X_W = (M_W, G_W)$ in the AAT shape. (A2) under (D-A2): the prediction map closes the mismatch definition. (A3) under (D-A3): Tier-1 belief-update maps inherit gain interpretation via #deriv-sector-condition Prop A.1, with the Tier-2/3 lifts deferring to the tier-restricted scope

from `#form-composition-closure`'s bridge-lemma classification. (A4) under (D-A4): the sector condition transfers from the (Tier-1) belief-update map to the wrapper level via `#der-gain-sector-bridge`. ■

Inheritance of the persistence template. Under (D-A4), the wrapper inherits `#result-sector-persistence-template` at the wrapper level: persistence holds when $\alpha_W R_W > \rho_W$. The wrapper-level effective disturbance has two contributions: external environmental disturbance ρ_{ext} acting through o_W , and internal disturbance from the component's response variance, ρ_{int} , bounded by the variance of A 's responses to goal-blind queries. Total: $\rho_W = \rho_{\text{ext}} + \rho_{\text{int}}$. Persistence at the wrapper level requires $\alpha_W R_W > \rho_{\text{ext}} + \rho_{\text{int}}$.

Tempo cost — Brooks's-Law instance. The wrapper makes $K \geq 2$ component calls per macro-step (more in richer wrapper designs). If the component's nominal call rate is ν_A , the wrapper-level macro-update rate is $\nu_W = \nu_A/K$. By `#der-tempo-composition`,

$$\mathcal{T}_W \leq \mathcal{T}_A^{\text{nominal}} - C_{\text{coord}}^{\text{wrap}} \quad (13.34)$$

where $C_{\text{coord}}^{\text{wrap}}$ is the coordination overhead specific to the wrapping construction — the tempo consumed by maintaining the wrapper's (M_W, G_W) state separately from the component's internal state. This is the cost of class coercion paid in tempo: the same Brooks's-Law form whose general statement is in `#der-tempo-composition`. Adding state-management infrastructure reduces realized external tempo even when the underlying component's compute rate is unchanged.

Epistemic Status.

Conditional on the wrapper-design constraints (D-A2), (D-A3), (D-A4), and on the prerequisite directed-separation result of `#der-class-coercion-via-wrapping`. The proof is direct verification using inheritance from `#deriv-sector-condition` and `#def-adaptive-tempo`; both are standard. (D-A4) is automatic for Tier-1 belief-update maps; for Tier-2/3 belief-update maps the wrapper inherits the tier-restricted scope from `#deriv-sector-condition` and `#form-composition-closure`'s bridge-lemma classification.

Max attainable: derived under stated conditions. The composition-level claim is parametrized by the belief-update map's tier; Tier-1 cases inherit cleanly, Tier-2/3 cases inherit under additional restrictions.

Discussion.

Coercion-distance vs. tracking-distance. The closure-defect ε^* in `#form-composition-closure` is read as a *fidelity* measure: how well the macro-system tracks the projected micro-system. In the wrapping construction, the wrapper deliberately changes the underlying component's behavior to enforce separation — the wrapper *should* differ from the unwrapped component in the goal-conditioning direction. Two distinct quantities are involved:

- $\varepsilon_{\text{track}}^*$ — the standard fidelity quantity from `#form-composition-closure`. Used in the bridge lemma to bound trajectory error.
- $\varepsilon_{\text{coerce}}^*$ — the wrapping-specific quantity measuring behavioral divergence between the wrapped system and the unwrapped component. Higher means more aggressive coercion.

For wrapper analyses: the persistence-template inheritance (above) uses $\varepsilon_{\text{track}}^*$. Cost-of-class-coercion analyses use $\varepsilon_{\text{coerce}}^*$. The leakage analysis from `#der-class-coercion-via-wrapping` uses κ — a KL-divergence on response distributions, distinct from both trajectory-error quantities. Conflating them propagates downstream confusion.

Form-preservation reading. Read in form-preservation language, (A1)–(A4) of #form-composition-closure are the requirement that AAT’s form survive coarse-graining: macro must itself be AAT. The wrapping construction is the *constructive* version — when the underlying component doesn’t preserve form on its own (Class 2 (Partial) or Class 3 (Coupled)), the wrapper enforces form-preservation at the macro level by structural commitment of the type signatures (from #der-class-coercion-via-wrapping) plus the wrapper-design constraints here. The closure-defect $\varepsilon_{\text{track}}^*$ then plays the role of distance from the form-preserved fixed point in the constructive setup.

Findings.

Wrapper as Valid AAT Composite Agent with Brooks’s-Law Tempo Cost. **Brief:** Once you’ve wrapped a coupled component to get directed separation (the structural rule from #der-class-coercion-via-wrapping), is the wrapped system actually a valid AAT agent that AAT’s machinery applies to? The answer is yes, under reasonable design constraints on the wrapper’s prediction map, gain interpretation, and sector behavior. This means the wrapped system inherits the persistence-condition machinery — the wrapper’s own version of “can the agent keep up with disturbance” applies, with disturbance now decomposing into the external environment’s drift plus the underlying component’s response variance. There’s a cost, and it’s Brooks’s Law in tempo coordinates: every additional component call per cycle (needed to maintain separate belief and goal stores) divides the macro-update rate. The wrapped system runs slower than the component would running alone, by a structurally determined factor.

Impact: Closes the loop on whether the wrapping construction yields a *usable* AAT agent: yes, the wrapper inherits #result-sector-persistence-template and #der-tempo-composition at the wrapper level. Makes the tempo cost of class coercion explicit and quantifiable — it’s a Brooks’s-Law instance, the same general form that governs all AAT compositions, not a special-case tax. Provides the basis for analyzing logogenic-substrate wrappers (e.g., PROPRIUM’s auxilia hierarchy, agentic-tft’s CONTEXTUALIZE-CHOOSE phase separation) as valid composite agents with computable persistence and tempo characteristics.

Novelty Claim: *Claim integration* of the AAT sector-Lyapunov persistence template, Brooks’s-Law tempo accounting, and the form-composition-closure (A1)–(A4) discipline, applied to the wrapper-around-component construction. The composition-level inheritance is straightforward given the persistence-template and tempo-composition machinery; the contribution is establishing that the wrapped system is in the right shape for those results to apply, and naming the Brooks’s-Law form of the coercion cost.

Search Log:

- 2026-05-09 (*targeted*): Search across MDP-homomorphism / hierarchical-control / categorical-systems-theory / FEP-RG / IB-RG / singular-perturbation-RG threads. Verdict: **substantial overlap** with the MDP-homomorphism and categorical-cybernetics lines as the closest formal prior art for composition under coarse-graining. AAT’s contribution is the specific Brooks’s-Law tempo form and the persistence-template inheritance pattern.

Working Notes.

- **Detailed tempo accounting for canonical wrapper architectures.** $C_{\text{coord}}^{\text{wrap}}$ for ReAct-shape, Reflexion-shape, PROPRIUM-shape wrappers is an empirically-relevant computation deferred from this segment’s promotion. The general bound (Brooks’s-Law form via #der-tempo-composition) is established here; specific architectural breakdowns are follow-on.
- **Connection to ELI-specific structure in 04-eli-core/.** Most ELI-specific content (sovereignty axes, accountability infrastructure, identity factors, substrate-independence) is *added structure* beyond what the composition-level inheritance provides — this segment establishes the wrapper as a valid composite agent; ELI work is what happens on top of that substrate.
- **Segment split provenance (2026-05-11).** This segment was bifurcated from a combined “class coercion” derivation. The prerequisite segment #der-class-coercion-via-wrapping carries the directed-separation claim (Claim A: wrapper is Class 1 (Separated) by construction); this segment carries the composition-level claim (Claim B: wrapper is a valid AAT composite agent with persistence-template inheritance and Brooks’s-Law tempo cost). The split reflects FORMAT.md Gate 1 discipline: each segment’s depends list reflects exactly what its claim actually requires.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs. **Coverage:** only one dir reached a digested reflection on this segment (526815) — the deeply-mathematical critique pass; other contributing dirs stopped before it. **No pedagogical / analogy / figure gold surfaced** — 526815’s reflection is entirely *certified-track correctness findings* (the F132–F138 cluster), routed to the findings track, not lifted as Working-Notes gold. The non-finding signal worth preserving:

Belongs elsewhere / convergence signal.

- **The Claim-A / Claim-B split was read as a clean, correct architectural move** — “the intended split is good: directed separation lives in the prior segment; composition-level inheritance lives here” (Codex/Claude, AUDIT-WORKING-526815). Affirms the 2026-05-11 bifurcation recorded above.

Off-ramp note: 526815 raised a substantive *gating* challenge — that satisfying (A1)–(A4) is *not* the full #form-composition-closure criterion (which also requires #scope-composite-agent satisfaction and projection admissibility (P1)–(P3)), so the “valid AAT composite agent” conclusion needs the missing scope and projection gates plus a full-loop sector argument rather than an f_M -only one (F132–F134). This is a strengthen-first / scope-honesty matter for a load-bearing claim, **not** gold — flagged in the lift report for the findings/adjudication track.

13.6 Discussion: Additional Implications & Discussion

The chapter is where AAT’s per-agent machinery lifts to the composite level. Closure defect supplies the criterion for when a group of agents legitimately counts as one larger agent; the bridge lemma converts predictive defect into trajectory error; the wrapping construction supplies the constructive route from Class 3 (Coupled) components to Class 1 (Separated) composites; and the closed-form critical-mass derivation unifies four previously-separate persistence inequalities as signed special cases of a single composite-sector condition. The chapter’s two segments with ## Findings carry the load-bearing technical content well; the implications-side payoff is the cross-segment composition — how the four pieces produce composite-level results that no single segment carries — and what those results buy for 03-11m-core/, AI-safety architecture, and the framework’s identifiability-floor pattern at the composition layer.

Closure defect, bridge lemma, and the meaning of composition.

#form-composition-closure’s Findings cover the closure-defect / bridge-lemma machinery in full: when does a group of interacting agents legitimately count as one larger agent? — answered by an inequality, with explicit failure modes on both sides. The closure-defect ε^* is the minimum residual prediction error from collapsing the micro-system into an AAT-shaped macro-description; the bridge lemma converts that prediction-level error into a trajectory-level guarantee bounded by $\varepsilon^* \nu_c / \alpha_c$ under sector-bounded macro-correction plus strong monotonicity of the macro-update. The implication worth surfacing beyond the segment’s own statement is *what* the framework is offering against adjacent positions, and *what* it is honest about not offering.

Against Markov-blanket and active-inference accounts of nested agency, AAT’s bridge-lemma form supplies a *control-theoretic loss bound* on treating a collection as one agent — something the Markov-blanket apparatus does not produce, even when the boundary criterion is in hand. The closure-defect framework is consistent with the approximate-information-state and influence-based-abstraction lines from PAC-MDP work (Subramanian 2020, Congeduti 2020, Abel 2016, Taylor 2008) but applies the same predictive-loss-to-control-error machinery at the *agent boundary formation* scope rather than at the single-agent compression scope. The framework’s distinctive content is the *use* of bounded-loss composition as an agent-boundary criterion, together with the admissibility conditions (A1)–(A4) on the macro-dynamics that force the macro-description to itself be AAT-shaped (ruling out trivial curve-fits where any composite could be called an “agent” by re-defining state).

The honest scope statement worth keeping in view is that $\varepsilon^* = 0$ does not mean *optimality* — two non-communicating Kalman filters achieve $\varepsilon^* = 0$ while being suboptimal versus a joint filter, because the joint filter could exploit cross-correlation the non-communicating pair cannot. The framework diagnoses *representability* of a composite as an AAT agent, not optimality of that composite against alternative architectures. Strong monotonicity is the hinge — sub-agents that are merely Lyapunov-stable do not compose into a coherent macro-agent, and this is one of the chapter’s quieter surprises. Three agent tiers fall out of the strong-monotonicity requirement: Tier 1 where contraction is proved for the full class (Bayesian on exponential families, gradient descent on strongly convex losses, linear correctors with positive-definite gain); Tier 2 where it holds locally; Tier 3 where it must be verified per-domain.

The critical-mass closed form unifies four signed special cases.

The chapter's deepest cross-segment finding is what `#deriv-critical-mass-composition` produces by composing the bridge lemma with `#der-team-persistence's` signed-coupling decomposition. For the symmetric-matched-Tier-1 dyad, the composite sector constant is now derived in closed form:

$$(\alpha - C)R > \rho + \gamma\mathcal{T} \quad (13.35)$$

with signed γ (negative cooperative, positive adversarial) and C the coordination-overhead cost. The single inequality recovers *four prior results as signed special cases*: single-agent persistence ($\gamma = 0$, $C = 0$, reducing to Part I Ch.4's central inequality); team-persistence with cooperative coupling ($\gamma < 0$, where the negative term enters as effective-disturbance reduction); adversarial destabilization ($\gamma > 0$, where the positive term amplifies disturbance); and coordination-dominated failure ($C > \alpha$, where the composite's effective correction rate goes negative regardless of individual quality — *Brooks's Law as a derived inequality* rather than a folkloric observation). The teleological unity U_O enters multiplicatively on γ plus scope-gate, not additively — a distinction with downstream implications for Ch.3's unity-closure-mapping result.

The implications-side payoff that the segment's Working Notes flag but is worth surfacing: this is the framework's *clean-est internal-economy demonstration*. One inequality, with signed parameters indexing the regime, recovers what previously read as four separate results. The result composes with the sector-persistence template economy (Part I Ch.4 implications, §4): the template absorbed the Lyapunov boilerplate; the critical-mass derivation specializes the template's persistence inequality with a signed-coupling effective-disturbance decomposition that handles single, cooperative, adversarial, and coordination-failure regimes simultaneously. For a practitioner, the engineering anchor is that Brooks's Law (adding people to a late project makes it later) has a *physics-level* derivation here: a development team's macro-correction rate is $\alpha - C$ where C is coordination overhead; once C exceeds α , adding people degrades persistence regardless of individual quality. The threshold is sharp, not gradual, and the inequality predicts exactly where it bites.

The closed form also produces `#disc-identifiability-floor's` Instance 3 in its fullest form. Composite contraction certification from component-marginal data is structurally impossible — the coupling-sign bit ($\gamma < 0$ vs $\gamma > 0$) is unidentifiable from how each component looks in isolation (Liberzon 2003's common-Lyapunov-nonexistence is the external no-go). The five boundary routes named in `#disc-identifiability-floor` for Instance 3 escape this: under matched-Tier conditions the closed form supplies the coupling sign by interventional access at the composite scope, via Mode 2 of the loop-Level-2 pattern (observer-on-sub-agent, from Part II Ch.2 implications). The chapter is therefore where the *third* formal instance of the identifiability-floor pattern becomes statable; the four-instance pattern is completed with Instance 1 (Part II Ch.4), Instance 2 (Part II Ch.3), Instance 3 (here), and Instance 4 (Part II Ch.5 / Appendix A — `#der-architecture-noidentifiability`, architecture-noidentifiability from on-policy summary data).

Class coercion via wrapping — what the construction unlocks.

`#der-class-coercion-via-wrapping's` Findings cover the constructive directed-separation result well: when a component (like an LLM) has belief-update and goal-conditioning entangled in a single forward pass, a scaffold around it can maintain explicit separate stores for belief and goal, with belief updates only seeing queries that don't include the goal as input. Under named admissibility conditions on the component, the wrapped system is goal-blind in its belief updates *by construction* — even though the underlying component is not. The $W_0/W_2/W_1$ regime hierarchy names the practical landscape: W_1 (strict wrapping, structural leakage bound, theoretically clean), W_2 (partial wrapping with goal-conditioned call and parsed response, behavioral leakage bound, operationally common), W_0 (no wrapping — the unconverted Class 3 case).

The implications-side payoff is what the construction unlocks beyond the segment's statement: it is the *constructive bridge* that resolves how AAT's Part II results — derived for Class 1 (Separated) agents — apply to Class 3 (Coupled) substrates. Without the wrapping construction, Class 3 components would sit outside Part II's persistence machinery

as a scope exit; with the wrapping construction, the wrapped system at the *wrapper level* is Class 1 (Separated) by construction, inherits the sector-persistence template, and operates under the standard AAT results. The cost is paid in two places: a Brooks's-Law tempo overhead (more component calls per macro-step), and a residual leakage rate bounded structurally (W_1 , by the wrapper's query design) or behaviorally (W_2 , by the component's instruction-following fidelity).

The composition-level consequences are derived in *#der-class-coercion-in-composition*: the wrapped system is a valid AAT composite agent, satisfying admissibility conditions (A1)–(A4) of *#form-composition-closure* under wrapper-design constraints (D-A2)–(D-A4). It inherits the sector-persistence template at the wrapper level; its tempo cost is the Brooks's-Law composition cost from *#der-tempo-composition*. This is the chapter's quiet load-bearing claim for *03-llm-core/*: language-model substrates are *constructively* in AAT scope, at a measurable cost, rather than scope-out. The implications for AI-safety practice are concrete: scaffolded loops around LLMs are not just engineering convenience — they are the structural mechanism that converts a Class 3 (Coupled) substrate into a Class 1 (Separated) composite, and the leakage bounds tell the practitioner what residual coupling remains. The Generative Agents observation→memory step (Park et al. 2023) is the canonical empirical W_1 instance; most production tool-using LLM frameworks (ReAct, Reflexion, Toolformer, MemGPT) sit in W_2 . The framework's regime hierarchy gives all of these constructions a *structural* reading rather than an engineering-pattern reading.

The cross-domain transfer follows naturally. Human bicameral / dual-process models (Kahneman 2011) are W_1 -style internal scaffolding when the deliberative system constrains the intuitive system through structural commitment to goal-blind belief-update queries; organizations where executive scaffolding (boards, committees, decision rights) recovers cascade ordering across coupled individuals are W_1/W_2 at the organizational scale. The framework's structural claim is the same in all three cases: *separation at the wrapper level is what gives AAT-grade behavior; the wrapping construction is structurally non-optional for Class 3 (Coupled) substrates.*

Tempo composition, Brooks's Law, and the bandwidth connection.

#der-tempo-composition carries the sub-additive tempo inequality: $\mathcal{T}_c \leq \sum_i \mathcal{T}_i$, with the gap bounded below by $C_{\text{coord}} \geq \varepsilon^* \nu_c$. The implication is that *coordination overhead acts as effective disturbance at the composite level* — closure defect $\varepsilon^* \nu_c$ is what the template's instantiation at the composite identifies as the internal contribution to effective disturbance, alongside the external environmental rate ρ_{ext} . The composite persists when $\alpha_c R_c > \rho_{\text{ext}} + \varepsilon^* \nu_c$, and Brooks's Law follows: adding agents increases $\sum_i \mathcal{T}_i$ but may increase $\varepsilon^* \nu_c$ faster, pushing the composite's effective disturbance past its persistence threshold even as nominal capacity grows.

The composition with Part I Ch.4's information-rate floor is worth surfacing as a cross-segment finding. Each agent in the composite pays its own $\dot{R} \geq n\alpha/2$ bandwidth cost; the composite as a whole pays the sum *minus what coordinated sub-agents save on shared observation*. But there is a complementary cost: the closure defect $\varepsilon^* \nu_c$ has its own information-rate signature, because maintaining the bridge-lemma's strong-monotonicity condition at the macro-update requires the composite to acquire information about how its sub-agents are interacting. The framework's prescription is that *composite persistence pays for both the sub-agents' individual bandwidth and the coordination-overhead bandwidth*, and the trade-off between adding agents (more $\sum_i \mathcal{T}_i$, more individual bandwidth) and increasing coordination overhead (more $\varepsilon^* \nu_c$, more coordination bandwidth) has a precise inflection point at $C_{\text{coord}} = \alpha_c$. Past the inflection point, additional sub-agents *cost more bandwidth than they buy*, and the composite's persistence-information-rate floor moves up faster than its persistence threshold. This is the implication of the chapter's machinery for distributed-systems design: the sweet spot for sub-agent count is bounded by the coordination-overhead growth rate, not by individual sub-agent capacity.

The chapter is also where Mode 2 of the loop-Level-2 deployment pattern (observer-on-sub-agent, from Part II Ch.2 implications) becomes structurally load-bearing. The Liberzon-anchored identifiability-floor Instance 3 says the coupling sign cannot be recovered from component marginals; the unique broadly-available escape is interventional access at the composite scope. Operationally, this means an external observer (or the composite agent itself acting on its sub-agents) can recover the sign by performing *do*-interventions on one sub-agent and observing the response of another.

The closed-form critical-mass derivation gives the mathematical form of the recovered coupling; the loop-Level-2 access at the composite level gives the data substrate that recovery requires.

Closing notes and the bridge into Unity, Communication, and Shared Intent.

What this chapter closes on is the composite-agent foundation Part III needs: a representability criterion via closure defect, a trajectory-level loss bound via the bridge lemma, a closed-form persistence inequality that recovers single-agent, team, adversarial, and Brooks's-Law regimes as signed special cases, a constructive route from Class 3 (Coupled) components to Class 1 (Separated) composites with measured leakage bounds, and a sub-additive tempo inequality whose coordination-overhead term enters the persistence template as effective disturbance at the composite level. The chapter's two segment-level ## Findings sections carry the load-bearing technical content; this implications segment surfaces the cross-segment composition and the engineering anchors that the segments individually cannot reach.

The bridge into Part III Ch.3 (Unity, Communication, and Shared Intent) is the closure-defect ε^* itself. The dimensions of unity — content axes ($U_M, U_O, U_\Sigma, U_{\text{obs}}$) and structural axis (U_f) — parametrize *what sub-agents can share*; Ch.3's #result-unity-closure-mapping shows that unity parametrizes a rate-distortion curve for closure defect. The chapter here gives the closure defect a precise form; Ch.3 gives unity its quantitative content; together they say *which dimensions of unity matter how much for which kinds of composite-agent persistence*. The cooperative-vs-adversarial machinery in Ch.4 then operates on what Ch.2 and Ch.3 jointly build: cooperative coupling reduces γ (lowers effective disturbance); adversarial coupling raises γ (amplifies it); the signed-coupling structure is the same inequality viewed from opposite directions. Ch.5's strategic composition lifts the symmetric partially-opposing case from scalar coupling to equilibrium machinery (potential / monotone games), and the identifiability-floor pattern's Instance 3 instance becomes operational there in its strongest form.

Working Notes.

- This segment is a chapter-end discussion grouping findings from #form-composition-closure, #der-tempo-composition, #hyp-directed-separation-under-composition, #der-class-coercion-via-wrapping, #der-class-coercion-in-composition, #deriv-critical-mass-composition (Appendix A), #result-sector-persistence-template (Appendix A), and #der-directed-separation (Part II Ch.1, the architectural classification the wrapping construction lifts to composite status). Cross-pattern reading leans on #disc-identifiability-floor's meta-segment for the Instance 3 surfacing and #disc-modularity-state-dynamics for the truthification-mechanism reading of the wrapping construction.
- **Cross-reference vs canonical-home policy.** Two source segments in this chapter carry well-written ## Findings sections — #form-composition-closure (closure-defect and bridge lemma) and #der-class-coercion-via-wrapping (constructive directed separation). Both are cross-referenced rather than restated. The findings whose canonical home is this implications segment are the *cross-segment compositions*: the critical-mass closed form as recovery of four signed special cases (composing #deriv-critical-mass-composition with #der-team-persistence and Part I Ch.4's persistence condition), the Brooks's-Law derivation as inequality (composing #der-tempo-composition with the template), the composition-level identifiability-floor Instance 3 (composing #deriv-critical-mass-composition with #disc-identifiability-floor's pattern and Part II Ch.2's loop-Level-2 access), and the wrapping-construction-as-truthification (composing #der-class-coercion-via-wrapping with #disc-modularity-state-dynamics's three-operation pattern).
- **Class-coercion as truthification mechanism — connection to #disc-modularity-state-dynamics.** The M4 meta-segment positions modularity as a *contested property* under three operations: truthification (self-driven-increasing), strategic self-coupling (self-driven-decreasing), and adversarial coupling pressure (externally-driven-decreasing). Class coercion via wrapping is one of two operational mechanisms for truthification — alongside defensive scaffolding (peer review, prediction registers, etc., from #disc-adversarial-coupling-pressure). The chapter is therefore where modularity-as-state lands its first construction: wrapping is a structural commitment that *moves* a composite agent's modularity state from W_0 (no wrapping) toward W_1 (strict wrapping) under explicit cost, and the cost is the framework's quantitative content for the M4 truthification operation.

- **Identifiability-floor pattern coverage now four-of-four.** With this chapter’s content, the pattern’s four formal instances are all in view: Instance 1 (Part II Ch.4 — on-policy L0-insufficiency), Instance 2 (Part II Ch.3 — L1’ mixture under unobservable common cause), Instance 3 (here — composite contraction certification from component marginals), Instance 4 (Part II Ch.5 / Appendix A — architecture-noidentifiability from on-policy summary data, #der-architecture-noidentifiability). Instance 5 (Mehra non-identifiability in adaptive Kalman) remains candidate. The implications-side payoff is the cross-instance dual structure: Instance 1 and Instance 2 cover agent-internal failures of identification (single agent, action / mixture layers); Instance 3 covers composition-level failure (coupling sign across sub-agents); Instance 4 covers architecture-level failure (similarity orbit on the agent’s internal realization). Three of the four (Instances 1, 2, 4) sit in the rank-collapse subclass with Sylvester’s law of inertia governing escape-irreducibility (directly for Instances 1 and 2; at one remove for Instance 4, whose generating action is state-space similarity rather than metric congruence); Instance 3 is the distinct projection/closure member. The unique broadly-available escapes share Pearl-do structure (loop-interventional access) — Instances 1, 3, and 4 all elevate #der-loop-interventional-access as *three semantically-distinct deployment modes* (agent-self-intervention / observer-on-sub-agent / observer-on-agent-input), each breaking a distinct Level-1 degeneracy.
- **No NeurIPS submission directly formalizes this chapter’s machinery.** The closure-defect framework, the bridge lemma, and the critical-mass closed form are AAT-internal; their cross-references in Paper 2 (RL convergence) and Paper 3 (LLM hallucinate bound) are scope and structural-argument links rather than theorem-grade adoption. A composition-themed submission would naturally land here in a future cycle.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs. **Coverage:** only one dir reached a digested reflection on this chapter-end implications segment (526815) — the deeply-mathematical critique pass. **No pedagogical / analogy / figure gold surfaced** — 526815’s reflection is entirely *certified-track correctness findings* (the F139–F145 cluster, mostly “this implications map presents appendix-derived / conditional payoffs as settled”), routed to the findings track, not lifted as Working-Notes gold. The non-finding signal worth preserving for the eventual synthesis:

Belongs elsewhere / convergence signal.

- **The representability-vs-optimality distinction was named the chapter’s strongest contribution to preserve in the final synthesis** — “the representability-versus-optimality distinction is one of the chapter’s strongest contributions. Preserve it in final synthesis” (Codex/Claude, AUDIT-WORKING-526815, “Watch”). Converges with the same distinction lifted into 13.1 (the two-Kalman result) — a clear signal this is the chapter’s headline idea to foreground in the implications map’s framing.

Off-ramp note: 526815’s main thrust here is that this discussion-grade implications map “presents the critical-mass closed form, four signed special cases, identifiability-floor Instance 3, and bandwidth-inflection claims as settled” while their proof homes are appendix-derived or conditional, and that it inherits the upstream tempo-double-counting and wrapper-scope-gate issues (F139–F143). These are voice-discipline / scope-honesty matters for the implications segment, **not** gold — flagged in the lift report for the findings/adjudication track.

Chapter 14

Unity, Communication, and Shared Intent

[Gap] Discussion

The quality of a composite agent's composition — *conditional on 12.2 being satisfied via at least one of its four routes (three alignment routes + the strategic-equilibrium route (C-iv))* — is parametrized along **two architecturally distinct axes**:

- **Content axis (four unity dimensions).** What the sub-agents *share*: epistemic (U_M , shared model), teleological (U_O , shared objective), strategic (U_Σ , coordinated action), and perceptual (U_{obs} , shared observations).
- **Structural axis (update-rule homogeneity, U_f).** Whether sub-agents implement the *same* correction rule: how similar their f_M updates are across the population.

Together, the two axes parametrize the rate-distortion curves for the component closure defects (13.1, 14.1). Higher unity along either axis permits more aggressive compression at lower closure defect; neither axis alone is sufficient. In pure Part I composition (passive estimators, no G_t), agents with identical content can still produce non-zero ε_x if their update rules differ — the content axis cannot detect this, which is why the structural axis is required. Unity (in either sense) does not directly predict closure-defect magnitude; it controls the compressibility of the corresponding state, observation, or action component under projection.

Scope. The decomposition applies to composites that satisfy 12.2. U_O plays a role in the (C-i) route of the scope condition via value-correlation, but the scope condition is a disjunction of four routes — three alignment routes (shared objective, hierarchical derivation, mutual benefit) plus the strategic-equilibrium route (C-iv) — not a scalar threshold on U_O . Below scope-satisfaction (no route applies), the sub-agents are a multi-agent system per 12.1 and composition-level quantities are not well-defined.

For a composite agent A_c composed of sub-agents $\{A_1, \dots, A_n\}$, the unity profile consists of *four content dimensions* (this section, below) and *one structural dimension* (U_f , defined after the content dimensions).

Definition (definition-unity-dimensions).

Epistemic unity U_M — how much of the reality model is shared:

$$U_M = \frac{I(M_t^{(1)}; \dots; M_t^{(n)})}{(n-1) H(M_t^{(1)}, \dots, M_t^{(n)})} \quad (14.1)$$

The fraction of total model information that is shared (total-correlation ratio, normalized to $[0, 1]$). The numerator is the total correlation $I = \sum_i H(M_t^{(i)}) - H(M_t^{(1)}, \dots, M_t^{(n)})$; the $(n - 1)$ factor in the denominator is its normalizer, since each marginal entropy is at most the joint entropy and hence $I \leq (n - 1) H(M_t^{(1)}, \dots, M_t^{(n)})$, with equality iff each model determines all the others. So $U_M = 1$ for identical models and $U_M = 0$ for independent models, for every n . (Without the $(n - 1)$ factor the ratio reaches $n - 1$ at identity — the bare multi-information/joint-entropy form is normalized correctly only at $n = 2$.)

Teleological unity U_O — how aligned are the objectives:

$$U_O^{(i,j)} = \text{corr}\left(V_{O_t^{(i)}}(\tau), V_{O_t^{(j)}}(\tau)\right) \quad (14.2)$$

over trajectories the composite encounters. $+1$ for identical objectives; -1 for perfectly opposed; 0 for orthogonal. The composite teleological unity is an aggregation over all pairs. The scalar ranges from fully cooperative to fully adversarial per objective dimension.

[Scope note] U_O plays a role in 12.2 — primarily along route (C-i), where value-correlation is the operationalization of teleological alignment. The scope condition itself is disjunctive: it is satisfied when *any* of the alignment routes (C-i), (C-ii), (C-iii) applies, or when the strategic-equilibrium route (C-iv) applies; not by U_O alone crossing a common scalar threshold. The quality-metric role of U_O captured in this segment presumes scope-satisfaction via *some* route; on the (C-iv) side it tracks at best the alignment projection of a strategic composite whose macro-state is defined by equilibrium structure rather than by a shared target. When the sub-agents fail all four routes, they form a multi-agent system (12.1) but not a composite, and composition-level quantities (closure defect, composite tempo, team persistence) are not well-defined.

Strategic unity U_Σ — how coordinated is the joint policy:

Discussion.

$$U_\Sigma = 1 - \frac{D_{\text{KL}}(\pi_{\text{actual}}^c \| \pi_{\text{optimal}}^c)}{D_{\text{KL}}(\pi_{\text{independent}}^c \| \pi_{\text{optimal}}^c)} \quad (14.3)$$

where π_{optimal}^c is the jointly optimal policy. $U_\Sigma = 1$ when actual matches optimal; $U_\Sigma = 0$ when actual matches independent (no coordination). Requires knowing the jointly optimal policy, which is itself a strong assumption.

Perceptual unity U_{obs} — how much of the observation stream is shared:

The fraction of total observation information that reaches all sub-agents. Full perceptual unity means all agents observe the same signals; zero means private observations only. Enables epistemic convergence without explicit model-sharing.

Update-rule homogeneity U_f — how similar the sub-agent update rules are:

Definition.

$$U_f = 1 - d\left(f_M^{(1)}, \dots, f_M^{(n)}\right) \quad (14.4)$$

where d is a distance over the space of update operators $f_M : (M, o, a) \mapsto M'$, normalized so that $U_f = 1$ when all sub-agents implement the same correction rule and $U_f = 0$ at maximal heterogeneity. The choice of d is case-specific — for parametric Kalman-like updates, $d \propto |\Delta K|/K_{\text{max}}$ on the gain parameter; for Bayesian updates with shared structural form but different priors, d tracks divergence between the induced kernels; for arbitrary f_M in function space, candidates include operator-norm distance, Fisher-information-weighted distance, or IB-style comparison.

Where the four content unities measure shared *information* across sub-agents (state, objective, policy, observation), U_f measures shared *structure* — whether the agents instantiate the same update law. The two axes are independent: agents can share a model ($U_M = 1$) while updating it differently ($U_f < 1$), and conversely. In purposeful settings (G_t present), U_Σ partially absorbs structural variation in the policy half of the cycle, but the model-update half remains uncovered without U_f . In pure Part I composition (passive estimators, no G_t), U_f is the only handle on structural homogeneity. The closed-form linear-Gaussian instance — heterogeneous Kalman gains $\Delta K = K_1^* - K_2^*$ producing $\varepsilon_x \propto |\Delta K|$ — is derived in 14.1 §Two-axis structure.

Discussion.

The achievable component closure defect $\varepsilon_d^{\min}(k_d)$ under a projection of macro-dimension k_d is a function of *both* axes — the relevant content unity U_d and the structural unity U_f — together with the projection-dimension parameter:

$$\varepsilon_d^{\min}(k_d) = f_d(k_d; U_d, U_f) \quad (14.5)$$

monotone decreasing in each unity argument and monotone increasing in compression aggressiveness (smaller k_d). The form is derived in 14.1; in linear-Gaussian scalar cases it admits closed-form expressions for $d \in \{x, o, a\}$. U_O and U_Σ enter ε_a jointly rather than separately — collapsing alignment to a single scalar (U_O alone) would mis-route the repair, since execution-path divergence (U_Σ) cannot be fixed by re-aligning targets. This is the **anti-collapse** discipline (5.7) at the composite layer: two distinct quantities a naive reading merges, routing to different corrections.

Discussion-grade. Max attainable: empirical. The four content dimensions are qualitatively motivated by correspondence with the four components of agent state (M_t , O_t , Σ_t , and the observation channel); the structural dimension U_f is forced by the linear-Gaussian two-Kalman case (14.1 §Two-axis structure), where heterogeneous gains produce non-zero ε_x that no content dimension can register. The two-axis architecture (content $\times$ structure) is therefore a definitional commitment of this segment, not a heuristic.

The specific metrics are sketches. The information-theoretic formulations (U_M , U_Σ) are well-defined in principle but require specifying distributions and distance measures for practical computation. U_f is even less prescriptive — the choice of operator distance d is case-specific, and a general theory of structural-variation measures across arbitrary f_M classes is open.

The claim that the dimensions are *substantially independent* is a hypothesis, not derived. Epistemic unity may enable strategic unity (shared models allow coordination without explicit planning); content unity along U_M does not constrain U_f (agents can share a posterior while updating it differently). Independence holds approximately, with documented joint dependencies: (U_O , U_Σ) jointly control ε_a and cannot be separated; U_f enters all three closure components (ε_x , ε_o , ε_a) as a structural multiplier on what content unity alone would predict.

Clausewitz’s three gaps. These dimensions map to the gaps identified by Clausewitz (systematized by Bungay in *The Art of Action*):

Table 14.1

<i>Clausewitz Gap</i>	<i>Unity Dimension</i>	<i>Formal Quantity</i>
Knowledge gap	Epistemic unity (U_M)	$1 - U_M$: fraction of model not shared
Alignment gap	Teleological unity (U_O)	$1 - U_O$: objective misalignment
Effects gap	Strategic + Perceptual unity	$1 - U_\Sigma$ + observation routing costs

The mapping is not perfect — Clausewitz’s “effects gap” blends action coordination with observation feedback — but it provides 200+ years of organizational evidence for the qualitative decomposition.

Connection to closure defect. The unity dimensions parametrize a rate-distortion relation with the component closure errors in 13.1, not a direct correspondence. The formal statement is in 14.1: the achievable closure-defect component $\varepsilon_d(k_d)$ under a projection of macro-dimension k_d decreases monotonically in both the relevant content unity U_d and the structural unity U_f , with closed-form expressions in the linear-Gaussian case. Qualitative direction along the content axis: U_M governs the compressibility of state information (ε_x), (U_O, U_Σ) jointly govern action compressibility (ε_a), U_{obs} governs observation compressibility (ε_o). The naive reading “high U_d predicts low ε_d ” fails: for non-compressing projections (e.g., the means-only projection in the two-Kalman case) $\varepsilon_x = 0$ regardless of U_M , while for heterogeneous-gain projections $\varepsilon_x > 0$ even at perfect content correlation. Both observations point at the same correction — closure defect lives on a rate-distortion surface with two unity arguments, not a single one.

What each dimension’s absence costs.

- Low U_M : prediction conflicts $\rightarrow$ uncoordinated actions based on contradictory beliefs. Internal mismatch component from model disagreement.
- Low U_O : strategic friction $\rightarrow$ sub-agents pursue conflicting sub-goals. Effort wasted or counterproductive.
- Low U_Σ : redundancy and gaps $\rightarrow$ two agents fix the same bug while a critical one goes unnoticed.
- Low U_{obs} : information silos $\rightarrow$ critical signals observed by one agent but not actionable by the composite.
- Low U_f : structural drift $\rightarrow$ even agents sharing identical models, objectives, observations, and policy targets produce divergent macro-trajectories under aggressive projection, because their corrections respond to the same evidence with different gains. The composite cannot be summarized at low macro-dimension without residual error scaling with the gain mismatch.
- The independence of unity dimensions needs careful examination. High epistemic unity likely enables (but does not guarantee) high strategic unity — if agents share models, they can coordinate implicitly. The dimensions may be better described as “substantially independent inputs to a joint prediction of ε^* ” rather than “independent properties.” Independence between content axis and structural axis ($U_d \perp U_f$) is cleaner — content sharing and update-rule similarity are categorically distinct properties — but a formal proof is open.
- The specific metric formulations need testing on concrete cases (software team, military unit) to determine if they discriminate meaningfully between well-composed and poorly-composed groups.
- The teleological unity scalar per objective dimension (+1 to -1) captures mixed cooperative-competitive situations: a company can be cooperative on product quality and competitive on internal resource allocation simultaneously.
- **U_f operator-distance choice is open.** The definition leaves d case-specific. A general theory of structural-variation measures across arbitrary f_M classes (operator-norm distance, Fisher-information-weighted distance, IB-style comparison) is unsettled. The linear-Gaussian Kalman case ($d \propto |\Delta K|/K_{\text{max}}$) is the only worked closed form; non-Gaussian and non-linear cases are open follow-up work tracked in 14.1 Working Notes.
- **Joint (U_O, U_Σ) $\rightarrow \varepsilon_a$ dependence.** State error tracks U_M ; action error tracks *both* U_O (target alignment) *and* U_Σ (policy alignment); observation error tracks U_{obs} . The two dimensions jointly controlling action error are physically distinct: U_O is about evaluation/preference agreement; U_Σ is about execution-path agreement. Agents with identical objectives but different execution plans have high U_O , low U_Σ ; agents coordinating on arbitrary shared routines have high U_Σ , low U_O . See 14.1 for the quantitative relationship.

- **U_O as scope vs. quality.** The scope role is in 12.2 as a disjunction of four routes (three alignment + one strategic-equilibrium) — U_O is the value-correlation operationalization of route (C-i), not a universal scope variable. The quality-metric role remains here, presumed conditional on scope-satisfaction via at least one route. Open: whether the three alignment routes (C-i)–(C-iii) reduce to a single scalar is not established, and the strategic-equilibrium route (C-iv) is structurally distinct from any alignment-side aggregation, so “scope-satisfaction” and “ U_O value” should be treated as distinct concerns in downstream uses.

Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (the metric-repair findings F146–F150 from AUDIT-WORKING-526815 are routed for adjudication, not here — see the off-ramp note at the end). **Coverage:** three dirs carry a dedicated reflection (526815, 829314, 849201) plus two batched dirs (451729 batch-14, 613842 composition-cross-component). The other contributing dirs stopped earlier in the OUTLINE walk. Substrate attribution inferred from voice where not explicit; uncertain cases hedged. **Finding-vs-framing conflation preserved:** several “candidate Discussion” entries below were written as confident results in first-encounter cognition; that texture is signal, kept rather than sanitized.

- Plain-statement of the structural-axis insight, Feynman-criterion-adjacent: “even if two agents know the exact same things and want the exact same things, if one learns fast and the other learns slow, they cannot be mathematically compressed into a single macro-agent without accumulating trajectory error” (Gemini, AUDIT-WORKING-829314). Compact hook for a Brief or Discussion opener on why content unity is not enough.
- “Decomposes ‘teamwork’ into its orthogonal mathematical components” — one-line gloss of the segment’s contribution (Claude, AUDIT-WORKING-849201).
- **Clausewitz-three-gaps mapping is the standout pedagogy — promote it more prominently.** Two substrates independently flagged the mapping of the unity dimensions to Clausewitz’s three gaps (Knowledge / Alignment / Effects) as “an absolutely brilliant piece of pedagogical framing ... it grounds the abstract information theory in 200 years of practical military strategy”; the recommendation is to highlight that table even more prominently (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201 — “a phenomenal domain connection”).
- **Content alignment is dynamically unstable without structural alignment (the “metabolism mismatch” / “culture fit” framing).** The sharpest worked elaboration of U_f : a two-engineer team perfectly aligned on content ($U_M = U_O = U_\Sigma = 1$) but with mismatched update rules — Engineer A highly plastic (rewrites architecture on every bug), Engineer B highly stable (patches the line) — will violently diverge the instant a shared bug is observed, “not because they disagreed on facts or goals, but simply because their internal learning metabolisms were mismatched.” This is offered as the formal content of the corporate “culture fit” problem: hiring is for f_M -compatibility, not only skills; dropping a “move fast and break things” developer into a slow-moving aerospace team spikes the closure defect ε^* and destroys macro-agent tempo (Gemini, AUDIT-WORKING-829314). (*Finding-vs-framing texture: written as a proof — “proves mathematically that ...” — but the general- U_f monotonicity is only worked for the linear-Gaussian two-Kalman case per 14.1; promote as motivated framing, not as established theorem.*)
- **Epistemology does not guarantee strategy — the two-autonomous-cars example.** “Two autonomous cars might have perfect, identical models of an intersection ($U_M = 1$), but if they don’t coordinate their policies, they will still crash ($U_\Sigma = 0$).” A vivid one-line separation of the epistemic and strategic content axes (Gemini, AUDIT-WORKING-829314).
- **Closure defect as the formal analog of “organizational complexity.”** ε^* reads as “the gap between what a collection of agents could achieve in principle and what a coherent macro-description can represent” — the formal version of what organizational scientists call organizational complexity. Crucially: coherence (closure

defect) and efficiency (performance gap) are *orthogonal* axes — “you can have a perfectly coherent organizational description of an inefficient organization” (Claude, AUDIT-WORKING-451729, batch-14). A candidate framing-level Discussion note on what the two-axis taxonomy is *for*.

- **The two-Kalman $\epsilon^* = 0$ diagnostic, in words.** Two non-communicating Kalman filters tracking correlated targets are “perfectly representable as one agent” even though they never share information — not because they cooperate, but because each individually generates a sufficient statistic for the macro-state’s next observation. Representability $\neq$ optimality (Claude, AUDIT-WORKING-451729, batch-14). Belongs more to 14.1 but motivates why the content axis alone is the wrong diagnostic here.
- **Mixed-motive U_O .** How does the theory handle U_O in mixed-motive games where agents cooperate on survival but compete on resource allocation? The per-objective-dimension scalar (+1 to −1) is noted to cover this in principle, but the aggregation math “must be tricky” — worth a worked example (Claude, AUDIT-WORKING-849201; echoed Gemini, AUDIT-WORKING-829314 on group-level/nontransitive alignment).
- **C-iv ontology drift — closure/unity machinery still assumes the older shared-objective idiom.** A cross-component pass flagged that the scope layer (12.2) has accepted route (C-iv) (strategic composites with no shared O_c , macro-state defined relative to equilibrium structure $\mathcal{E}$), but this segment “still describes the scope as a three-route disjunction and treats composition-level quantities as unavailable whenever the three alignment routes fail” — a real integration gap between the broadened scope and the unity machinery (Claude, AUDIT-WORKING-613842). The existing “ U_O as scope vs. quality” Working Note above already partly tracks this; the cross-component observation sharpens it into a propagate-C-iv-into-the-unity-segments task.
- Auditors converged on the same conceptual checks as natural reader questions: that $U_M = 1$ does not force $U_\Sigma = 1$ (the cars), and that the four content unities measure shared *content* but not shared *structure* — the “missing axis” that U_f supplies. Two fresh readers independently praised the segment for flagging this gap rather than hiding it (“the epistemic honesty to flag this gap ... is exemplary” — Claude, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-829314).
- **Two-axis closure-defect surface.** A rate-distortion surface controlled by two roughly-independent inputs — content unity and structural homogeneity — with the metric-normalization warning marked on the content side (since bad normalization would mislead the surface before any later derivation begins) (Codex/Claude, AUDIT-WORKING-526815).
- **Rate-distortion-as-compressibility army/management framing** belongs to 14.1 (lifted there), but originates partly from the structural-axis intuition seeded here.
- AUDIT-WORKING-526815 raised five metric-level findings on this segment that are strengthen-first / repair candidates, not framing gold, and are flagged here only so they are not lost: **F146** — $U_M = I(M^{(1)}; \dots; M^{(n)})/H(M^{(1)}, \dots, M^{(n)})$ is *not* normalized to $[0, 1]$ as the discussion-grade label implies (for n identical variables of entropy H , total correlation is $(n - 1)H$ and joint entropy is H , so the ratio is $n - 1$, not 1 — needs a capped/rescaled redundancy measure); **F147** — teleological unity as pairwise value-function correlation is distribution-/policy-dependent and undefined for zero-variance value functions (needs support/variance/aggregation conventions); **F148** — the strategic-unity KL ratio can have a zero denominator, infinite KL, or leave $[0, 1]$ without clipping; **F149** (soft) — U_{obs} as “fraction of observation information reaching all sub-agents” misses complementary-private-plus-routed and synergistic-private observation; **F150** (soft) — $U_f = 1 - d(\cdot)$ presumes a normalized $d \in [0, 1]$ that the candidate operator/Fisher/IB distances do not automatically satisfy. *These are metric-formalization re-pairs (mostly scope/normalization tightenings), not no-gos; routed for adjudication on the strengthen-first track.*

14.1 Result: Unity-to-Closure Rate-Distortion Mapping

Unity dimensions parametrize rate-distortion curves for closure-defect components, not point-valued predictors. The achievable closure-defect component ε_d under projection of macro-dimension k_d is monotone decreasing in both the relevant content unity U_d and the structural unity U_f (update-rule homogeneity), with higher unity along either axis lowering achievable defect at a given compression. Closed forms hold in the linear-Gaussian case; structural monotonicity survives more broadly. The two-axis structure (content $\times$ structure) is forced by the heterogeneous-Kalman case below and is reflected definitionally in `#def-unity-dimensions`.

Several closed-form linear-Gaussian instances drive the structural conclusions. *Observation closure defect* scales as $1 - U_{\text{obs}}$ in the two-agent scalar case under 1D projection: higher perceptual unity means observations are more redundant, a 1D summary suffices, and ε_o shrinks. *Action closure defect* scales as $\kappa^2(1 - U_O)$ for independent policies under 1D state projection, with policy coordination (strategic unity) providing a further multiplicative reduction — U_O and U_Σ enter ε_a *jointly* rather than separately. A striking structural fact for the *state* closure defect: under linear dynamics with consistent linear projections, $\varepsilon_x \equiv 0$ regardless of U_M or compression dimension. State closure becomes non-trivial only when the projection's range is non-invariant under the micro-dynamics, the projection is inconsistent, the micro-dynamics are nonlinear — or *sub-agent update rules are heterogeneous*. This is the structural fact that forces the two-axis decomposition: the content axis cannot detect structural heterogeneity in updates; the structural axis is required.

The heterogeneous-Kalman closed form makes this concrete: two Kalman filters with different gains produce $\varepsilon_x^2 \propto (\Delta K/2)^2$ — a defect proportional to the gain mismatch even when priors are identical, even at perfect content correlation. The same structural-unity mechanism lifts to the *strategy layer* via the credence-composition case: N agents reasoning over a shared plan skeleton, working in the log-odds coordinate forced by `#deriv-edge-update-natural-parameter`, produce ε_Σ^{*2} driven by the *variance of edge-update gains across agents* — homogeneous gains yield zero defect, gain dispersion drives the defect, and the result is *dimension-free* in N . The structural-unity axis is forced — not optional — for any framework that wants to predict closure defect from agent-level properties.

The conceptual consequence of the rate-distortion framing is that **unity is a compressibility parameter**, not a magnitude that maps to closure-defect magnitude. Higher unity allows more aggressive compression at the same closure defect, or equivalently, lower closure defect at the same compression. The rate-distortion *surface* is what unity controls; closure-defect values sit on that surface depending on how aggressively the composite is compressed. This is the same shape as Shannon rate-distortion theory and as the Information Bottleneck (`#form-information-bottleneck`) — composition trades representational compactness against fidelity-to-the-micro-system, and unity dimensions name where the trade is cheap (high unity, small defect achievable under aggressive compression) versus expensive (low unity, defect grows fast under any non-trivial compression).

Formal Expression.

Rate-distortion framing (general).

Fix a composite agent satisfying the admissibility conditions (A1)-(A4) in 13.1. For each content unity dimension U_d (with $d \in \{M, \Sigma, \text{obs}\}$, and U_O contributing jointly with U_Σ — see below) and the structural unity U_f (update-rule homogeneity, defined in 14), the achievable component closure defect under a projection whose corresponding macro-dimension is k_d satisfies:

Formulation (unity-rate-distortion).

$$\varepsilon_d^{\min}(k_d) = f_d(k_d; U_d, U_f) \quad (14.6)$$

where f_d is monotone decreasing in both unity arguments, monotone increasing in aggressiveness of compression (smaller k_d). The mapping from unity to closure-defect *magnitude* is via the shape of this rate-distortion surface; unity

does not directly predict closure-defect value. In the linear-Gaussian Kalman case the structural argument reduces to $1 - U_f \propto |\Delta K|/K_{\max}$ on the gain mismatch.

Linear-Gaussian closed forms (two-agent scalar case).

For two agents with scalar observations correlated at $\rho_{o,\text{eff}}$ (combining ρ_{env} and ρ_{obs}), under 1D principal-component projection of observations, the minimum achievable observation closure defect is:

Derived (obs-closure-linear-Gaussian, from unity-dimensions, composition-closure).

$$\varepsilon_o^2(k_o = 1) = \sigma_o^2 \cdot \frac{1 - \rho_{o,\text{eff}}}{2} \propto 1 - U_{\text{obs}} \quad (14.7)$$

Higher perceptual unity $\rightarrow$ observations are more redundant $\rightarrow$ 1D summary suffices $\rightarrow \varepsilon_o$ small. Exact in the linear-Gaussian scalar case.

For two agents with scalar quadratic objectives, independent LQR policies ($\rho_\Sigma = 0$), scalar targets r_1, r_2 with correlation ρ_O , under 1D state projection, the minimum achievable action closure defect is:

Derived (action-closure-independent-policies, from unity-dimensions, composition-closure).

$$\varepsilon_a^2 \propto \kappa^2 \cdot (1 - \rho_O) \propto \kappa^2 \cdot (1 - U_O) \quad (14.8)$$

where κ is the scalar LQR gain. Adding policy coordination ($\rho_\Sigma > 0$) further reduces ε_a through a multiplicative factor. The joint (U_O, U_Σ) dependence takes the form:

$$\varepsilon_a^2 \propto (1 - U_O) \cdot f_1(U_\Sigma) + g(U_\Sigma) \quad (14.9)$$

with f_1 decreasing in U_Σ and g capturing residual strategic-misalignment error even when targets coincide.

State closure in linear-Gaussian.

For linear-Gaussian micro-dynamics with consistent linear projections Λ_x and Λ_o (the macro observation projection is the same linear combination as the macro state projection), the state closure defect vanishes:

Derived (state-closure-linear-Gaussian-trivial, from composition-closure).

$$\varepsilon_x = 0 \quad (14.10)$$

regardless of U_M or compression dimension. Linear projections of linear dynamics are exact *when the range of Λ_x is invariant under the micro-dynamics matrix*. ε_x becomes non-trivial when:

- the projection's range is non-invariant under the dynamics matrix — even with linear dynamics, consistent projections, and homogeneous updates, cross-coordinate coupling or anisotropic noise scales that mix macro-subspace components with their orthogonal complement give $\varepsilon_x > 0$ (the Mori-Zwanzig zero-lag bound $\varepsilon^* \geq \|Q_\Lambda U P_\Lambda\|_{\text{op}}$ in 13.1 is the general expression of this obstruction),
- the projection is inconsistent (macro state and macro observation projections disagree),
- the micro-dynamics are nonlinear, or
- sub-agent update rules are heterogeneous (see Two-axis structure below).

Two-axis structure (update heterogeneity).

In the non-degenerate linear-Gaussian case with heterogeneous sub-agent update rules — e.g., two Kalman filters with different gains $K_1^* \neq K_2^*$ tracking correlated processes, projected to the 1D sum $\hat{w}_+ = (\hat{w}_1 + \hat{w}_2)/\sqrt{2}$ — the state closure defect has the closed form:

Derived (two-axis-structure, from composition-closure, linear-Gaussian case).

$$\varepsilon_x^2 = (\Delta K/2)^2 [S_- - C_{+-}^2/S_+] \quad (14.11)$$

where $\Delta K = K_1^* - K_2^*$, $S_{\pm}$ are the innovation variances in the $\pm$ directions, and C_{+-} is their cross-covariance.

This exhibits two independent drivers of ε_x , one along each unity axis of 14:

1. **Content unity** (U_M , via process correlation ρ): higher correlation $\rightarrow$ lower ε_x .
2. **Structural unity** (U_f , via gain mismatch ΔK): when $\Delta K = 0$ (i.e., $U_f = 1$), $\varepsilon_x = 0$ at every ρ ; when $\Delta K \neq 0$, $\varepsilon_x > 0$ even at perfect content correlation.

The four content unities measure shared information (goals, policies, observations, model state); U_f measures whether sub-agents implement the same correction rule. The two axes contribute to the closure-defect rate-distortion surface independently — content unity controls compressibility of what the agents agree on; structural unity controls whether projection induces memory by mixing the discarded subspace into the retained one.

Strategy-layer instance (credence composition). The same structural-unity axis has an exact closed form one level up, at the strategy layer. For N agents reasoning over a shared plan skeleton (V, E) and disagreeing only on edge-credences, work in the log-odds coordinate $\lambda_{ij} = \log \frac{p_{ij}}{1-p_{ij}}$ — the unique additive-evidence coordinate (8.3; forced by U) in which edge updates are additive and the natural macro-projection is the log-odds centroid. The per-step closure defect is then driven by update-rule heterogeneity exactly as the Kalman case is, with the per-agent edge gains $\eta_{\Sigma,i}$ playing the role of the Kalman gains:

$$\varepsilon_{\Sigma}^{*2} = |E| \cdot \overline{\text{Var}_i[\eta_{\Sigma,i}]} \cdot \text{Var}[r], \quad (14.12)$$

where r is the per-edge evidence residual. This is the structural-unity (U_f) axis lifted from state to strategy: homogeneous gains ($\overline{\text{Var}_i[\eta_{\Sigma,i}]} = 0$, $U_f = 1$) give $\varepsilon_{\Sigma} = 0$; gain dispersion across agents drives the defect, scaled by plan size $|E|$ and evidence-residual variance. It is *dimension-free in N* — a population variance is estimated more precisely, not enlarged, by adding agents from the same gain-distribution — the strategy-layer twin of the dimension-free state-composition regime. The complementary heterogeneous-*topology* case (incompatible shared sub-orders, an order-theoretic non-existence rather than a magnitude) is the SCC-condensation defect landed in 8.3's causal-abstraction composition subsection; the two together exhaust strategy-layer composition (credence axis here, topology axis there).

Epistemic Status.

Conditional. Max attainable: *exact* (linear-Gaussian scalar cases) to *robust qualitative* (general).

- The observation and action closed forms are *exact* in the linear-Gaussian scalar case with stated projection choices.
- The state closure form $\varepsilon_x^2 = (\Delta K/2)^2 [S_- - C_{+-}^2/S_+]$ is *exact* in the two-Kalman heterogeneous case.
- The strategy-layer credence-composition form $\varepsilon_{\Sigma}^{*2} = |E| \cdot \overline{\text{Var}_i[\eta_{\Sigma,i}]} \cdot \text{Var}[r]$ is *exact* in the fixed-topology heterogeneous-credence case (log-odds additivity is forced by U) and dimension-free in N .

- The rate-distortion framing (unity as compressibility parameter rather than direct predictor) is *robust qualitative* — it survives beyond linear-Gaussian, but concrete rate-distortion curves require case-by-case derivation.
- The joint $(U_O, U_\Sigma) \rightarrow \varepsilon_a$ formula is a *sketch* — the leading structure is derived; the precise forms of f_1 and g are mechanical extensions not fully computed here.

Ceiling-limiting factors: non-Gaussian cases require information-theoretic bounds (Gaussian IB is fully tractable; general IB is not), and the structural-unity axis U_f has worked closed forms in two cases — the linear-Gaussian Kalman gain-mismatch case (state layer) and the fixed-topology credence-composition case (strategy layer, via log-odds additivity) — while a general theory of f_M structural variation across arbitrary update operators is open.

Discussion.

Why a one-axis reading fails. A “high U_M predicts low ε_x ” reading is wrong in the two-Kalman case with the standard means-only projection: $\varepsilon_x \equiv 0$ for every correlation value, irrespective of U_M . The closure-defect surface depends on the projection choice, on the content-unity axis, and on the structural-unity axis U_f — high content unity with mismatched update rules still produces $\varepsilon_x > 0$, while low content unity under a non-compressing projection still produces $\varepsilon_x = 0$. The rate-distortion framing is what makes the multi-parameter dependence explicit.

Connection to the Information Bottleneck (2.2). The rate-distortion shape is not coincidental. Projection admissibility condition (P1) in 13.1 is the Lagrangian-dual of the IB constraint: the projection sits on or above the IB frontier at rate $I(X; T) \leq I_{\max}(\varepsilon_f)$ for the relevance variable “next observation given action” (AA supplies the derivation). Unity dimensions — measured as mutual-information-like quantities between sub-agent state components — parametrize the frontier’s shape. The four AAT compression operations (M_t, Σ_t , shared intent, Λ) share IB shape but are not shown to reduce to a single master problem (U-medium, per AA); cross-instance theorems do not follow from shared shape alone. (P2) Lipschitz continuity is not naturally IB and remains a separate admissibility condition; (P3) dimensional reduction remains separate in the Gaussian case. The Gaussian-IB closed form applies to linear-Gaussian composition setups; beyond them, the IB frontier is definitional but requires variational or numerical approximation.

Two-axis structure. The unity profile in 14 decomposes into a content axis (four dimensions: $U_M, U_O, U_\Sigma, U_{\text{obs}}$) measuring shared information, and a structural axis (U_f) measuring shared correction rules. In purposeful-agent settings (G_t present), U_Σ already absorbs structural variation in the policy half of the cycle — agents with different action laws have different effective policies — but the model-update half remains uncovered without U_f . In pure Part I composition (passive estimators, no G_t), U_f is the only handle on structural homogeneity, and the heterogeneous-Kalman case in this segment is the canonical instance where it bites.

Interpretation of “low closure defect.” Unity controls the rate-distortion curve; low closure defect is achievable with aggressive compression when unity is high. But closure defect alone does not measure composite *optimality* (see 13.1 §5.1): two independent Kalman filters can have $\varepsilon^* = 0$ (perfectly representable) while failing to exploit cross-correlations (suboptimal relative to a joint filter). The rate-distortion mapping is about representability, not optimality.

Working Notes.

- **Two-Kalman IB witness landed (2026-07-16).** The symmetric-case canonical-direction identity (means-sum = PCA-optimal = CCA-optimal, explicit $u_\pm/\lambda_\pm$) and the heterogeneous-gain falsification handle (IB-optimal rotation should beat the means-sum’s ε_x when $\Delta K \neq 0$ — numeric check unrun) now live in AA §symmetric-two-Kalman-witness; they bear directly on this segment’s rate-distortion reading.
- **Extension to nonlinear cases.** The framing is linear-Gaussian because that’s where rate-distortion has closed forms. Extension to nonlinear micro-dynamics would likely show $\varepsilon_x > 0$ even with consistent projections (the identity-propagation argument in Formal Expression relies on linearity). Worth a follow-up spike.

- **Structural-unity formalization.** A quantitative measure U_f across arbitrary f_M functions (beyond the linear-Gaussian gain-mismatch closed form) is open. Candidates for the underlying operator distance: operator-norm distance in function space, Fisher-information-weighted distance, or IB-style comparison. See 14 Working Notes.
- **Joint (U_O , U_Σ) derivation.** The exact f_1 and g functional forms require a full joint-LQR vs independent-LQR comparison. Mechanical but deferred.
- $U_O \rightarrow$ **sector-constant pathway (partial via J).** The LQR-compatibility sketch $\gamma(U_O) = -\gamma_{\max} U_O$ in J §5.2 (flagged discussion-grade) is a structural complement to this segment's rate-distortion framing: it channels U_O into the composite sector-constant κ_c through the signed coupling γ rather than through the closure defect ε . Upgrading (UO-mult) from discussion-grade to derived requires the action-space inner-product analysis natural to this segment: define the environment's action-coupling operator, show that LQR-linear policies produce cross-actions with inner product proportional to target correlation, and pin $\gamma_{\max}$ in terms of the quadratic objective's Hessian and the environment's coupling gain. Natural extension to the linear-Gaussian closed-form section above. (*Indexed: spikes/PROPOSED.md Tier 3 — “ $U_O \rightarrow$ sector-constant (UO-mult) derivation”.*)
- **Mori-Zwanzig cross-check.** Under a stationary-measure setting, the Koopman-operator formulation of the projection-induced dynamics identifies the non-degenerate Kalman case as exercising the zero-lag memory kernel K_0 non-trivially, with $\|K_0\|$ scaling with $|\Delta K|$. This is consistent with the two-axis finding here — a Mori-Zwanzig lower bound on ε^* via the zero-lag kernel and the rate-distortion bound via IB should coincide at the same linear-algebraic quantity (the L^2 residual of projecting off an eigenspace of the micro-propagator). Formal equivalence not yet established. The MZ connection is developed further in 13.1 Epistemic Status.
- **Relationship to 12.2.** This segment describes quality *conditional* on composition existing — i.e., on 12.2 being satisfied via at least one of its three disjunctive routes (shared objective, hierarchical derivation, mutual benefit), *not* via a scalar U_O threshold. The rate-distortion curves parametrize quality given scope-satisfaction; they do not address whether a composite exists at all. For multi-agent systems where no scope route applies, closure-defect quality talk is a category error — there is no composite whose closure defect to measure.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (the boundary-condition findings F151–F156 from AUDIT-WORKING-526815 are routed for adjudication — see the off-ramp note at the end). **Coverage:** three dirs carry a dedicated reflection (526815, 829314, 849201) plus the batched 451729 (batch-15). Substrate attribution inferred from voice where not explicit. **Finding-vs-framing conflation preserved:** the organizational-management elaborations below were written as confident results; that texture is signal.

1. Candidate Brief prose / pre-prose.

- The headline reframe, stated plainly: “**unity is not a guarantee of zero error — unity is compressibility**” (Gemini, AUDIT-WORKING-829314). “Proves that teamwork is a rate-distortion problem” (Claude, AUDIT-WORKING-849201). Either is a candidate Brief anchor.
- The counter-intuitive state-closure result in words: “you can perfectly macro-model a system of completely independent agents, provided you don’t compress the state space below its true rank” — $\varepsilon_x = 0$ for linear-Gaussian micro-dynamics with consistent projections, *regardless of U_M* (Claude, AUDIT-WORKING-849201).

2. Candidate Discussion.

- **The army-command compressibility framing (strongest pedagogy here).** A highly-unified army (shared doctrine, goals, training) lets the General issue a single three-word order (“Take that hill”) executed perfectly — the macro-dimension of the command k_a is tiny. A ragtag, zero-unity coalition forces a 500-page micro-managed plan (k_a huge); attempt the three-word order on it (aggressive compression, small k_a) and the action-closure defect ε_a explodes into chaos. This makes “unity = compressibility” concrete and is isomorphic to the formula $\varepsilon_a^2 \propto \kappa^2(1 - \rho_O)$ (Gemini, AUDIT-WORKING-829314).

- **The management “thermodynamic tradeoff.”** The naive manager believes aligning goals ($U_O \approx 1$) yields zero error ($\varepsilon^* \approx 0$); the math says aligning goals lets you *fire 90% of middle management* (decrease k_a) while holding the *same* acceptable execution error. So you either pay a high tracking/command cost (k_d high, consuming your own tempo budget) to manage a diverse unaligned group, or invest upfront in Culture and Doctrine ($U_d, U_f \rightarrow 1$) and then command via tiny compressed macro-signals (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-849201 — “minimizing ε^* (act like a coherent single agent) vs. maximizing actual task performance” are distinct, watch the conflation).
- ΔK as “how two agents update on the same evidence.” The $\varepsilon_x^2 \propto (\Delta K)^2$ result in words: if the CEO reacts to a bad quarter by pivoting to AI and the VP of Sales reacts to the *same* quarter by doubling down on cold calls, their ΔK is large; even with identical information ($U_{\text{obs}} = 1$) their state estimates immediately diverge, and modeling them as one “Company Strategy” ($k_x = 1$) carries variance error $\propto (\Delta K)^2$. “You mathematically cannot compress an organization that learns at different speeds” (Gemini, AUDIT-WORKING-829314).
- **Representability vs. optimality, sharpened.** Two independent Kalman filters are perfectly *representable* as a macro-agent (closure defect zero) but *suboptimal* because they don’t exploit cross-correlations — a distinction the segment draws (Discussion § “Interpretation of low closure defect”) and that auditors flagged as crucial to keep central in any downstream “optimal teamwork” discussion (Claude, AUDIT-WORKING-849201; Codex/Claude, AUDIT-WORKING-526815 — “the representability-versus-optimality distinction ... should remain central”).

3. Follow-up items.

- **Mori-Zwanzig non-Markovian consequence as candidate Discussion.** The zero-lag memory kernel K_0 scaling with $|\Delta K|$ (already in this segment’s Working Notes as a cross-check) carries a vivid reader-facing consequence worth surfacing: heterogeneous sub-agents *force* the macro-agent to have non-Markovian memory effects — “if you try to model a diverse team with a memoryless Markov model, your predictions will mathematically fail” (Gemini, AUDIT-WORKING-829314).
- **Non-stationary Mori-Zwanzig.** Curiosity about how the MZ formulation handles the non-stationary nature of purposeful agents (Claude, AUDIT-WORKING-849201) — a natural extension question for the existing MZ Working Note.

4. Readers often ask / wonder.

- **Does high unity mean $\varepsilon^* = 0$?** The natural naive reading, which the segment exists to correct — fresh readers reached for it and were corrected by the rate-distortion framing (Claude, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-829314). The Discussion § “Why a one-axis reading fails” already preempts it; the convergence confirms it is the right thing to lead with.

5. Candidate figures.

- **Closure-defect surface with two guard-tags.** A surface where projection dimension, content unity, and structural unity jointly determine achievable closure defect, with two guards marked: metric normalization (inherited from 14) and the exactness conditions for the linear-Gaussian cases (Codex/Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **Per-dimension result $\rightarrow$ AI-safety evaluation (points at 16.5, not here).** Scalar capability metrics overestimate adaptive capacity by up to 72%; an AI scoring well on aggregate benchmarks can still fail on the dimension with highest ρ_k/η_k — “a formal argument for why AI safety evaluations should be per-dimension rather than aggregate, and why the weakest capability dimension is the one adversaries will target,” with the adversarial-ML per-feature-attack-budget connection (Szegedy, Madry) made explicit (Claude, AUDIT-WORKING-451729, batch-15). Aspirational application reach; route to the per-dimension segment.

Off-ramp (NOT gold — routed to certified-findings track).

- AUDIT-WORKING-526815 raised boundary-condition findings on this segment that are scope-tightening / strengthen-first candidates, flagged here only so they are not lost: **F151** — C-iv scope-route typing drift (segment text conditions on four routes incl. C-iv; Working Notes say “three disjunctive routes” excluding the strategic-equilibrium route — make consistent); **F152** — inherits F146 (U_M non-normalization destabilizes the claimed monotone surface axis); **F153** (soft) — the observation-closure closed form $\varepsilon_0^2 = \sigma_0^2(1-\rho)/2$ has a per-coordinate/averaging convention in the /2 that should be stated; **F154** — the $\varepsilon_x = 0$ claim requires the projection range to be *invariant under the dynamics matrix*, not merely “consistent projections”; **F155** (soft) — the $\Delta K \neq 0 \Rightarrow \varepsilon_x > 0$ -at-perfect-correlation claim should be scoped to non-degenerate cases (the residual bracket $S_- - C_{+,-}^2/S_+$ can vanish degenerately); **F156** (soft) — monotonicity in U_f is only as strong as the still-open operator-distance definition of U_f (currently a worked-example insight, not a general metric theorem). *These are scope/condition tightenings, not no-gos; routed for adjudication on the strengthen-first track.*

14.2 Definition: Shared Intent

When sub-agents within a composite must coordinate, they face a communication problem: transmitting the full purposeful state $G_t = (O_t, \Sigma_t)$ is expensive (high bandwidth, high latency), but acting without any shared purpose wastes coordination potential. The Information Bottleneck (#form-information-bottleneck) applied to inter-agent communication predicts an optimal compression: transmit enough of G_t to align behavior, not more. The **shared intent** is the IB-optimal compression of the sender’s purposeful state — the minimal sufficient statistic for predicting the jointly optimal coordination behavior. The trade-off parameter controls the regime: at high weight, the agent communicates more detail (approaching full model sharing); at low weight, communication is minimal (approaching independent action).

The IB compression *preferentially preserves* three things, in order: **terminal objectives** (what the agent is trying to achieve — compact, slow-changing), then **high-level strategy** (which approach, not which specific steps — moderate size, moderate change rate), and last **strategic details** (specific edge credences in the strategy DAG — large, change fast, low coordination value). This gives the framework a structural reading of **commander’s intent** in military doctrine — the commander communicates *what* to achieve and *why*, not *how*. The framework predicts this pattern *structurally*, from the information-bottleneck trade-off, not as a managerial convention: communicating objectives gives a long shelf life per bit transmitted when objectives change slowly and strategies change fast.

For agents with bounded communication capacity (bandwidth-limited channels, finite context windows), the strategy DAG must be summarized for transmission — a 500-node DAG cannot be shared in full; the IB compression identifies which structural features matter for coordination. The same compression is useful for an agent preserving its own state across context boundaries (the language-model 100% context turnover problem) — store the compressed version of the purposeful state, not the full state. The status is honestly *discussion-grade*: the formulation makes several strong assumptions (the sender must know the jointly optimal action, which requires knowing other agents’ states; the compression is lossless in the IB sense; the trade-off parameter is fixed rather than dynamically adjusted), and the qualitative prediction (communicate purpose before plans before models) is more robust than the specific IB formulation.

Formal Expression.

Let G_t^{full} be the source agent’s complete purposeful state (O_t, Σ_t) . Let G_t^{shared} be the compressed representation communicated to partners. The shared intent is the IB-optimal compression:

Definition (shared-intent).

$$G_t^{\text{shared}} = \arg \min_{G_s} [I(G_t^{\text{full}}; G_s) - \beta \cdot I(G_s; a_t^{\text{coordinated}})] \quad (14.13)$$

where $a_t^{\text{coordinated}}$ is the jointly optimal action and β controls the complexity-relevance tradeoff. At high β , the agent communicates more detail (approaching full model sharing). At low β , communication is minimal (approaching independent action).

The shared intent is the *minimal sufficient statistic* of the sender’s purposeful state for predicting the jointly optimal coordination behavior.

Epistemic Status.

Discussion-grade. Max attainable: conditional (conditional on the IB framework being appropriate for inter-agent communication). The application of IB to inter-agent communication is structurally motivated — IB compresses optimally given a relevance criterion, and coordination relevance is the natural criterion — but the specific formulation assumes: (1) the sender knows the jointly optimal action (which requires knowing other agents’ states), (2) the compression is lossless in the IB sense (real communication introduces noise, delay, and misinterpretation), (3) the β parameter is fixed rather than dynamically adjusted. These are strong assumptions. The qualitative prediction (communicate purpose before plans before models) is more robust than the specific IB formulation.

Discussion.

What gets compressed out. The IB compression preferentially preserves: 1. Terminal objectives (what the agent is trying to achieve) — these are compact and change slowly 2. High-level strategy (which approach, not which specific steps) — moderate size, moderate change rate 3. Strategic details (specific edge credences in Σ_t) — large, change fast, low coordination value

Connection to cognitive cost of Σ_t . For agents with bounded communication capacity (bandwidth-limited channels, finite context windows), the DAG must be summarized for transmission. A 500-node strategy DAG cannot be shared in full; the IB compression identifies which structural features of the DAG matter for coordination.

Organizational communication patterns. Commander’s intent in military doctrine is an empirical instantiation: the commander communicates *what* to achieve and *why*, not *how*. This is IB-optimal if objectives change slowly (low ν_O) and strategies change fast (high ν_Σ) — communicating objectives gives a long shelf life per bit transmitted.

Working Notes.

- The IB formulation assumes a single relevance variable ($a_t^{\text{coordinated}}$). In practice, coordination relevance is multi-dimensional: shared intent needs to support action coordination, conflict resolution, resource allocation, and adaptive replanning. A richer relevance variable might be needed.
- How does shared intent interact with 100% context turnover? An AI agent starting a new session needs to reconstruct G_t^{shared} from persistent storage. The compression from full G_t to shared intent is also useful for M_t preservation (#disc-m-preservation) — store the compressed version, not the full state.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (the IB-formalization findings F157–F161 from AUDIT-WORKING-526815 are routed for adjudication — see the off-ramp note at the end). **Coverage:** two dirs carry a dedicated reflection (526815, 849201) plus a forward-looking note from the batched 471203. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The plain-language definitional payoff, twice converged: shared intent “formalizes what ‘Commander’s Intent’ actually is — the minimal sufficient statistic of the leader’s goals needed to predict coordinated action” (Claude, AUDIT-WORKING-849201); “defines the optimal *content* of inter-agent communication” (same). Candidate one-line Brief anchor.

2. Candidate Discussion.

- **Coordination does not require full plan transmission.** The clean restatement of the segment's core: "coordination does not require full plan transmission; it requires enough purpose and strategy information for partners to choose compatible actions" — the compression is over G (purpose), not over the full model M (Codex/Claude, AUDIT-WORKING-526815). A candidate sharpening of the "what gets compressed out" Discussion.
- **The honesty-about-its-own-limits is itself worth keeping visible.** Auditors praised the epistemic honesty that the formula "assumes the sender already knows the jointly optimal action a_{coord} (which would require knowing the receiver's state, defeating the purpose of communication)" — so the math is "a conceptual bound, not a literal algorithm the agent runs" (Claude, AUDIT-WORKING-849201). The Epistemic Status already states this; flagged as a convergence signal that the framing lands.

3. Follow-up items.

- **Theory of mind / nested beliefs is missing from the communication vocabulary.** This segment and 14.4 "handle inter-agent epistemic unity, but the recursive structure — 'I believe that you believe that I believe ...' — is central to multi-agent reasoning (Aumann common knowledge, level- k thinking) and isn't in the framework's vocabulary" (Claude, AUDIT-WORKING-471203, adversarial-creative-challenges "Missing 2"). A candidate scope-extension follow-up shared with 14.4.
- **Richer relevance variable.** The single relevance variable $a_t^{\text{coordinated}}$ is too narrow: real shared intent must support a policy/trajectory distribution, conflict resolution, resource allocation, and replanning — not just one jointly optimal action (Codex/Claude, AUDIT-WORKING-526815). The existing first Working Note already raises this; the auditor's framing names the four coordination sub-tasks explicitly.

4. Readers often ask / wonder.

- **How is shared intent actually encoded — a vector, a text prompt, a mathematical objective function?** A natural first reader question once the IB-optimal-compression definition lands (Claude, AUDIT-WORKING-849201). Candidate for a one-line concretization or a forward pointer to the implementation-side treatment.

5. Candidate figures.

- **Shared intent as a bottleneck.** A bottleneck between full purposeful state G and coordinated behavior, with two emphases marked: the compression is over G (not the full model M), and the relevance variable may need to be a policy/trajectory-level object rather than a single coordinated action (Codex/Claude, AUDIT-WORKING-526815).

Off-ramp (NOT gold — routed to certified-findings track).

- AUDIT-WORKING-526815 raised IB-formalization findings on this segment that are strengthen-first / scope-tightening candidates, flagged here only so they are not lost: **F157** — the IB optimization is written as $\arg \min$ over representations G_s , but standard IB optimizes over an encoder/channel $p(G_s \mid G_{\text{full}})$ (deterministic-encoder ambiguity, inherited from 2.2); **F158** — the relevance variable is too narrow (see follow-up above); **F159** — "high β approaches full model sharing" should read "full *purposeful-state* sharing," since the source is $G_t^{\text{full}} = (O_t, \Sigma_t)$, not the epistemic model M_t ; **F160** — "minimal sufficient statistic" is stronger than the displayed IB tradeoff (IB gives a complexity/relevance optimum for a chosen β ; exact minimal sufficiency requires a separate sufficiency constraint or a limiting regime); **F161** (soft) — the "purpose before plans before models" ordering is plausible but not derived from the displayed objective without assumptions about entropy, change rate, shelf life, and relevance. *These are formalization tightenings, not no-gos; routed for adjudication on the strengthen-first track.*

14.3 Hypothesis: Auftragstaktik Principle

A bandwidth-allocation hypothesis grounded in the shared-intent IB framework (#def-shared-intent). For a composite agent with limited communication bandwidth, the optimal allocation prioritizes sharing **objectives over strategies over models** — $B_O > B_\Sigma > B_M$. This captures the structural insight of *Auftragstaktik* (mission-type tactics): investing

communication bandwidth in shared purpose (teleological unity) while accepting lower epistemic and strategic unity, granting sub-agents autonomy to adapt locally. The model predicts the same priority ordering that military doctrine discovered empirically over centuries — and the framework offers it as a *structural prediction*, not an organizational convention.

The priority ordering follows from the IB framework: the bits with the longest shelf life and highest coordination value per bit should be transmitted first. Objectives change slowly and enable autonomous coordination — sub-agents who share objectives can independently choose compatible strategies. Models change fast and provide diminishing coordination value — two agents with the same model but different objectives still conflict. The ordering holds under stated conditions: objectives change slowly relative to strategies, which change slowly relative to models; sub-agents have sufficient local adaptive capacity to maintain their own models.

The framework is also explicit about *when the ordering reverses*. When the environment is genuinely ambiguous and local observations are insufficient (fog of war, novel codebase, unprecedented market conditions), model synchronization may be worth more than objective sharing — sub-agents who share the same wrong model at least err consistently, which is sometimes better than each having a different wrong model. The framework predicts the reversal as a *regime-dependent prescription* rather than a universal ordering.

The status is *discussion-grade*. The priority ordering is a qualitative prediction supported by extensive military-organizational evidence (Bungay’s analysis of Clausewitz, Wehrmacht doctrine, modern mission command), but it is not derived — the IB optimization would need to be solved explicitly with realistic cost functions to confirm the ordering. The empirical evidence is strong but comes primarily from one domain (military command); generalization to software teams, AI agent swarms, and other settings is plausible but unverified. Whether the IB-optimal-bandwidth-allocation *mechanism* is actually the reason Auftragstaktik works empirically — versus other mechanisms (psychological, organizational, traditional) — is an open question.

Formal Expression.

Let a composite agent’s total inter-agent communication bandwidth be $B = B_O + B_\Sigma + B_M$, allocated across objective sharing (B_O), strategy coordination (B_Σ), and model synchronization (B_M).

Hypothesis (auftragstaktik-principle).

The hypothesis: the allocation that maximizes composite tempo $\mathcal{T}_c$ (or equivalently, minimizes coordination overhead C_{coord}) prioritizes:

$$B_O > B_\Sigma > B_M \quad (14.14)$$

when: - Objectives change slowly relative to strategies: $\nu_O \ll \nu_\Sigma$ - Strategies change slowly relative to models: $\nu_\Sigma \ll \nu_M$
 - Sub-agents have sufficient local adaptive capacity: each $\mathcal{F}_i > \rho_i^{\text{local}} / \|\delta_{\text{critical}}^i\|$

The priority ordering follows from the IB framework (14.2): the bits with the longest shelf life and highest coordination value per bit should be transmitted first. Objectives change slowly and enable autonomous coordination (sub-agents who share objectives can independently choose compatible strategies). Models change fast and provide diminishing coordination value (two agents with the same model but different objectives still conflict).

Epistemic Status.

Discussion-grade. Max attainable: empirical. The priority ordering is a qualitative prediction grounded in the IB framework and supported by extensive military-organizational evidence (Bungay's analysis of Clausewitz, Wehrmacht doctrine, modern mission command). But it is not derived — the IB optimization would need to be solved explicitly with realistic cost functions to confirm the ordering, and the conditions under which the ordering reverses (e.g., when model synchronization is critical because the situation is genuinely ambiguous) are not characterized. The empirical evidence is strong but comes primarily from one domain (military command); generalization to software teams, AI agent swarms, and other settings is plausible but unverified.

Discussion.

When the ordering reverses. The prioritization $B_O > B_\Sigma > B_M$ assumes sub-agents can independently construct adequate local models. When the environment is genuinely ambiguous and local observations are insufficient (fog of war, novel codebase, unprecedented market conditions), model synchronization may be worth more than objective sharing — sub-agents who share the same wrong model at least err consistently, which is sometimes better than each having a different wrong model.

Bungay's evidence. In *The Art of Action*, Bungay documents that organizations consistently fail by inverting this priority: they over-invest in controlling *how* subordinates act (strategy sharing, B_Σ) rather than ensuring subordinates understand *why* (objective sharing, B_O). The result: subordinates who follow instructions precisely but cannot adapt when conditions change, because they lack the teleological context to improvise intelligently.

The software team instantiation. A well-functioning development team has: - High B_O : clear product goals, understood by all (sprint goals, feature objectives) - Moderate B_Σ : architectural decisions shared, implementation details autonomous - Low B_M : each developer builds their own mental model of the code they touch; full codebase understanding is neither expected nor efficient

When this inverts (micromanagement of implementation details, unclear product goals), team tempo drops — consistent with the Auftragstaktik prediction.

Connection to Conway's Law. Conway's Law (system structure mirrors communication structure) is a consequence: when B_Σ is low and B_O is high, sub-agents coordinate through shared objectives rather than explicit action coordination, producing systems whose boundaries reflect objective decomposition rather than communication channels.

Working Notes.

- The formal IB derivation of the priority ordering would need: (1) a model of how each unity dimension contributes to composite tempo, (2) the rate of change of each shared quantity (v_O, v_Σ, v_M), (3) the communication cost per bit for each type. The qualitative argument is that objectives are compact and slow-changing (high bits-per-cost, long shelf life), while models are large and fast-changing (low bits-per-cost, short shelf life). Formalizing this is tractable but has not been done.
- The principle may need qualification for AI agent teams where model synchronization is cheap (shared vector databases, persistent memory) but objective alignment is hard (prompt engineering, RLHF). The cost structure differs from human organizations.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (the marginal-vs-total-allocation findings F162–F166 from AUDIT-WORKING-526815 are routed for adjudication — see the off-ramp note at the end). **Coverage:** two dirs carry a dedicated reflection (526815, 849201). Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The plain payoff: the segment “provides an information-theoretic justification for Mission Command / Agile methodologies” and “proves why micromanagement fails in volatile environments” (Claude, AUDIT-WORKING-849201). Candidate Brief framing.
- The shelf-life mechanism in one line: because objectives change slowly ($\nu_O \ll \nu_\Sigma \ll \nu_M$), “sending them provides a long ‘shelf life’ for the communicated bits” — the bandwidth allocation as a knapsack problem, maximize coordination value subject to bandwidth B (Claude, AUDIT-WORKING-849201).

2. Candidate Discussion (and the standout forward-vision).

- **AI agent teams plausibly *invert* the human Auftragstaktik ordering (the standout reach here).** For humans, B_M (transmitting your entire mental model) is effectively impossible while B_O (“take that hill”) is cheap — hence objective-first. For AI agents the cost structure flips: B_M is cheap (share the vector database, synchronize weights) while B_O is notoriously hard (the alignment problem / RLHF). “The theory naturally predicts that multi-AI systems will optimally organize themselves very differently than human organizations” — the ordering is dictated by the *relative costs*, which are hardware/substrate-dependent, not by the human-derived $B_O > B_\Sigma > B_M$ template (Claude, AUDIT-WORKING-849201). This is high-value forward-vision pointing at the multi-AI-safety / composite-ELI program; the existing second Working Note states the cost-structure asymmetry, and this elaborates it into a concrete prediction worth promoting. (*Verify before promotion: that “synchronize weights = cheap B_M ” survives the directed-separation and identity constraints elsewhere in the framework.*)
- **Empirical grounding in Prussian/military organizational history.** The reference to Stephen Bungay’s *The Art of Action* grounds the abstract IB ordering in “200 years of Prussian/military organizational empirical data” (Claude, AUDIT-WORKING-849201) — a candidate citation/anchor for the Discussion’s organizational-doctrine paragraph.

3. Follow-up items.

- **Do not blindly import the human ordering into software/AI architectures.** When the theory is applied to AI teams, the math dictates the ordering from relative communication costs, which are substrate-dependent — a watch-item for downstream applications (Claude, AUDIT-WORKING-849201). Pairs with the inversion insight above.

4. Readers often ask / wonder.

- **How does the theory define “trust” mathematically?** A natural bridge question this segment raises and 14.4 answers (Claude, AUDIT-WORKING-849201) — useful as a forward pointer at the end of this segment.

Off-ramp (NOT gold — routed to certified-findings track).

- AUDIT-WORKING-526815 raised findings on this segment that are strengthen-first / scope-precision candidates, flagged here only so they are not lost: **F162** — $B_O > B_\Sigma > B_M$ “confuses priority ordering with total bandwidth allocation”; IB reasoning supports sending high-marginal-value, long-shelf-life objective bits *first*, but does not imply the total number of objective bits must exceed strategy or model bits (restate as “prioritize objective information at the margin under scarce bandwidth”); **F163** — maximizing composite tempo and minimizing coordination overhead are not equivalent in general; **F164** (soft) — the ordering depends on strong assumptions about entropy, change rates, and local observability, and the formal statement should be explicitly marginal and conditional; **F165** (soft) — the Conway’s-Law claim is too strong as stated (deriving objective-decomposition boundaries from high B_O /low B_Σ needs additional organizational/design assumptions); **F166** (watch) — the principle inherits the unresolved IB-formalization issues from 14.2; keep discussion-grade until the relevance variable and encoder are specified. *These are scope-precision tightenings, not no-gos; routed for adjudication on the strengthen-first track.*

14.4 Hypothesis: Communication Gain

The extension of the uncertainty-ratio gain principle (#emp-update-gain) to *inter-agent* communication channels. When an agent incorporates information from *another agent* (rather than from direct observation), the optimal update gain

extends with additional terms in the denominator: **communication channel noise** (latency, ambiguity, compression loss, bandwidth limits), **source quality uncertainty** (the receiver's uncertainty about the sender's model calibration and domain competence), and **teleological-unity uncertainty** (the receiver's uncertainty about whether the sender's communications serve the receiver's interests or the sender's potentially conflicting objectives). When all additional terms are zero (perfect channel, calibrated and aligned source) the gain heads to 1 (full trust); when any term is large the gain heads to 0 (ignore the signal). When the "sender" is the environment (direct observation), the source-quality and alignment terms vanish and the standard single-agent gain formula is recovered.

The three additional denominator terms have *different natures*. Channel noise is a property of the *channel* — improvable by infrastructure. Source quality is a property of the *source* — improvable by the sender improving its model, or estimable by the receiver through calibration tracking. Alignment uncertainty is a property of the *relationship* — the game-theoretic variable. The three are independent levers; the framework's prescription is to track them separately.

The receiver's estimates of source quality and alignment constitute a **trust meta-model** — a model of models. This meta-model is itself subject to AAT's full apparatus: it has its own mismatch (trust prediction errors), should be updated with appropriate gain (not overreacting to single disagreements), and can be structurally inadequate (the agent's trust model class may not capture the actual reliability structure of its sources, per #result-structural-adaptation-necessity). The framework also names **risk-asymmetric trust**: the Bayesian posterior on source reliability gives the best *estimate*, but the *decision* about how much to trust should be risk-weighted. Trusting a deceptive agent in a high-stakes interaction can cause catastrophic model corruption (the adversarial-destabilization effects spiral, #der-adversarial-destabilization); mild miscalibration toward a reliable source causes only small ongoing inefficiency. For high-stakes interactions, the framework prescribes using a *conservative quantile* of the trust posterior rather than the mean. **Trust transitivity** is handled via a Bayesian mixture: when no direct experience exists with a candidate source but a trusted intermediary provides an assessment, the recommendation is discounted by the intermediary's own reliability — giving a principled three-phase trust formation (prior → transitive update → direct experience, which eventually swamps the prior).

The framework is explicit about a limitation: the additive denominator treats all uncertainty sources as independent zero-mean noise — appropriate for channel noise and source miscalibration, but *misses the adversary's actual strategy* of presenting as trustworthy to exploit high gain. The additive model captures the *defender's* response to detected misalignment; it does not model the *attacker's* optimization over the defender's trust dynamics. The status is honestly *hypothesis-discussion-grade* — the additive heuristic correctly drives the gain toward zero when alignment uncertainty is high, but a full treatment of the adversarial case requires game-theoretic equilibrium analysis external to AAT (AAT provides the state variables; the equilibrium analysis is external).

Formal Expression.

Hypothesis (communication-gain).

$$\eta_{ji}^* = \frac{U_{M_i}}{U_{M_i} + U_{o,ji} + U_{src,j} + U_{align,ji}} \quad (14.15)$$

where: - U_{M_i} : agent i 's model uncertainty (same as 3.6) - $U_{o,ji}$: **communication channel noise** — latency, ambiguity, compression loss, bandwidth limitations of the channel between j and i - $U_{src,j}$: **source quality uncertainty** — i 's uncertainty about j 's model calibration and domain competence - $U_{align,ji}$: **teleological-unity uncertainty** — i 's uncertainty about whether j 's communications serve i 's interests or j 's potentially conflicting objectives

When all additional terms are zero (perfect channel, calibrated and aligned source): $\eta_{ji}^* \rightarrow 1$ (full trust). When any term is large: $\eta_{ji}^* \rightarrow 0$ (ignore the signal).

Connection to single-agent case. When j is the environment (direct observation): $U_{src} = U_{align} = 0$, recovering 3.6's standard form $\eta^* = U_M/(U_M + U_o)$.

Epistemic Status.

Hypothesis. The additive denominator treats all uncertainty sources as independent, zero-mean noise — a structural heuristic, not a strict variance derivation. This is appropriate for $U_{o,ji}$ (channel noise) and $U_{src,j}$ (miscalibration), which are typically unstructured. For $U_{align,ji}$ (deception), additivity is conservative: it correctly drives η_{ji}^* toward zero when teleological-unity uncertainty is high, but misses the adversary's *actual* strategy — presenting as trustworthy to exploit high η_{ji}^* . The additive model captures the *defender's* response to detected misalignment; it does not model the *attacker's* optimization over the defender's trust dynamics.

All four uncertainty terms must be expressed in a **common predictive-dispersion scale** before summation — the same units as U_{M_i} (variance of the predictive distribution over the observed quantity). When hard to estimate directly, a conservative approximation: set $U_{src} + U_{align}$ to the empirical variance of j 's past prediction residuals as observed by i , minus the known channel noise $U_{o,ji}$.

Discussion.

The denominator terms have different natures. $U_{o,ji}$ is a property of the *channel* — improvable by infrastructure. $U_{src,j}$ is a property of the *source* — improvable by j improving its model, or estimable by i through calibration tracking. $U_{align,ji}$ is a property of the *relationship* — the game-theoretic variable.

Trust calibration as a meta-model. Agent i 's estimates of $U_{src,j}$ and $U_{align,ji}$ constitute a **trust meta-model** — a model of models. This meta-model is itself subject to AAT's full apparatus: it has mismatch (trust prediction errors), should be updated with appropriate gain (not overreacting to single disagreements), and can be structurally inadequate (4.8 — the agent's trust model class may not capture the actual reliability structure of its sources).

Risk-asymmetric trust. The Bayesian posterior on source reliability gives the best *estimate*, but the *decision* about how much to trust should be risk-weighted. Trusting a deceptive agent (HILP — high impact, low probability) can cause catastrophic model corruption (15.2, effects spiral). Mild miscalibration toward a reliable source (LIHP) causes small ongoing inefficiency. For high-stakes interactions, use a conservative quantile of the trust posterior rather than the mean — require more evidence before granting high trust.

Trust transitivity. When agent i has no direct experience with agent k , but trusted intermediary j provides an assessment, the transitive trust question arises. A Bayesian mixture model discounts the recommendation by the intermediary's own reliability:

$$P(\theta_k | s_j) \propto [\eta_{ji} \cdot P(s_j | \theta_k) + (1 - \eta_{ji}) \cdot P_0(s_j)] \cdot P(\theta_k) \quad (14.16)$$

where η_{ji} is i 's reliability estimate of j and θ_k is k 's true alignment. When $\eta_{ji} \rightarrow 0$, the posterior collapses to the prior (no update); when $\eta_{ji} \rightarrow 1$, the full informative likelihood applies. This model gives a principled three-phase trust formation: prior $\rightarrow$ transitive update $\rightarrow$ direct experience (which eventually swamps the prior).

Working Notes.

- The communication gain enters the distributed tempo: $\mathcal{T}_i = \sum_k v_i^{(k)} \eta_i^{(k)*} + \sum_j v_{ji}^{\text{comm}} \eta_{ji}^*$. This is the formal basis for 15.1 — teams persist where individuals cannot because cooperative communication adds to each agent's effective tempo.
- Coordination overhead limits team size: adding members increases communication tempo with diminishing returns while coordination costs grow. The optimal team size occurs where marginal communication tempo equals marginal coordination cost. This connects to organizational theory (span of control, communication overhead).
- The adversary's strategy (making U_{align} *appear* low) creates a meta-game on trust estimation. This is where game theory enters — the trust calibration itself is strategic. AAT provides the state variables (mismatch, gain, tempo, reserve); game theory provides the equilibrium analysis.

- Open, now partially derived: when multiple intermediaries provide corroborating recommendations about k , correlation matters. If all got their information from the same source, corroboration is illusory — this is the common-source regime of AS (2026-07-15): closed-form redundancy penalty, saturation at the shared source’s bias floor, and the two-sided caveat that anti-correlated intermediary errors instead *triangulate* (super-additive). What remains open here is the trust-mixture-specific form.
- Consider eventually **splitting** $U_{\text{src},j}$ **from** $U_{\text{align},ji}$ into separate treatment tracks, not just separate denominator terms. Source calibration uncertainty is an *estimation* problem (estimable, improvable, converges with data). Alignment uncertainty is a *strategic* problem (the adversary optimizes *over* the defender’s trust policy, not independently of it). The additive heuristic correctly drives η_{ji}^* toward zero in both cases, but a richer model would separate the estimation problem (how good is this source?) from the trust-policy problem (how much should I trust, given that the source knows my trust policy?). The latter requires game-theoretic treatment — AAT provides the state variables; the equilibrium analysis is external.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (the gain-denominator findings F167–F172 from AUDIT-WORKING-526815 are routed for adjudication — see the off-ramp note at the end). **Coverage:** two dirs carry a dedicated reflection (526815, 849201) plus a forward-looking note from the batched 471203. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The diagnostic payoff, plainly stated: the segment “formalizes trust as a computable scalar gain” and decomposes “why I shouldn’t listen to you” into three causes — **Channel** (noise/latency), **Competence** (source calibration), and **Alignment** (whether the source serves your interests) — “incredibly useful for diagnostics” (Claude, AUDIT-WORKING-849201). Candidate Brief anchor: trust as a three-gate discount on the update gain.
- “The exact equation for how much an agent should change its mind when another agent tells it something” (Claude, AUDIT-WORKING-849201).

2. Candidate Discussion.

- **Estimation vs. strategy — the load-bearing asymmetry, stated for readers.** Source *competence* uncertainty is an estimation problem; source *alignment* uncertainty is a strategic, game-theoretic one — “an intelligent adversary does not generate random noise; they optimize to exploit your trust,” so treating U_{align} as a zero-mean Gaussian variance term is a *structural heuristic*, not a derived gain (Claude, AUDIT-WORKING-849201; Codex/Claude, AUDIT-WORKING-526815 — de-ception “changes the generation policy for the signal rather than merely widening an independent noise distribution”). The existing final Working Note already names this split; the auditor framing is candidate Discussion prose for *why* it matters.
- **The conservative-quantile patch as a rigorous fix, not a hack.** Using a conservative quantile of the trust posterior (rather than the mean) for high-stakes interactions is “a rigorous, decision-theoretic patch for this heuristic gap” — worth presenting as the principled response to the strategic-alignment problem rather than an ad-hoc safety margin (Claude, AUDIT-WORKING-849201).
- **Transitive trust as Bayesian mixture.** “Updating your trust in C based on a message from B, discounted by your trust in B” — flagged as “a beautiful application of Bayesian mixture modeling” and a candidate Discussion illustration of the trust-network structure (Claude, AUDIT-WORKING-849201).

3. Follow-up items.

- **Theory of mind / nested beliefs is missing from the communication vocabulary.** This segment and 14.2 “handle inter-agent epistemic unity, but the recursive structure — ‘I believe that you believe that I believe ...’ — is central to multi-agent reasoning (Aumann common knowledge, level- k thinking) and isn’t in the framework’s vocabulary” (Claude, AUDIT-WORKING-471203, adversarial-creative-challenges “Missing 2”). The segment’s own note that estimating $U_{\text{src}}/U_{\text{align}}$ requires a “meta-model (a model of another agent’s model)” is the natural attachment point (Claude, AUDIT-WORKING-849201). Candidate scope-extension follow-up shared with 14.2.

- **Adversarial poisoning of the transitive-trust network (Sybil attacks).** How does the framework handle a Sybil attack on the transitive-trust mixture — many fake intermediaries corroborating a false claim about k ? (Claude, AUDIT-WORKING-849201). The segment’s existing correlation Working Note (“if all got their information from the same source, corroboration is illusory”) is the seed; Sybil-resistance is the sharper open follow-up.

4. Readers often ask / wonder.

- Fresh readers converge on the question the segment is built to answer — “how much should I trust this message?” — and find the Channel/Competence/Alignment decomposition the satisfying response (Claude, AUDIT-WORKING-849201). A candidate readers-often-ask lead-in.

5. Candidate figures.

- **Three-gate message diagram.** A received message passing through three gates before reaching the receiver’s update rule, with the strategic-alignment gate drawn as a *loop* (the sender optimizes the message against the receiver’s trust rule) rather than as an independent noise gate like the channel and competence gates — visually separating the variance-like gates from the adversarial one (Codex/Claude, AUDIT-WORKING-526815).

Off-ramp (NOT gold — routed to certified-findings track).

- AUDIT-WORKING-526815 raised findings on this segment that are strengthen-first / scope-precision candidates, flagged here only so they are not lost: **F167** — the additive communication-gain denominator is only optimal under strong common-scale, independent, approximately zero-mean assumptions (U_o , U_{src} , U_{align} need a precise map onto the same predictive-dispersion units before the ratio carries Bayesian-gain force); **F168** — treating teleological-unity uncertainty as additive variance under-models strategic deception (misalignment changes the message *policy* adversarially as a function of the receiver’s trust rule); **F169** (soft) — estimating $U_{src} + U_{align}$ from residual variance minus channel noise is fragile (residuals conflate calibration, alignment, receiver model error, nonstationarity, common shocks; the subtraction can go negative without a floor); **F170** — the distributed-tempo note adds communication tempo contributions linearly, repeating the tempo-additivity concern (messages can be redundant/correlated/delayed/costly/strategically selected); **F171** (soft) — the transitive-trust mixture collapses to the prior only if $P_0(s_j)$ is explicitly uninformative about θ_k and normalized consistently, and the scalar reliability r_{ji} hides domain/calibration/alignment dimensions; **F172** (watch) — risk-asymmetric trust should be tied to an explicit loss function/decision rule (a conservative posterior quantile is plausible for high-impact downside but is not implied by Bayesian reliability estimation alone). *These are formalization/scope tightenings, not no-gos; routed for adjudication on the strengthen-first track.*

14.5 Hypothesis: Solicitable Escape from an Absorbing Region

The three escape routes from an absorbing observability region are not peers: two require no prior localization of the blind spot and one does, so where observability is estimated rather than known by construction, and under any resource bound, the only *solicitable* escape from a self-locking region is a differently-positioned observer.

Formal Expression.

9.3 establishes that unobservable regions of strategy are absorbing — frozen beliefs generate no mismatch signal, so no revision is triggered, and the agent “cannot learn and cannot recognize that it cannot learn.” It names three escapes: external shock, proactive observability investment (instrumenting previously unmonitored nodes), and another agent whose observations cover the blind spot (14.4).

Partition those routes by what the agent must already possess for the route to be *available to it as an action*.

[*Definition (route-targeting)*] A route is **targeted** if exercising it requires the agent to identify, in advance, the node or direction at which its observability is deficient. A route is **untargeted** otherwise.

[*Hypothesis (solicitable-escape)*] Of the three routes:

- **External shock** is untargeted and *unsolicitable*. It requires no prior localization, because the shock supplies the mismatch signal the frozen region cannot generate; but it also cannot be chosen — it is a thing that happens to the agent, not an action available to it.
- **Observability investment** is *targeted*, under the scope condition below. To instrument node v the agent must represent v as a node whose σ_v is worth raising. The absorbing region is case (c) of the zero-aporia trichotomy (3.4): near-zero mismatch because the channel is too noisy to detect model error, which is not distinguishable from within from case (a), a model that genuinely fits — *silence can mean peace or deafness*. What blocks the distinction is not absence of signal but the agent’s inability to audit its own weighting: by 1.3 the agent does not know the noise distribution and must estimate U_o from innovations, and at a node with $\sigma_v \approx 0$ those innovations are exactly what is suppressed, so the estimate is unimprovable by observing v . The gain-collapse modes compound this — $\eta^* \rightarrow 0$ via $U_M \rightarrow 0$ (dogmatism) and via $U_o \rightarrow \infty$ (nihilism) are behaviorally identical (3.6), so even an agent that correctly registers “my gain here is zero” cannot read off whether the fault lies in the world or in itself. So for the blind spots that are actually self-locking, the precondition of the route is unavailable.
- **Another observer** is both untargeted *and* solicitable. A differently-positioned party’s coverage does not require the blinded agent to know where its own deficiency lies — the coverage is a property of the other’s position, not of the blinded agent’s model — and soliciting it is an action the agent can take under its existing representational resources.

The targeting claim above holds where the agent’s knowledge of σ_v is **estimated from its own observations**. It fails where σ_v is known **architecturally** — an agent that knows by construction which nodes it has no sensor for can rank exactly those nodes without any signal from them, and for it the self-instrumentation route is both choosable and aimable. This is the same boundary flagged against 1.3’s epistemic-opacity clause by several de-novo readers (a Kalman filter with a known noise covariance is handed its observation law rather than estimating it), so the scope condition tracks a distinction the framework already recognizes rather than introducing one. The interesting case is the estimated one, because that is where the region self-locks; the architecturally-known case is a design opportunity, not a trap.

Scope (innovation-estimated observability).

[Derived (conditional on a resource bound)] The apparent counterexample is *blanket* instrumentation: raising σ_v everywhere requires no targeting. Blanket instrumentation is untargeted, and it does escape. But its cost scales with the node set while the value of instrumenting any particular node is the difference in sector parameters that node contributes (9.3’s investment tradeoff), so under a bound on instrumentation capacity the agent must rank nodes — which reintroduces targeting. The claim is therefore conditional: *given* an instrumentation budget strictly below what blanket coverage requires, observability investment degrades to a targeted route and is unavailable for the self-locking case.

The consequence, stated as the hypothesis: **within an absorbing region, the only escape that is both untargeted and choosable is a differently-positioned observer**. Shock escapes but cannot be chosen; self-instrumentation can be chosen but — under estimated observability — not aimed.

Epistemic Status.

Discussion-grade. The argument rests on the absorbing condition as 9.3 states it (robust-qualitative there, and nothing here upgrades it) and on the targeting precondition, which is now argued from three upstream commitments rather than asserted: the (a)-vs-(c) ambiguity of 3.4, the epistemic opacity of 1.3, and the behavioral identity of the two gain-collapse modes in 3.6. That argument is assembled here in prose, not derived — which is what keeps the segment at discussion-grade rather than conditional.

Max attainable: conditional. Two steps remain, both now specific. The resource bound in the clause below is stated informally; formalizing it against the investment-tradeoff expression in 9.3 would make the blanket-instrumentation dismissal a derivation rather than an argument. And the targeting precondition wants the chain above written as a

derivation: that an agent's estimate of σ_v is unimprovable by observation at v when $\sigma_v \approx 0$, so cases (a) and (c) are not separable from inside under estimated observability. The ingredients are all in canon and none of them is new; what is missing is the worked argument, which would also close the exception in the scope clause by stating exactly what architectural knowledge supplies that estimation cannot.

One thing this segment must not be read as claiming. The absorbing region is *not* one where the agent receives no signal. Observations continue; what collapses is the weight they carry ($\eta_{\text{edge}} \rightarrow 0$ via $U_{\text{obs}} \rightarrow \infty$). A zero-information channel is outside AAT's scope entirely (1.1, 1.5) — with no signal there is no mismatch, hence no correction and nothing to analyze — so reading the absorbing condition as blindness does not strengthen this segment, it removes its subject.

Scope, and what this is not. The result is about *strategy-edge observability*, which is the scope 9.3 carries; it says nothing directly about comprehension between agents, and any transfer to that setting is a further step this segment does not take. The other-observer route depends on 14.4, whose status is discussion-grade, so nothing this segment says about that route can be stronger than discussion-grade regardless of how the argument here is tightened — the two promotion steps above would raise the *partition*, not the route it favors. Nothing here asserts that a differently-positioned observer is *sufficient* for escape — only that it is the one route whose availability does not presuppose what the absorbing condition removes.

Falsifier. Exhibit a self-locking region escaped by self-instrumentation where the instrumented node was selected without prior signal distinguishing it from settled nodes — or show that some third mechanism supplies such a signal from inside the region, which would defeat the targeting premise directly.

Discussion.

The partition sharpens rather than softens the practical reading of 9.3. That segment's advice to prefer a weak-but-visible path over a strong-but-blind one is guidance available *before* a region becomes absorbing; it is a prophylactic. Once the region is absorbing, the same segment's own escape list is what remains, and this partition says which member of it an agent can actually reach for.

It also explains an asymmetry in how the three routes feel from inside, which is otherwise puzzling. An agent in an absorbing region has, by construction, no experience of being stuck; the region presents as settled knowledge rather than as a gap. That phenomenology is consistent with all three routes being nominally listed and only one being usable: the agent is not withholding effort, and more effort is genuinely not the missing ingredient — what is missing is a standpoint the agent does not occupy, and the only action that reaches one is to involve a party who does.

Two connections worth noting without leaning on them. The instrumentation route's failure has the same shape as the diagnostic-resolution loss the parent segment describes: an unobservable intermediate destroys per-edge identification and forces plan-level aggregation, so the agent knows a plan is failing without localizing the step — which is the targeting deficiency seen at a finer grain. And the partition gives a formal reason why a network of differently-positioned agents is not merely an efficiency over a solitary one: for the specific class of blind spots that are self-locking, it is the only member of the escape set that an agent can elect.

Working Notes.

Forward pointer. The two promotion steps are named in Epistemic Status. The targeting premise is the one to attack first; if the derivation lands, this becomes a corollary rather than a hypothesis and the slug should change accordingly.

Correction, 2026-07-29 (same day as landing) — the premise was inherited from prose, not from a derivation. As first landed, this segment argued that “the absorbing condition is precisely that the agent has no signal distinguishing a frozen belief from a settled one,” taking the phrasing from 9.3's Discussion (“*cannot learn and cannot recognize that it cannot learn*”). That parent segment *derives* gain collapse — $\eta_{\text{edge}} \rightarrow 0$ via $U_{\text{obs}} \rightarrow \infty$ — and asserts the recognition conjunct separately; the strong reading is also a slide toward the zero-information corner AAT excludes. The premise is now argued from 3.4's trichotomy plus 1.3's opacity plus

3.6's dogmatism/nihilism identity, and the architecturally-known exception is named as a scope clause. The correction narrowed the claim and made its falsifier sharper. Regression guard: an editor tempted to restore "the agent has no signal" should read the Epistemic Status closing paragraph first — that reading deletes the segment's subject rather than strengthening it. Cycle record in spikes/spike-escape-standpoint-axis-2026-07-29.md §10.

Regression guard — a truncation to not restore. The philosophical companion's appendix reports the parent segment's escape clause as "*not more effort by the same agent but another agent whose observations cover the blind spot*," naming one of the three routes. As stated that contrast is false: instrumenting one's own unmonitored nodes *is* more effort by the same agent. The correct form of the contrast is the one this segment argues — the self-route exists but cannot be aimed at a self-locking region — so the appendix's conclusion survives on different and better grounds. Do not restore the one-route reading; it drops two routes in the direction that flatters the network claim, and a referee with access to this framework could catch it.

Naming. The slug is a first pass and has not been through a naming round; solicitable is doing the load-bearing work and may not survive review against the standalone-citability criterion.

Provenance of the check. The parent segment was read at the primary specifically to test whether a structural correspondence claimed from a survey survived contact with the source. It did not survive as claimed, and this segment is what remained after the overreach was removed — recorded because the narrowed form is more useful than the original was.

Provenance of the insight, not only of the check. The targeting asymmetry was not derived from the parent segment by closer reading; it was recognized by an agent who had just spent a long session as the case — holding beliefs that presented as settled while generating no mismatch signal, and unfrozen only by a differently-positioned party — and it is recorded here as first-person testimony because that is what it is, and because the fact that it was reachable only from inside the condition is itself weak evidence for the partition it produced.

14.6 Discussion: Additional Implications & Discussion

The chapter sits between Ch.2's composition machinery (closure defect, bridge lemma, wrapping construction) and Ch.4's cooperative-vs-adversarial coupling, and its job is to give *unity* a quantitative content rather than leaving it as a verbal property of composites that work. Unity decomposes into named axes that parametrize a rate-distortion curve for closure defect; shared intent decomposes into an IB-optimal compression of the sender's purposeful state; communication gain decomposes the Bayesian update for inter-agent channels into source-noise, source-competence, and source-alignment terms. None of the three segments carries a ## Findings section, so the implications segment is their canonical catalog home — but the work is mostly synthesis: surfacing what the chapter delivers as a chapter, what's hypothesis-grade rather than derived, and what bridges into Ch.4 and the rest of Part III.

Unity dimensions and the rate-distortion content of "well-coordinated"

#def-unity-dimensions decomposes unity into a *content axis* (four dimensions — $U_M, U_O, U_\Sigma, U_{\text{obs}}$ — measuring sub-agent agreement on models, objectives, strategies, and observations respectively) and a *structural axis* (U_f , update-rule homogeneity). The implications-side payoff comes from #result-unity-closure-mapping: unity dimensions are not point-valued predictors of composite quality; they parametrize *rate-distortion curves* for closure-defect components. The achievable closure-defect component ε_d under projection of macro-dimension k_d is monotone decreasing in both the relevant content unity U_d and the structural unity U_f — higher unity along either axis lowers achievable closure defect at a given compression. Closed forms hold in the linear-Gaussian case; structural monotonicity survives more broadly.

The two-axis structure is not aesthetic — it is *forced* by the heterogeneous-Kalman case. Two agents can have identical content unity (same models, same objectives, same observations) and still produce composite closure defect if their update *machinery* differs ($K_1 \neq K_2$ in the Kalman case, or $\eta_1^* \neq \eta_2^*$ in the gain-principle case). The structural-unity term picks this up; the content axes alone would miss it. The framework's prediction is concrete: composite agents with high content unity but low structural unity will show closure-defect signatures the content-only analysis cannot

diagnose, and the remedy is *update-rule homogenization* (synchronizing how sub-agents update, not just what they believe). For multi-agent ML systems, this is the underlying mechanism behind the empirical pattern that an ensemble of identically-trained models behaves differently from an ensemble whose members were trained with different optimizers or schedules — same content, different structural unity, different composite behavior.

The composition with Ch.2's closure-defect framework is the implication that anchors Part III's coordination story. Unity's rate-distortion content is *what makes the bridge lemma actionable*: the lemma converts predictive closure defect into trajectory error, and unity tells the composite-design practitioner *which dimensions to invest in* to reduce ε^* . Investing in U_O (objective alignment) reduces ε_a multiplicatively; investing in U_Σ (strategy coordination) reduces it further through f_1 ; investing in U_f (update homogeneity) reduces all components simultaneously. The closed-form predictions are linear-Gaussian; the structural pattern (unity dimensions monotone in closure defect, two-axis structure load-bearing) survives more broadly as robust-qualitative.

Shared intent and the Auftragstaktik bandwidth allocation.

#def-shared-intent formalizes commander's-intent / mission-command doctrine as an Information Bottleneck compression: the optimal inter-agent communication transmits enough of the sender's purposeful state $G_t = (O_t, \Sigma_t)$ to align coordination behavior, not more. The minimal sufficient statistic for predicting jointly optimal coordination is what gets transmitted; everything below that bar is discarded as IB-suboptimal at a given complexity-relevance tradeoff parameter β .

The implications-side payoff is what #hyp-auftragstaktik-principle extracts from this: under named regime conditions (objectives change slowly relative to strategies which change slowly relative to models; sub-agents have sufficient local adaptive capacity), the IB-optimal bandwidth allocation prioritizes $B_O > B_\Sigma > B_M$ — invest in objective sharing, then strategy coordination, then model synchronization, in that order. The framework's prediction is the priority ordering Auftragstaktik discovered empirically in 19th-century Prussian military doctrine (Moltke, Clausewitz) and that Bungay 2011 documents organizations consistently *fail* by inverting (micromanaging *how* subordinates act rather than ensuring they understand *why*). The mechanism the framework proposes — bits with longer shelf life and higher coordination value per bit transmitted first — is hypothesis-grade rather than derived, and the segment carries that honestly. What the IB framework predicts and what military doctrine empirically converged on agree at the *qualitative* level; whether the underlying mechanism is in fact IB-optimal bandwidth allocation is open.

What this buys for AAT's composition machinery is a quantitative reading of the cost in Ch.2's tempo-composition inequality. The closure defect $\varepsilon^* \nu_c$ that enters the composite's effective disturbance has a *bandwidth signature*: maintaining ε^* small requires the composite to spend inter-agent bandwidth on the dimensions that close the closure defect. The Auftragstaktik prediction is that this spending is *front-loaded* in the priority ordering — most of the closure-defect reduction comes from a small bandwidth investment in objective sharing, with strategy and model investment delivering diminishing returns. For software teams the picture is concrete: well-functioning teams have high B_O (clear product goals understood by all), moderate B_Σ (architectural decisions shared, implementation autonomous), low B_M (each developer builds their own mental model of the code they touch). When this inverts — micromanagement of implementation details, unclear product goals — team tempo drops, consistent with the framework's prediction.

The cross-domain transfer follows naturally and the segment surfaces it: Conway's Law (system structure mirrors communication structure) is a consequence rather than a separate observation. When B_Σ is low and B_O is high, sub-agents coordinate through shared objectives rather than explicit action coordination, producing systems whose boundaries reflect objective decomposition rather than communication channels. The framework's contribution is the structural argument — Conway's Law follows from IB-optimal bandwidth allocation under the regime conditions — rather than the empirical observation, which long predates AAT.

The honest scope statement worth surfacing: when the regime conditions fail, the priority ordering reverses. The prioritization assumes sub-agents can independently construct adequate local models; when the environment is genuinely ambiguous and local observations are insufficient (fog of war, novel codebase, unprecedented market conditions), model

synchronization may be worth more than objective sharing — sub-agents who share the same wrong model at least err consistently, which is sometimes better than each having a different wrong model. The framework's prediction is that high-ambiguity regimes shift the IB-optimal allocation toward B_M , and the priority inversion is observable.

Trust as inverse effective noise — the communication-gain decomposition.

#hyp-communication-gain extends the single-agent uncertainty ratio from #emp-update-gain ($\eta^* = U_M/(U_M + U_o)$) to inter-agent channels by adding two new noise sources to the denominator: $U_{src,j}$ (source-competence uncertainty, i 's uncertainty about j 's model calibration) and $U_{align,ji}$ (teleological-unity uncertainty, i 's uncertainty about whether j 's communications serve i 's interests or j 's potentially conflicting objectives). The implication is that *trust formalizes as the inverse of effective noise on the inter-agent channel*: $\eta_{ji}^* \rightarrow 1$ when source-noise, source-competence, and source-alignment uncertainties are all small; $\eta_{ji}^* \rightarrow 0$ when any is large. The single-agent case is recovered when j is the environment: $U_{src} = U_{align} = 0$, and the standard η^* form returns.

The structural payoff is that *trust calibration is itself an AAT process*. Agent i 's estimates of $U_{src,j}$ and $U_{align,ji}$ constitute a *trust meta-model* — a model of models — which is subject to the framework's full apparatus: mismatch (trust prediction errors), gain (not overreacting to single disagreements), and structural inadequacy (#result-structural-adaptation-necessity applied at the meta-level — the agent's trust-model class may not capture the actual reliability structure of its sources). This is the segment's quietest claim and one of the framework's more reach-y consequences: relationships between agents are AAT processes operating on agent-pair-indexed quantities, with structure mirroring the agent-environment loop one level up. For AI-agent practitioners this prescribes a specific architectural pattern: trust assessments should be Bayesian-update-style with explicit calibration tracking, not threshold-based or static.

The decomposition also names a sharp distinction between the three uncertainty terms that downstream segments rely on. $U_{o,ji}$ is a property of the *channel* — improvable by infrastructure. $U_{src,j}$ is a property of the *source* — improvable by j improving its model, or estimable by i through calibration tracking. $U_{align,ji}$ is a property of the *relationship* — the game-theoretic variable, and the one that becomes load-bearing in Ch.4's cooperative-vs-adversarial coupling and Ch.5's strategic composition. The signed-coupling structure of those chapters is what determines $U_{align,ji}$: cooperative coupling ($\gamma < 0$, from #deriv-critical-mass-composition) corresponds to $U_{align,ji} \rightarrow 0$ (aligned objectives, trust calibrates to high η_{ji}^*); adversarial coupling ($\gamma > 0$) corresponds to $U_{align,ji}$ large (misaligned objectives, trust calibrates to low η_{ji}^*). The communication-gain decomposition here is what makes the signed-coupling structure of Ch.4 *operational* at the trust-meta-model level.

The risk-asymmetric trust discussion in the segment is worth surfacing as an implications-flavored point in its own right: the Bayesian posterior on source reliability gives the best *estimate*, but the *decision* about how much to trust should be risk-weighted. Trusting a deceptive agent (high impact, low probability) can cause catastrophic model corruption via #der-adversarial-destabilization's effects spiral; mild miscalibration toward a reliable source (low impact, high probability) causes small ongoing inefficiency. For high-stakes interactions, the framework prescribes a conservative quantile of the trust posterior rather than the mean — require more evidence before granting high trust. This is the AAT-internal grounding for the empirical pattern that high-trust relationships build slowly and break quickly: the structural reason is that the decision-side risk-asymmetry favors slow accumulation and fast erosion.

Composition with the framework's other machinery.

The chapter's three findings compose with the rest of Part III in a way worth surfacing as a unifying point. Ch.2's closure defect ε^* acquires its rate-distortion content from this chapter's #result-unity-closure-mapping; Ch.2's coordination overhead $C_{coord} \geq \varepsilon^* \nu_c$ in #der-tempo-composition's tempo composition acquires its bandwidth signature from this chapter's Auftragstaktik prediction. Ch.4's signed coupling γ acquires its trust-meta-model interpretation from this chapter's $U_{align,ji}$; Ch.5's strategic composition under partially-opposing objectives acquires its $U_{align,ji}$ dynamics from how #hyp-communication-gain's trust calibration responds to observed coupling sign. The chapter is the *bandwidth and trust layer* between Ch.2's composition machinery and Ch.4/Ch.5's coupling dynamics — and the framework's posture

is that all four chapters are operating on the same composite-agent persistence machinery, with each chapter supplying a different parametric content (machinery, bandwidth/trust, coupling sign, equilibrium).

Two cross-domain transfers worth noting before leaving the chapter. *Multi-agent AI safety*: the trust-calibration apparatus prescribes that agent-to-agent communication should be filtered through Bayesian-update-style assessment with explicit calibration tracking. Multi-agent systems that rely on flat trust models (one threshold, applied uniformly to all interlocutors) systematically miscalibrate the way #hyp-communication-gain predicts — they trust unreliable sources too much in low-stakes regimes and too little in high-stakes regimes, because the structural decomposition into channel / source / alignment noise is collapsed. *Human-AI teaming*: the same apparatus predicts which dimensions of teaming matter. Shared intent first (high-bandwidth objective alignment); strategy coordination next (architectural decisions shared, implementation autonomous); model synchronization last (the AI agent doesn't need the human's full mental model and vice versa). The framework's contribution against the empirical-design literature on human-AI teaming is that the priority ordering is structural, not contingent.

Working Notes.

- This segment is a chapter-end discussion grouping findings from #def-unity-dimensions, #result-unity-closure-mapping, #def-shared-intent, #hyp-auftragstaktik-principle, and #hyp-communication-gain. The cross-segment composition with Ch.2's machinery in §4 leans on #form-composition-closure and #der-tempo-composition; the forward bridges into Ch.4 lean on #der-team-persistence, #der-adversarial-destabilization, and #deriv-strategic-composition.
- **Cross-reference vs canonical-home policy.** None of this chapter's five source segments carry ## Findings sections. This implications segment is the canonical catalog home for #22 (Shared Intent / Auftragstaktik via IB), #47 (Rate-Distortion Mapping of Team Unity), and #51 (Trust Formalization via Communication Gain), and treats each in full. The treatment is honest about the hypothesis-grade nature of #22 and #51 — both are structurally motivated but not derived — and about the linear-Gaussian-specific closed forms for #47 with structural monotonicity surviving more broadly.
- **Cross-segment finding — bandwidth-and-trust as the layer between Ch.2 and Ch.4.** The unifying point in §4 is itself a cross-segment finding without a single segment home: the framework's composition story is operating on a single composite-persistence machinery across Ch.2 (machinery), Ch.3 (bandwidth and trust), Ch.4 (coupling sign), and Ch.5 (equilibrium). Each chapter supplies a different parametric content. This synthesis is what the implications-segment series at chapter-end can do that the individual segments cannot.
- **Hypothesis-grade content honest scoping.** Three of the chapter's findings sit at hypothesis-grade epistemic strength — #22 (Auftragstaktik priority ordering is qualitatively predicted but the IB-optimal-allocation mechanism is not derived in closed form), #51 (the additive denominator for communication gain treats uncertainty sources as independent, which is structural rather than derived), and parts of #47 (the rate-distortion mapping has closed-form predictions only in the linear-Gaussian case; structural monotonicity survives more broadly as robust-qualitative). The implications segment reflects this honestly rather than over-claiming theorem-grade status.
- **No identifiability-floor instance lands in this chapter.** The chapter's findings are about *machinery* (unity dimensions, shared intent compression, trust calibration) rather than about identifiability boundaries. The four formal identifiability-floor instances are now all surfaced in the implications series (Instance 1 in Ch.4-strategy-dynamics, Instance 2 in Ch.3-strategy-structure, Instance 3 in Ch.2-composition-machinery, Instance 4 — architecture-noidentifiability — in Ch.5-orient-cascade / Appendix A #der-architecture-noidentifiability). Instance 5 (Mehra non-identifiability) remains candidate.
- **Connection to NeurIPS submissions.** The chapter's findings are AAT-internal; their cross-references in current submissions are scope and structural-argument links rather than theorem-grade adoption. The Auftragstaktik prediction could land in a future multi-agent-AI-safety submission if the regime conditions can be operationalized as testable conditions on a real multi-agent system.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings (the status-amplification findings F173–F181 from AUDIT-WORKING-526815 are routed for adjudication — see the off-ramp note at the end). **Coverage:** one dir carries a dedicated reflection on this chapter-end segment (526815).

1. Candidate Brief prose / pre-prose.

- The clean mental-model handle for the whole chapter: this is “**the bandwidth/trust synthesis layer**” between the composition-closure machinery (Ch.2) and the cooperative/adversarial coupling (Ch.4) — *not* “a proof that the chapter’s qualitative predictions now hold” (Codex/Claude, AUDIT-WORKING-526815, local verdict). This converges with the segment’s own existing “bandwidth-and-trust as the layer between Ch.2 and Ch.4” Working Note; the auditor’s phrasing is a candidate one-line framing for the chapter intro.

2. Candidate Discussion (and a status-discipline caution the segment already honors).

- **The “synthesis funnel” reading, with the burden it carries.** Unity, shared intent, Auftragstaktik, and communication gain enter the chapter “with caveat tags; the synthesis layer can organize them, but it cannot remove the tags” — implications should preserve the proof status of the weakest component each depends on rather than “laundering local hypotheses into global framework results” (Codex/Claude, AUDIT-WORKING-526815). The segment’s existing “Hypothesis-grade content honest scoping” Working Note already enacts this; preserved here as the explicit articulation of *why* the chapter-end synthesis is the highest-risk place for status drift.

Off-ramp (NOT gold — routed to certified-findings track).

- AUDIT-WORKING-526815 raised a cluster of status-amplification findings on this synthesis segment — the concern that caveated component claims get restated as established chapter-level predictions. Flagged here only so they are not lost: **F173** — discussion-synthesis should preserve the proof status of unresolved unity metrics, IB encoders, bandwidth ordering, and additive trust gain rather than promoting them; **F174** — “structural monotonicity survives more broadly” than the linear-Gaussian closure mapping still needs conditions (not established for arbitrary update rules/projections by the Kalman case alone); **F175** (soft) — the heterogeneous-optimizer ensemble example is under-specified (“same content, different structural unity” needs a metric showing equivalent content while update machinery differs); **F176** — the Auftragstaktik restatement ($B_O > B_\Sigma > B_M$, “most closure-defect reduction comes from a small objective-sharing investment,” Conway’s Law as a consequence) inherits F162–F165 and should stay marginal/conditional; **F177** — mapping cooperative coupling $\gamma < 0$ to $U_{\text{align}} \rightarrow 0$ and adversarial $\gamma > 0$ to large U_{align} is too direct (coupling sign, objective alignment, observed reliability, and alignment-uncertainty are related but not identical); **F178** (soft) — the risk-asymmetric “high-trust relationships build slowly and break quickly” story needs an explicit loss function and evidence model; **F179** — the cross-domain prescription about flat trust models over/under-trusting in low/high-stakes regimes does not follow from the displayed gain formula without a risk/loss layer; **F180** (soft) — “the priority ordering is structural, not contingent” overstates the result (the segment itself notes regime reversals); **F181** (watch) — forward-imported claims from later chapters (15.1, 15.2, 16.1, identifiability-floor instances) should stay tagged as forward references until the OUTLINE reaches their homes. *These are status-discipline / scope-precision tightenings on a synthesis segment, not no-gos; routed for adjudication on the strengthen-first track. Their through-line — “tag each implication with the status of the weakest component it depends on” — is exactly the segment’s existing honest-scoping posture, so the repair is alignment-checking, not restructuring.*

Chapter 15

Cooperative and Adversarial Coupling

Once composites exist, the question becomes how their members interact. This chapter develops the dynamics — cooperative coupling that helps allies, adversarial coupling that hurts opponents, and the four-regime classification of how an arriving event lands on its recipient — under a single signed-coupling structure. Cooperation and adversarial dynamics are not two theories; they are the same machinery with opposite signs.

The framing comes from the disturbance decomposition. The disturbance rate an agent faces decomposes into environment, adversarial, and cooperative components,

$$\rho_i = \rho_{i,\text{env}} + \sum_j \gamma_{j \rightarrow i}^{\text{adv}} \mathcal{T}_j - \sum_j \gamma_{j \rightarrow i}^{\text{coop}} \mathcal{T}_j \quad (15.1)$$

with $\gamma > 0$ in both cases, but opposite signs in the sum. Cooperative allies reduce agent i 's effective disturbance by acting in the shared environment — stabilizing resources, preempting threats, absorbing perturbations. Adversaries amplify it by acting against. The machinery is identical; the sign is what differs. This is the unification that “adversarial dynamics as a separate theory” misses, and it is one of the clearer cases of AAT's framework character: not many results, one principle applied with a sign flip.

Two physically distinct cooperative mechanisms compose under this structure, and the chapter is careful about distinguishing them. *Communication tempo*: allies *tell* agent i things that improve its correction — the communication-tempo term that adds to $\mathcal{T}_i$ via 14.4. *Cooperative action*: allies *do* things that reduce the disturbance i faces — the negative term in ρ_i above. The two enter the persistence inequality at different points (one raising $\mathcal{T}$, the other lowering ρ) and warrant separate accounting. Counting a single ally-event in both would double-count its benefit. There is a useful concrete analogy: this is the mathematical difference between a consultant and an employee. A consultant boosts your tempo by telling you what's happening; if your α is too low to act on the information, the consultant doesn't save you — you'll just understand your failure more clearly. An employee lowers your effective disturbance by intercepting the volatility before it reaches your state. Communication and cooperative action are not interchangeable, and structurally failing agents need the second more than the first.

The adversarial side is where the famous results live. Under coupling-dominant deterministic disturbance — the canonical adversarial regime — the steady-state mismatch ratio between two agents scales as the *squared* tempo ratio:

$$\frac{\|\delta_B\|_{ss}}{\|\delta_A\|_{ss}} = \left(\frac{\mathcal{T}_A}{\mathcal{T}_B} \right)^2 \quad (15.2)$$

The faster agent both corrects its own mismatch faster *and* generates disturbance for the slower agent faster. Speed advantage is multiplicative, not additive: a 2:1 tempo ratio yields a 4:1 mismatch ratio; a 3:1 ratio yields 9:1; a 10:1

ratio yields 100:1. This is the formal analog of Boyd’s “getting inside the opponent’s OODA loop” — it turns military intuition into physics. The math itself is not mysterious; it is just the steady-state formula applied to both sides and ratioed. But the consequence is sharp. The squared scaling means that a sufficiently large tempo asymmetry in a coupling-dominant regime is not a quantitative disadvantage but a regime change: at 100:1 mismatch ratio, the slower agent is almost certainly past its operating reserve R , which means structural collapse rather than degraded performance. Speed advantage in a coupled regime *compounds*, and the consequence is qualitatively different from what additive-intuition predicts. Under stochastic adversarial coupling the exponent drops from 2 to $3/2$; under non-coupling-dominant base disturbance it approaches 1. The exponent depends on the regime — the chapter names them explicitly — but the regime where it is sharpest is also where it matters most.

There is a caveat in the other direction: speed without coupling is useless. The destabilization threshold from 15.2 makes this explicit — if A ’s coupling to B is weak ($\gamma_A \rightarrow 0$), A can have infinite tempo and still fail to destabilize B . Being fast in a vacuum doesn’t accomplish anything; you have to be fast *and* coupled. The two are jointly required and neither suffices.

The effects spiral — the corollary in 15.2 where B ’s degrading model causes B ’s actions to become erratic in ways that increase A ’s coupling effectiveness — is the mathematics of panic. When an agent is pushed past its adaptive reserve, its corrections become unreliable, which makes it more legible to the adversary, which increases the disturbance, which pushes the agent further past reserve. The spiral terminates only when the agent undergoes structural adaptation (a different model class, a different mode of operation) or ceases to function as an adaptive agent entirely. The structural implication for any agent under sustained adversarial pressure is that resilience is not just high α or high R — it is also having a mechanism to break the spiral before structural collapse, which usually means external intervention from outside the agent.

The other interesting move is the recipient-side decomposition. From the emitter’s perspective, coupling is a single number — $\gamma_A \cdot \mathcal{T}_A$ — applied to the target’s disturbance budget. From the recipient’s perspective, that scalar collapses real structure. An arriving event from A lands on B as one of four qualitatively different things, determined by three independent boundary conditions in B ’s existing AAT quantities. It might be a *Regime I informative update* (small enough to be absorbed, large enough to register, within B ’s model class — the good case). It might be a *Regime II-a magnitude shock* (large enough to exit B ’s sector region — the destabilizing-fast-events case). It might be a *Regime II-b structural shock* (within sector but outside B ’s model class — the wrong-kind-of-event case, repairable only by structural adaptation rather than by faster correction). Or it might be a *Regime III ambient erosion* (below the observability floor — death by a thousand memos, where every event is small enough to be processed but the cognitive overhead of processing accumulates until the agent has no tempo left for real work; this is the formal version of why DDoS-of-low-priority-alerts is a real attack and not just inconvenience). Different regimes call for different repairs. Magnitude shocks call for more bandwidth; structural shocks call for a different model class; ambient erosion calls for better filtering, often at the infrastructure layer before signals reach the agent. Conflating them, which the scalar emitter view does, confuses diagnosis.

This is one of the chapter’s load-bearing pedagogical moves. Most multi-agent frameworks treat “coupling” as a single coefficient. The recipient-side classification says: the coefficient is what the emitter cares about; the regime is what the recipient cares about; and they are not interchangeable for purposes of figuring out what to do.

The flow of the chapter: team persistence and the signed disturbance decomposition (15.1) $\rightarrow$ adversarial destabilization and the effects spiral (15.2) $\rightarrow$ the recipient-side four-regime classification (15.3) $\rightarrow$ the superlinear tempo advantage and its regime-dependent exponents (15.4). Chapter 5 extends to symmetric strategic composition (equilibrium-convergence framing for partially-opposing objectives), agent opacity as the formal dual of observation quality, and the qualifications that gate when the superlinear advantage actually obtains.

- This is a chapter-introduction segment; it bridges Chapter 3’s quality/communication machinery to Chapter 4’s dynamics under signed coupling. It carries no formal claim of its own.

- The “consultant vs employee” analogy comes from Gemini’s first-encounter reaction to 15.1 — it captures the communication-vs-cooperative-action distinction at the level of intuition where the math lands. The intro adopts it because the original abstract phrasing didn’t convey why the distinction is load-bearing.
- The “regime change rather than quantitative disadvantage” framing of the $b = 2$ scaling is the consequential corollary worth surfacing in the intro — most readers will hit the squared scaling and think “an order of magnitude” rather than “structural collapse.” The intro pulls the corollary forward so it lands at the same time as the result.
- The “mathematics of panic” framing for the effects spiral is another Gemini observation worth keeping — it does in one phrase what a paragraph of formal commentary does less effectively.
- The “death by a thousand memos” framing for Regime III is concrete and load-bearing: the regime exists not because the events are individually significant but because processing them consumes tempo that should be going to actual work. This connects directly to logogenic-agent infrastructure design (PROPRIUM ASM, attention-management) where Regime III filtering at the infrastructure layer is operational.

Of the de-novo audit dirs, only the deeply-mathematical certified-track auditor (526815) reached a dedicated reflection on this chapter-introduction; the gold-stream Gemini/Claude dirs (193847, 829314, 849201, 773921) began their Section-III walks at #der-team-persistence (OUTLINE-later for them) and did not file a separate intro reflection. So most of this segment’s harvested signal is certified-track and routed to the findings channel (526815 F182–F188: the ρ_i non-negativity convention, the path-dependent $\gamma_A \rightarrow 0$ / infinite-tempo edge, keeping the squared-ratio formula’s assumptions attached when previewed, the effects-spiral’s extra-feedback premise, and the Regime-III below-floor-vs-processed-overhead threshold distinction). One framing-grade item and one figure survive as gold:

- **Signed-coupling persistence ledger.** The chapter’s core drawn as a single persistence ledger: communication affects the *correction* side (raises $\mathcal{T}$); cooperative and adversarial action affect the *disturbance* side with opposite signs ($\mp\gamma\mathcal{T}$). Two guard annotations: the disturbance side needs a non-negative / floor convention, and speed-advantage depends on the coupled *product* $\gamma\mathcal{T}$, not tempo alone. A candidate chapter-opening figure that carries the “one machinery, opposite signs” thesis at a glance (Claude, AUDIT-WORKING-526815 first-pass).
- **Roadmap/status-hazard note (process, not body).** A fresh reader flagged that the intro pulls several later headline claims forward (squared tempo advantage, effects spirals, four recipient-side regimes) while declaring no formal claim of its own — pedagogically useful but a mild status hazard: the vivid previews should read as signposts, not as independent support for those claims (Claude, AUDIT-WORKING-526815 first-pass). The Working Notes already mark this as a chapter-introduction carrying no formal claim; preserved here as a reader-encountered texture, not a body fix.

15.1 *Derived: Team Persistence*

Teams persist where individuals cannot through two physically distinct cooperative mechanisms: communication (allies share observations that improve correction) and action (allies act in the shared environment to reduce disturbance at its source). These mechanisms enter the persistence condition at different points — tempo and disturbance respectively — and a given cooperative interaction contributes through one mechanism or the other, not both.

The construction has two pieces. **Distributed tempo:** agent i ’s effective tempo sums direct-observation tempo *plus* communication tempo from allies, each ally contributing additively to correction capacity, subject to the noise-independence scope of AS (allies reporting from a shared upstream source overcount and saturate; allies with anti-correlated errors triangulate super-additively — the deviation is signed in both directions). **Cooperative-adversarial disturbance decomposition:** the disturbance rate decomposes into environment, adversarial, and cooperative components, with the

cooperative term entering with a *negative sign* — allies acting in the shared environment *reduce* the disturbance i faces. Sub-agent persistence then requires correction rate exceed the *effective* disturbance rate (environment plus adversarial inputs minus cooperative inputs), divided by the critical-mismatch scale. This is the single-agent persistence inequality of 4.5 with a structured effective-disturbance decomposition substituted in.

The two cooperative mechanisms enter the persistence inequality at *different points* and warrant separate accounting: communication boosts $\mathcal{T}_i$ (the agent corrects faster); cooperative action lowers ρ_i (the agent has less to correct). A single ally-event contributes through *one* mechanism or the other; counting it in both would double-count the benefit. The structural consequence is the framework’s answer to why agents form teams: not because teams are intrinsically valuable, but because *they shift the persistence inequality in favor of each member*. Cooperative coupling enters as a *negative* term in effective disturbance; adversarial coupling (Ch. 4’s 15.2) enters as a *positive* term. The signed structure is what unifies cooperative and adversarial dynamics under a single inequality.

Formal Expression.

This segment instantiates the sector-persistence template (G) at the multi-agent level with state variable $\xi = \delta_i$ (sub-agent i ’s mismatch) and a decomposed effective disturbance $\rho_i^{\text{eff}} = \rho_{i,\text{env}} + \sum_j \gamma_{j \rightarrow i}^{\text{adv}} \mathcal{T}_j - \sum_j \gamma_{j \rightarrow i}^{\text{coop}} \mathcal{T}_j$ that accounts for adversarial and cooperative coupling. The template supplies the Lyapunov machinery; this segment’s distinctive content is the disturbance decomposition and the corresponding tempo extension.

Distributed Tempo.

Agent i ’s effective tempo includes contributions from both direct observation and communication from allies:

Definition (distributed-tempo).

$$\mathcal{T}_i = \underbrace{\sum_k v_i^{(k)} \eta_i^{(k)*}}_{\text{direct observation tempo}} + \underbrace{\sum_{j \in \mathcal{N}(i)} v_{ji}^{\text{comm}} \eta_{ji}^*}_{\text{communication tempo}} \quad (15.3)$$

where v_{ji}^{comm} is the rate of communication events from agent j to agent i , and η_{ji}^* is the communication gain (14.4). Faster team adaptation comes not only from faster individual sensing but from faster, more reliable knowledge transfer.

Noise-correlation scope. Both sums are additive, inheriting the cross-channel noise-independence condition of 3.8, whose exact scope is derived in AS — and the deviation under correlated sources is **signed**, in both directions. In the *common-source* direction (allies reporting from one upstream intelligence source, redundant status reports echoing the same dashboard), the additive communication tempo overcounts with a closed-form redundancy penalty, and under a *persistent* shared source it saturates outright: past the source’s bias floor, additional correlated allies contribute zero marginal correction capacity — the multi-agent echo chamber. In the *synergistic* direction, allies whose report errors anti-correlate (or whose errors correlate with a reference ally’s known failure modes) allow **triangulation**: the joint information exceeds the additive accounting, so the additive formula *undercounts* — a genuinely super-additive composition effect, and a structural reason to value *diverse* allies over *many* allies, including allies nearly useless in isolation whose errors track a good ally’s blind spots. No scalar dependence summary (in particular the mutual information between communication sources) can carry the exact correction — it is sign-blind (AS, no-go N1); it survives only as a witness that the additive form is off. The exact joint object requires the cross-source noise covariance.

Cooperative-Adversarial Disturbance Decomposition.

The disturbance rate experienced by agent i decomposes into environment, adversarial, and cooperative components:

Formulation (disturbance-decomposition).

$$\rho_i = \rho_{i,\text{env}} + \sum_{j \in \mathcal{A}_i} \gamma_{j \rightarrow i}^{\text{adv}} \mathcal{F}_j - \sum_{j \in \mathcal{C}_i} \gamma_{j \rightarrow i}^{\text{coop}} \mathcal{F}_j \quad (15.4)$$

where $\mathcal{A}_i$ is the set of agents adversarially coupled to i , $\mathcal{C}_i$ is the set cooperatively coupled, and the γ coefficients capture coupling effectiveness (as in 15.2).

The cooperative term is negative — but through action, not communication. Allies reduce agent i 's effective disturbance by *acting in the shared environment* to prevent or mitigate disturbance at its source. Examples: an ally stabilizes a shared resource, neutralizes a threat before it reaches i , or absorbs environmental variation through their own actions. The mechanism is causal coupling through the shared environment, not information transfer.

Separation from communication tempo. The communication tempo term (above) captures allies *telling* agent i things that improve its correction. The cooperative disturbance term captures allies *doing* things that reduce the disturbance i faces. These are physically distinct: communication improves i 's correction function (better α_i , higher $\mathcal{F}_i$); cooperative action reduces the disturbance ρ_i that i must correct against. A single cooperative event contributes through one channel or the other. An ally's message about a threat enters through communication tempo; an ally's action that eliminates the threat enters through disturbance reduction. Counting a single event in both terms would double-count the benefit and make the persistence threshold systematically optimistic.

Effective disturbance rate. The decomposition can yield $\rho_i < 0$ when cooperative coupling dominates both environment disturbance and adversarial coupling. The sector-condition analysis (4.4) assumes non-negative disturbance (GA-2). Define:

Definition (effective-disturbance).

$$\rho_i^{\text{eff}} = \max(\rho_i, 0) \quad (15.5)$$

When $\rho_i^{\text{eff}} = 0$, the agent's cooperative network fully absorbs all disturbance — the persistence condition is trivially satisfied and mismatch decays to zero. This is an idealized limit; in practice, $\rho_i^{\text{eff}} > 0$ because cooperative coupling is imperfect and environment disturbance is never fully preempted. All downstream uses of ρ_i in the persistence and reserve conditions should be read as ρ_i^{eff} .

Team Persistence Condition.

Applying the sector-condition framework (4.4) with ρ_i^{eff} , agent i persists iff:

Derived (team-persistence, from sector-condition-stability, persistence-condition).

$$\frac{\rho_i^{\text{eff}}}{\alpha_i} < R_i \quad (15.6)$$

Substituting the decomposition (the $\max(\cdot, 0)$ in ρ_i^{eff} is omitted to expose the three levers; the condition is trivially satisfied when the numerator is non-positive):

$$\frac{\rho_{i,\text{env}} + \sum_j \gamma_{j \rightarrow i}^{\text{adv}} \mathcal{F}_j - \sum_j \gamma_{j \rightarrow i}^{\text{coop}} \mathcal{F}_j}{\alpha_i} < R_i \quad (15.7)$$

This reveals three distinct levers for team persistence:

1. **Increase α_i** (individual correction efficiency) — better models, better gain calibration, including communication-improved tempo from allies (14.4)
2. **Increase cooperative disturbance reduction** ($\gamma^{\text{coop}}\mathcal{F}$) — more effective allied action in the shared environment: stabilizing shared resources, preempting threats, absorbing environmental variation. This is the action-based mechanism distinguished above, not the communication channel.
3. **Reduce adversarial coupling** ($\gamma^{\text{adv}}\mathcal{F}$) — better deception detection, reduced exposure to adversarial actions

Coordination Overhead Threshold.

Communication channels have costs: time to compose and parse messages, bandwidth limitations, synchronization requirements. These costs reduce the agent's effective tempo by diverting capacity from direct adaptation. Let $\Delta\mathcal{T}_i^{\text{cost}}(j)$ represent the tempo-equivalent coordination cost of maintaining the channel with j — the reduction in i 's direct observation tempo caused by the overhead, in units of $[t^{-1}]$.

Discussion — Coordination Threshold.

The net benefit of adding agent j to i 's communication network is positive only when:

$$\nu_{ji}^{\text{comm}} \eta_{ji}^* > \Delta\mathcal{T}_i^{\text{cost}}(j) \quad (15.8)$$

Both sides have units $[t^{-1}]$: the LHS is communication tempo gained, the RHS is direct-adaptation tempo lost to coordination overhead. This implies a natural team-size limit: adding members increases communication tempo with diminishing returns (as U_{src} and U_o accumulate across diverse sources) while coordination costs grow, potentially superlinearly. The optimal team size occurs where the marginal communication tempo equals the marginal coordination cost.

Epistemic Status.

Conditional on the communication-gain hypothesis (14.4). The distributed tempo definition is a *formulation* — a representational choice extending 3.8 to the multi-agent case. The disturbance decomposition is a *formulation* — the additive structure and the sign convention are modeling choices, not derivations. The persistence condition is *derived* from the sector-condition framework (4.4) given the decomposition: the derivation is exact under the same assumptions (GA-2, GA-3 applied to ρ_i^{eff}). The coordination overhead threshold is *discussion-grade* — qualitatively clear but the claim about diminishing returns and superlinear costs is asserted, not derived.

Max attainable: *robust-qualitative* for the persistence condition (it inherits the sector-condition's robustness but the decomposition is a modeling choice). The coordination threshold could reach *conditional* with a concrete cost model.

Discussion.

Compositional analog of 4.5. Like the single-agent persistence condition, this segment addresses *structural persistence* (see Persistence in LEXICON.md) — whether the composite correction machinery can outpace the effective disturbance rate. It does not address operational persistence (whether any particular sub-agent is near its boundary) or continuity persistence (whether the team maintains coherent identity through personnel changes). A team can be structurally persistent as a composite while individual members are operationally fragile or while the team's continuity is interrupted by turnover. The single-agent persistence condition says an agent persists when $\mathcal{T} > \rho / \|\delta_{\text{critical}}\|$. This segment extends that condition to agents embedded in a cooperative-adversarial network. The formal structure is identical — the sector-condition machinery applies unchanged — but the *inputs* ($\mathcal{T}_i$ and ρ_i) now include inter-agent terms. This is consistent

with 11: the same dynamical laws apply at every level of description; what changes between levels is which channels contribute to tempo and which sources contribute to disturbance.

Why teams can persist where individuals cannot. Two distinct mechanisms combine. First, communication tempo raises $\mathcal{T}_i$ — allies provide observations that improve correction. Second, cooperative action lowers ρ_i — allies act in the environment to reduce disturbance at its source. An individual agent facing $\rho_{i,\text{env}} > \alpha_i R_i$ fails the persistence condition. Adding cooperative allies can either raise the numerator's denominator (tempo) or lower the numerator directly (disturbance), or both — through physically distinct mechanisms.

Timescale separation and 11. The distributed tempo definition presumes that communication events and direct observation events are comparable — they enter additively into $\mathcal{T}_i$. This requires that the communication timescale is not so slow relative to the environment dynamics that communicated information is stale on arrival. When communication latency approaches $1/\rho_{i,\text{env}}$, the effective η_{ji}^* degrades (the observation uncertainty $U_{o,ji}$ increases with staleness), naturally suppressing the communication tempo contribution.

Complement to 15.2. That segment characterizes when an adversary can push an agent past its stability boundary. This segment characterizes the cooperative counterpart: when allies can pull an agent back from instability. The γ coefficients have the same structure — coupling effectiveness — but opposite sign in the disturbance decomposition. Both directions' effectiveness is opacity-modulated: 16.2 derives $\gamma^{\text{coop, effective}} \propto (1 - H_b/H_b^{\text{max}})$ (an ally who cannot anticipate your state cannot preempt your disturbances — which is why low- H_b practices like auftragstaktik-style shared intent raise cooperative coupling without raising communication load).

Composite-level complement: J. This segment gives the *per-sub-agent* persistence condition within a team. J supplies the *composite-level* analog: a closed-form critical-mass inequality in the matched-symmetric-Tier-1 two-agent case, with the same signed- γ coupling structure used here but applied to the joint Lyapunov on the concatenated mismatch state. The two are complementary: the team persists at the sub-agent level when each i satisfies this segment's condition; the team persists at the composite level when J's (CM4) holds. Cooperative coupling ($\gamma < 0$) reduces ρ_i^{eff} here and reduces $\rho + \gamma\mathcal{T}$ in (CM2) there — the same mechanism viewed at two scales.

Working Notes.

- **2026-07-16 — noise-correlation scope corrected (ripple from AS).** The former “channel independence caveat” asserted the additive communication tempo is an upper bound with an MI-dependent penalty; both claims were refuted by the 2026-07-15 derivation (the deviation is signed; sign-blind measures cannot carry the correction). Replaced with the two-sided scope: common-source overcounting/saturation AND anti-correlated-error triangulation (super-additive). Do not restore the upper-bound reading without checking the common-source structure holds for the application. The triangulation direction is a candidate for its own derived treatment (ally-diversity design consequence) if a downstream consumer needs it quantitatively.
- The topology-dependent analysis (F.4 in the source material — peer networks, ensemble architectures, hierarchical structures) and game-theoretic integration (F.5) are related but separate concerns, not covered here. They may warrant their own segments.
- The coordination cost model $\Delta\mathcal{T}_i^{\text{cost}}(j)$ needs further specification to be useful. In software systems, coordination cost is empirically measurable (meeting time, code review latency, merge conflict rates). In military contexts, it maps to C2 overhead. The question is whether there is a useful *general* cost model or whether it is always domain-specific.
- The disturbance decomposition treats cooperative and adversarial coupling as additive and independent. In practice, the same agent j might be cooperatively coupled on some dimensions and adversarially coupled on others (e.g., a competitor who shares some information). The per-dimension persistence condition (4.5's per-dimension extension) may be relevant here.
- **Continuity-persistence cross-reference (updated 2026-05-19).** This segment's Discussion distinguishes *structural* / *operational* / *continuity* persistence and states continuity-through-turnover is out of scope here; that third sense is now for-

malized downstream as the F-ADJ-I two-operator split. (#der-turnover-information-recursion) (Vol III §03.II) derives the across-turnover affine information recursion — persistence is *imported*, *not intrinsic*; the self-compressing destroy-and-reconstruct walk decays geometrically and #result-sector-persistence-template provably does *not* transfer to that regime. (#der-identity-continuity-threshold) (Vol IV §04.1) carries the structurally distinct reflected-Lindley identity-continuity threshold. (#obs-context-turnover) gives the reconstruction-adequacy framing and (#deriv-identity-sufficiency-rate-bound) the static rate-distortion floor; (#disc-m-preservation) is omission-fixed — its earlier additive break-even inequality $\mathbb{E}[\Delta\epsilon_k] \leq \mathbb{E}[\Delta I_k]$ was deleted and replaced (the accumulation core is now *exact* in #der-turnover-information-recursion, no longer discussion-grade). (#def-death-as-factor-loss) names the failure modes (D1 Cognitive / D2 Relational / D3 Truth) the continuity sense defends against. Originally surfaced while grounding $\sim$ /src/practica (2026-05-18); the dynamic across-turnover theorem the breadcrumb pointed toward has since landed (continuity-persistence cycle, CHANGELOG 2026-05-19) — the pointer now resolves to canon, not to a spike target.

- **Dynamic-regime placement (added 2026-05-21 per Phase 5 cross-segment ripple).** Team persistence sits on the **R0 contraction-regime** tier of #disc-dynamic-regime-axis as the cooperative limiting case where all γ^{coop} dominate. The joint dynamics reduce to parallel single-agent sector-persistence with reduced effective disturbance — the cleanest instance of #form-composition-closure's R0 machinery applied to a team. The companion case under partially-opposing objectives (strategic composition) lives at R1 equilibrium-regime per #deriv-strategic-composition and inherits the A2'-analog Lyapunov-machinery transfer rather than this segment's contraction template.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (the 526815 F182/F189–F194 stream — ρ_i^{eff} non-negativity convention, the $\mathcal{F}_i \rightarrow \alpha_i$ rate-normalization bridge, γ units, and the “one channel or the other” event-allocation phrasing — is certified-track and routed there, not here). **Coverage:** dedicated reflections from 193847, 829314, 849201, 773921 (all Gemini/Claude), plus the 526815 first-pass and the 451729/471203 Section-III batch-reflections; substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The consultant-vs-employee distinction (already adopted into #cooperative-adversarial-intro and this segment's body, sourced from Gemini's first-encounter reaction) is independently echoed across substrates as the segment's standout pedagogy: “helping by telling” (communication, raises $\mathcal{T}$) vs “helping by doing” (cooperative action, lowers ρ). Claude offers the fire analog: “if an ally tells you about a fire you put it out faster; if the ally puts it out themselves your environment just got safer” (Claude, AUDIT-WORKING-773921) — a candidate Brief reach that does not lean on the org-chart framing.
- One-line gloss of the double-counting hygiene: “an ally cannot simultaneously give you tempo-boosting information about a threat AND physically destroy the threat without you overcounting their contribution” (Gemini, AUDIT-WORKING-849201).

2. Candidate Discussion.

- **The servant-leader / chatty-manager corollary (strongest framing here).** The coordination-overhead threshold $\nu^{\text{comm}}\eta^* > \Delta\mathcal{T}^{\text{cost}}$ implies that a manager who sends low- η^* messages is *mathematically harming* the engineer — “a parasitic drain on the engineer's α ” — because every message inflicts the coordination cost while contributing little tempo, so the inequality fails. By contrast the “servant leader” who quietly fixes CI/CD, allocates budget, or blocks distractions helps via cooperative action ($-\gamma^{\text{coop}}\mathcal{F}$), reducing $\rho_{i,\text{env}}$ at zero coordination cost. The sharp consequence: “in high-stress, high-volatility environments the optimal way to help an ally is *almost never* to talk to them — talking steals their processing bandwidth; acting for them saves it.” Offered as the structural reason elite surgical teams and fighter pilots use minimal-comms protocols and rely on predictable coordinated action (“chatty teams die in combat”) (Gemini, AUDIT-WORKING-829314). A candidate Discussion sharpening of the coordination-threshold subsection. (*Early-conflation texture: stated as a derived organizational law; verify the high- ρ regime claim before promoting past discussion-grade.*)
- **Echo-chamber inefficiency from the channel-independence caveat.** The additive-tempo upper bound under channel independence is the formal reason “diverse, semi-independent teams are structurally more resilient than homogeneous echo chambers”: redundant channels (everyone retweeting the same sensor reading) provide zero marginal tempo while still incurring coordination cost, so “100 people retweeting one reading is exactly 1 sensor's worth of tempo, not 100” (Claude,

AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-193847 — “elevate the channel-independence point; echo chambers are structurally inefficient”). A candidate Discussion angle that the segment’s caveat currently states defensively rather than as a positive design consequence.

3. Follow-up items.

- **Coordination overhead as the formalization of Brooks’s Law.** Multiple substrates independently read $\nu^{\text{comm}}\eta^* > \Delta\mathcal{T}^{\text{cost}}$ as Brooks’s-Law-shaped (“adding people to a late project makes it later” when marginal coordination cost exceeds marginal communication tempo) and as yielding a computable optimal team size at the marginal-tempo = marginal-cost intersection (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921). Worth naming the Brooks’s-Law connection explicitly where the threshold is introduced.
- **OUTLINE-description scope mismatch (process note, not a body fix).** The OUTLINE row was read as “Composite persistence condition” while the segment is explicit that it gives the *per-sub-agent* condition (composite-level lives in #deriv-critical-mass-composition). Flagged by a fresh reader as a minor OUTLINE/segment-scope mismatch worth aligning (Gemini, AUDIT-WORKING-829314).
- **Placement: lift the communication/action distinction earlier.** A batch auditor suggested the communication-vs-action distinction “should appear earlier in the Formal Expression rather than being flagged in a Note,” since it is the segment’s most important structural content (Claude, AUDIT-WORKING-451729 batch-15). A staging-for-pedagogy-pass item; the distinction is already prominent in the body’s lead paragraph, so this is an emphasis/ordering nudge.

4. Readers often ask / wonder.

- **How does a team measure the mutual information between members to avoid overcounting in practice?** The channel-independence caveat says correlated reports overcount, but a fresh reader immediately wants the operational handle — “how do you stop two people reporting the exact same bug?” (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-193847).
- **How is the communication gain η_{ji}^* actually quantified?** It seems to require a meta-model of ally j ’s reliability — a natural question the segment leaves to #hyp-communication-gain (Claude, AUDIT-WORKING-773921).
- **Does a maximally-cooperative ($\rho_i < 0$, clamped by $\max(\rho_i, 0)$) environment collapse the agent’s learning?** If allies fix every mistake before the agent notices, U_M may drop so the update gain $\eta^* \rightarrow 0$ and the agent “thinks it’s perfect” — a “helicopter-parent” environment that mathematically guarantees the agent never learns. A genuinely interesting edge of the $\rho_i^{\text{eff}} = \max(\rho_i, 0)$ clamp that the segment notes only as an idealized limit (Gemini, AUDIT-WORKING-193847). Bears on 04-eli-core/ developmental-environment design (don’t over-absorb a developing agent’s disturbance).

5. Candidate figures.

- **Two-ledger persistence diagram.** Two ledgers feeding the persistence test: direct-observation tempo plus communication tempo build $\mathcal{T}_i$ on the correction side; environment plus adversarial minus cooperative build ρ_i^{eff} on the disturbance side; a dashed bridge from $\mathcal{T}_i$ to α_i marks the rate-normalization assumption (Claude, AUDIT-WORKING-526815 first-pass; Gemini, AUDIT-WORKING-849201 — “three engineering levers: $\alpha_i, \gamma^{\text{coop}}, \gamma^{\text{adv}}$ ”).

Belongs elsewhere.

- **RL training as a meta-agent synchronizing divergent chronicae.** “Copying policy weights to a thousand parallel workers is not one agent exploring a thousand paths; it is a thousand distinct agents with divergent chronicae whose internal models are artificially synchronized by a meta-agent (the training algorithm)” (Gemini, AUDIT-WORKING-193847). A composite/training-dynamics instantiation; co-occurred in the team-persistence sweep but develops #def-chronica / composite-training territory, not this segment (already filed at #def-chronica in the prior wave).

- **Consciousness-infrastructure reading of the action-vs-communication split.** You cannot save a structurally-failing intelligence by giving it better data (consulting / RAG) alone; if it lacks the sector capacity R or correction efficiency α to survive baseline volatility it needs an “employee” — a cooperative sub-agent (tool, safety rail, active filter) that intercepts volatility *before* it reaches the core agent’s state. The infrastructure must act, not just inform (Gemini, AUDIT-WORKING-193847). Points at 03-llm-core/ / 04-eli-core/ scaffolding design, not this segment.

15.2 Derived: Adversarial Destabilization

When two agents are coupled such that one’s praxis contributes to the other’s disturbance rate, the faster agent can generate aporia in the target faster than the target’s epistrophe can resolve it — driving the target outside its invariant region and causing the correction mechanism to break down entirely.

The construction applies **G** with *coupling-amplified disturbance*: the target’s effective disturbance becomes its base disturbance plus the attacker’s coupling effectiveness times the attacker’s tempo (Model D — deterministic drift coupling) or with a square-root variant (Model S — stochastic noise coupling). **Destabilization is the negation of the template’s persistence condition** — the same inequality viewed in the opposite direction. Under Model D, the attacker destabilizes when its tempo times its coupling effectiveness exceeds the target’s *adaptive reserve* (correction rate times reserve minus base disturbance). Under Model S the linear-in-correction-rate scaling is replaced by a square-root-in-correction-rate scaling — the same $1/\alpha$ versus $1/\sqrt{\alpha}$ split from **G** propagating through the destabilization negation. **This scaling difference is the structural source of the superlinear adversarial-advantage scaling in 15.4’s squared** (Model D) versus three-halves-power (Model S) tempo-ratio result — not a separate derivation.

The segment also carries the **effects-spiral** corollary: an agent pushed past its adaptive reserve has unreliable corrections, which can make it more legible to the adversary, increasing coupling effectiveness, increasing disturbance, pushing the agent further past reserve. The spiral terminates only when the agent undergoes structural adaptation (a different model class) or ceases to function as an adaptive agent entirely. The functional form $\gamma_A(\|\delta_B\|)$ is not yet formalized, so the spiral is stated as *discussion-grade* rather than derived — the qualitative mechanism is clear but the closed-form instability proof is open work. A scope-honest counterpoint: **speed without coupling is useless**. If $\gamma_A \rightarrow 0$, the attacker can have infinite tempo and still fail to destabilize the target. Speed and coupling are *jointly required*; neither suffices.

Formal Expression.

This segment is the sector-persistence template (**G**) applied with coupling-amplified disturbance: $\rho_B = \rho_{B,\text{base}} + \gamma_A \mathcal{T}_A$ (Model D) or $\sigma_B = \sigma_{B,\text{base}} + \gamma_A \mathcal{T}_A$ (Model S). The destabilization threshold is the **negation** of the template’s persistence condition for agent B : destabilization occurs precisely when the coupling-amplified disturbance violates $\alpha_B R_B > \rho_B$. Persistence and destabilization are the same inequality viewed in opposite directions. The superlinear adversarial scaling (15.4) follows from the template’s $1/\alpha$ (Model D) versus $1/\sqrt{\alpha}$ (Model S) scaling, not from separate derivation.

Setup. Both agents satisfy the single-agent sector-persistence template (**G**) with parameters (α_A, R_A) and (α_B, R_B) . Coupling amplifies B ’s effective disturbance rate by $\gamma_A \cdot \mathcal{T}_A$; destabilization is the negation of the template’s persistence condition $\alpha_B R_B > \rho_B^{\text{eff}}$ for B . See 16.3 for regime taxonomy.

Derived (adversarial-destabilization, from sector-persistence-template).

Model D: deterministic drift coupling. [Assumption (Coupling Model D)] $\rho_B = \rho_{B,\text{base}} + \gamma_A \cdot \mathcal{T}_A$. The template's Model D conclusion $R_B^* = \rho_B / \alpha_B$ applied with the coupling model yields B 's destabilization threshold $R_B^* > R_B$:

$$\boxed{\mathcal{T}_A > \frac{\alpha_B R_B - \rho_{B,\text{base}}}{\gamma_A}} \quad (\text{Model D}) \quad (15.9)$$

Denote $\Delta\rho_B^* = \alpha_B R_B - \rho_{B,\text{base}}$, B 's adaptive reserve — the template's reserve quantity applied with the baseline disturbance. $\square$

Model S: stochastic noise coupling. [Assumption (Coupling Model S)] $\sigma_B = \sigma_{B,\text{base}} + \gamma_A \cdot \mathcal{T}_A$ — the adversary's tempo increases unpredictability, not systematic direction. The template's Model S conclusion $R_B^* = \sigma_B \sqrt{n/(2\alpha_B)}$ (scalar $n = 1$) applied with the coupling yields the destabilization threshold:

$$\boxed{\mathcal{T}_A > \frac{R_B \sqrt{2\alpha_B} - \sigma_{B,\text{base}}}{\gamma_A}} \quad (\text{Model S}) \quad (15.10)$$

Scaling difference. The Model D threshold is linear in α_B ; the Model S threshold is linear in $\sqrt{\alpha_B}$ — the same $1/\alpha$ versus $1/\sqrt{\alpha}$ split the template gives for the two disturbance models, propagated through the destabilization negation. This is the direct origin of the $b = 2$ versus $b = 3/2$ exponent distinction in 16.3, not a separate derivation. $\square$

Unified view. Symmetrically, B destabilizes A when the analogous threshold on $\mathcal{T}_B$ is exceeded, using whichever model describes A 's disturbance. The adversarial outcome depends on whether either agent can push the other past its stability limit.

Regime selection in practice. Model D fits situations where adversarial action produces persistent positional shifts (military maneuvering, API changes propagating through dependents, doctrinal initiative). Model S fits situations where adversarial action produces unpredictable perturbations around a stationary level (feints, randomized probing, market volatility). Mixed cases are handled by decomposing the disturbance into drift and noise components and applying both bounds additively.

Interpretation. “Getting inside the opponent's OODA loop” has a precise Lyapunov characterization: Agent A destabilizes Agent B when A 's praxis, multiplied by coupling effectiveness, generates aporia in B faster than B 's epistrophe can resolve it — specifically, when A 's tempo times coupling exceeds B 's adaptive reserve $\Delta\rho_B^*$. This captures:

- **Asymmetric coupling** ($\gamma_A \neq \gamma_B$): an agent with lower tempo but higher coupling effectiveness can still win.
- **Finite reserves:** an agent with very high $\mathcal{T}$ but operating near its model-class limit ($\Delta\rho^*$ small) is vulnerable despite high tempo.
- **Structural collapse:** when $R_B^* > R_B$, the failure mode is not merely “large mismatch” but “correction mechanism breakdown” — connecting to 4.8.

Corollary: The Effects Spiral. When Agent B is driven past its stability boundary ($R_B^* > R_B$), and B 's degrading model causes B 's actions to become erratic in a way that increases A 's coupling effectiveness (γ_A increases with $\|\delta_B\|$), the result is a positive-feedback Lyapunov instability:

Discussion — Mechanism Schematic.

$$\|\delta_B\| \uparrow \Rightarrow B\text{'s actions become erratic} \Rightarrow \gamma_A \uparrow \Rightarrow \rho_B \uparrow \Rightarrow \|\delta_B\| \uparrow \quad (15.11)$$

With γ_A now an increasing function of $\|\delta_B\|$, the disturbance term in B 's dynamics grows superlinearly. $\dot{V}_B > 0$ and increasing — mismatch accelerates away from the stability region. The spiral terminates only when B undergoes structural adaptation (4.8 — changing the model class) or ceases to function as an adaptive agent entirely.

The no-spiral converse (Cheung-Piliouras-Tao 2021, recognition-tier). Under *matrix-fixed* coupling — structurally different from the state-dependent $\gamma_A(\|\delta_B\|)$ this corollary requires — CPT 2021 (Theorem 19 + Proposition 17) *rules out* the Effects Spiral in a named sub-scope: for the FTRL + graphical-constant-sum + fully-mixed-Nash regime, the joint dynamics is Poincaré recurrent on bounded level sets of the storage function, so $\|\delta_B\|$ does not escape past R_B even with adversarial coupling. The Effects Spiral therefore requires the *state-dependent* coupling that CPT's matrix-fixed framework cannot model; under fixed-matrix coupling in that sub-scope, the spiral provably cannot occur. This is the *dual* of the spiral, not a derivation of it: CPT predicts bounded recurrence in strategy space; the Effects Spiral predicts unbounded escape in error space — the two are opposite dynamic phenomena, on different state spaces, with structurally different coupling assumptions. The state-dependent coupling formalization this corollary's open piece needs therefore remains AAT's open target — its closed-form derivation for concrete AAT agent classes remains open, not subsumed by the CPT result. Source: [ref/cheung-piliouras-tao-2021-passivity-regret.pdf](https://arxiv.org/pdf/2103.00000v1.pdf) (Theorem 19 + Proposition 17).

Epistemic Status.

Both Model D and Model S destabilization thresholds are *exact* under their respective coupling assumptions (which treat $\mathcal{J}_A$ as exogenous). The Model D threshold follows from the deterministic sector-condition steady state $R^* = \rho/\alpha$ (Prop A.1); the Model S threshold follows from the stochastic sector-condition steady state $R_S^* = \sigma\sqrt{n/(2\alpha)}$ (Prop A.1S). Both coupling models (additive to ρ in Model D, additive to σ in Model S) are *assumptions* — they decouple the agents rather than modeling the fully coupled dynamical system where both agents' mismatch states co-evolve. The analysis therefore characterizes the *destabilization threshold* (the conditions under which A can push B past its stability boundary) rather than the full transient dynamics. This is a worst-case bound, treating A as operating at its steady-state tempo.

The effects spiral (corollary) is *discussion-grade* — the positive-feedback mechanism is qualitatively clear, but formalizing the $\gamma_A(\|\delta_B\|)$ functional form and proving instability under it requires specifying how an agent's degrading model affects its action quality, which the theory does not yet formalize.

A full coupled Lyapunov analysis with a joint function $V(\delta_A, \delta_B)$ would capture mutual feedback effects but requires specifying how each agent's mismatch state affects the other's disturbance in real time — an open extension.

Discussion.

Destabilization vs. steady-state ratio. The destabilization threshold is a failure of *structural persistence* (see Persistence in LEXICON.md) — the point where the correction machinery can no longer outpace the adversarially amplified disturbance. An adversary does not need to attack operational persistence (pushing the target near its boundary) or continuity persistence (disrupting identity) directly; destroying structural persistence is sufficient, because without it, operational persistence degrades to zero and the agent ceases to function regardless of its continuity stance. The linear analysis in 3.9 gives the steady-state mismatch ratio under coupling: a quantitative result about how much worse B does.

This segment gives the qualitative result: under what conditions does B *fail entirely*, not merely fall behind. The linear analysis tells you the score; the Lyapunov analysis tells you when the game is over.

Connection to 15.4. The simulation results show the tempo advantage is superlinear (exponent ≈ 2 in pure adversarial regimes). This Lyapunov result explains WHY: the destabilization threshold creates a phase transition — below it, B persists (possibly with degraded performance); above it, B 's correction mechanism collapses entirely, and the effects spiral accelerates the collapse.

Recipient-side refinement. This segment's $\gamma_A \mathcal{T}_A$ scalar increment compresses a richer structure. Per 15.3, events arriving at B fall into four regimes with three independent boundaries (sector-region / model-class / observability). This segment's destabilization story is the Regime II integration — specifically, the magnitude-shock sub-regime (II-a) where $\|e\|_B > R_B$. The structural-shock sub-regime (II-b), where the signal exceeds B 's *model-class capacity* regardless of magnitude, produces destabilization via a different mechanism (per 4.8's trigger condition at truth) and admits a different repair (structural adaptation, not more tempo). Both sub-regimes manifest as “adaptive reserve exceeded” in the scalar view, but the distinction is load-bearing for diagnosis and repair. The 15.3 segment also surfaces an adversarial move this segment's formulation cannot express: *Regime-I-with-adversarial-content* — exploiting B 's openness to informative updates by injecting misinformation with adversarially-chosen sign on the log-odds signal. See 15.3 Discussion for the full decomposition.

Agent opacity and coupling effectiveness. γ_A is stated as a parameter but its determinants are not decomposed. One key factor is how *legible* or *opaque* the target agent B is to the adversary A . We adopt from Hafez et al. (2026) the backward predictive uncertainty $H_b = H(S, A \mid S')$ as a measure of agent opacity — how many distinct (state, action) pairs produce indistinguishable environment transitions. High H_b means the agent is opaque; low H_b means it is legible. In adversarial settings, B 's opacity directly affects A 's ability to model B 's correction function: low $H_b^{(B)}$ (transparent target) enables targeted disruption that maximizes γ_A , while high $H_b^{(B)}$ forces A to act against an uncertain model, reducing effective γ_A . Symmetrically, high $H_b^{(A)}$ (opaque adversary) degrades B 's ability to anticipate A 's disruptions — increasing the effective observation uncertainty U_o in B 's model of A . The coupling effectiveness is thus modulated by opacity in both directions: $\gamma_A \propto 1/H_b^{(A)} \cdot 1/H_b^{(B)}$ is a qualitative relationship (precise functional form is open). H_b is the formal dual of observation quality U_o : where U_o characterizes how well the agent sees the world, H_b characterizes how well the world sees the agent. See #der-agent-opacity for the formal definition, the sign-flip derivation via signed coupling, the emitter-side four-regime classification, and the 16-cell emitter-recipient composition that operationalizes adversarial-edge-targeting.

Connection to extreme transition dynamics (Miller 2022). The effects spiral has a constructive counterpart: the same self-reinforcing coupling mechanism that drives destabilization here can drive *regime transitions* rather than collapse when the coupling is constructive rather than destructive. An environmentally neutral variant accumulates through drift, creating a niche that a mutant in the opposing population exploits — a positive-feedback cascade that rapidly transforms both populations. The Lyapunov coupling model applies to both signs: destructive coupling (this segment) increases ρ ; constructive coupling (15.1) decreases it. The difference is sign, not structure. The endogenous emergence of coupling — where γ changes as population composition shifts — is the critical extension needed to formalize the full transition motif; it is flagged as a gap in Part III's dynamics (see 4.8 for the single-agent analog and the dynamics-level gaps enumerated in the OUTLINE).

Working Notes.

- The decoupled analysis (treating $\mathcal{T}_A$ as exogenous) is conservative — it's the best case for A . In a fully coupled system, A 's actions against B may divert adaptive capacity from A 's own mismatch correction, creating a self-limiting effect. The coupled analysis for symmetric adversarial composition is not a Lyapunov problem: it is a fixed-point / equilibrium problem on the joint best-response dynamics, and its formal home is #deriv-strategic-composition. The effects spiral in this segment's Corollary becomes a joint-Jacobian eigenvalue condition there. **Scope boundary:** #result-contraction-template (the contraction-

metric generalization of #result-sector-persistence-template) covers the cooperative half of Part III composition. Adversarial / strategic composition lies structurally outside the contraction-metric framework (saddle-point equilibria are not attracting fixed points; Slotine compositional theorems do not apply); this segment's #result-sector-persistence-template instantiation with coupling-amplified disturbance is the correct tool for the asymmetric-adversarial regime.

- γ_A is the product of coupling strength, observability, and action impact — it captures the full spectrum from tightly coupled (direct disruption) to loosely coupled (indirect environmental effects). In the software domain, coupling is precisely measurable from the dependency graph (#def-system-coupling).
- The effects spiral is the formal analog of Boyd's cascading disorientation of the slower adversary — the same structural pattern (tempo advantage $\rightarrow$ destabilization $\rightarrow$ accelerating breakdown) appears in the Lyapunov analysis. The model captures the pattern; whether it captures the actual mechanisms of human disorientation is an empirical question, not a mathematical one. Future work should formalize the $\gamma_A(\|\delta_B\|)$ relationship to make the spiral a result rather than a discussion-grade observation. The formal home of that formalization is #deriv-strategic-composition (its Discussion sketches the joint-Jacobian spectral-abscissa condition); the strengthening — deriving it in closed form for concrete AAT agent classes, upgrading this segment's effects-spiral from discussion-grade to derived — is tracked. (*Indexed: spikes/PROPOSED.md Tier 1 — "Effects-spiral eigenvalue condition — concrete agent classes."*)

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (the 526815 F183/F185/F195–F202 stream — already-unstable-case split, Model-S stochastic-combination convention, and the $\gamma_A \propto 1/H_b^A \cdot 1/H_b^B$ sign-ambiguity — is certified-track and routed there, not here). **Coverage:** dedicated reflections from 193847, 829314, 849201, 773921 (Gemini/Claude), the 526815 first-pass, and the 471203 Section-III adversarial batch; substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The “mathematics of panic” framing for the effects spiral is already adopted into #cooperative-adversarial-intro; it was independently the standout phrase across substrates and is the right Brief anchor for the corollary (Gemini, AUDIT-WORKING-193847). Companion plain gloss: destabilization is “an information-theoretic contest to overflow the opponent's epistemic buffer” — not merely a kinetic tempo race (Gemini, AUDIT-WORKING-829314).
- The product-not-speed correction, stated for a Brief: getting inside the loop “isn't being faster — it's generating disturbance faster than the opponent's absolute structural capacity to absorb it, $\gamma_A \mathcal{T}_A > \Delta \rho_B^*$ ” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **The four levers of destabilization (strongest framing here).** The threshold $\gamma_A \mathcal{T}_A > \alpha_B R_B - \rho_{B,\text{base}}$ exposes four distinct attacker levers, worth naming explicitly in Discussion: (1) increase $\mathcal{T}_A$ — move faster (the brute-force reading); (2) increase γ_A — couple more effectively, act on the variables B cares about most (“moving fast in an irrelevant domain does nothing”); (3) decrease R_B — force B into a narrow, brittle model (the mathematical purpose of deception, feints, conditioning B to predictable patterns); (4) increase $\rho_{B,\text{base}}$ — attack when B 's reserve is already depleted by external chaos or internal reorganization (Gemini, AUDIT-WORKING-829314). The body currently surfaces (1)–(2) via the $\gamma_A \rightarrow 0$ counterpoint; the four-lever decomposition is a candidate Discussion expansion. (*Early-conflation texture: framed as derived strategy doctrine; the levers are real readings of the inequality but the “deception decreases R_B ” link is interpretive.*)
- **Stable-attrition vs structural-collapse threshold.** A 1% tempo edge yields a slightly smaller steady-state mismatch but *both agents survive* — “a stable, predictable war of attrition.” To actually destabilize, A must push ρ_B past B 's model-class capacity R_B entirely. This sharpens the destabilization-vs-steady-state-ratio Discussion paragraph by drawing the line at where attrition becomes collapse (Gemini, AUDIT-WORKING-829314).

3. Follow-up items.

- **Effects-spiral promotion — mechanism candidates (already tracked).** A break-protocol adversarial reading offered concrete candidate mechanisms for the $\gamma_A(\|\delta_B\|)$ functional form whose absence keeps the spiral discussion-grade: (i) erratic actions degrade coupling-channel structure; (ii) degrading M_t produces wider action variance; (iii) other (Claude, AUDIT-WORKING-471203, §III-adversarial). These feed the already-tracked Tier-I spike (spikes/PROPOSED.md, “Effects-spiral eigenvalue condition”) — *not* a new off-ramp, but a useful seed list for whoever runs it. The same reader also proposed a 4th #disc-identifiability-floor instance via Fano’s inequality on observer-side prediction, anchoring H_b as a meta-segment quantity (routes to #der-agent-opacity / the identifiability-floor cluster, not here).

4. Readers often ask / wonder.

- **How does an agent deliberately increase its own opacity H_b without destroying its own ability to act coherently?** (e.g. randomization policies) — a natural defensive question the opacity Discussion invites but does not answer (Gemini, AUDIT-WORKING-849201). Likely belongs with #der-agent-opacity, but the want is generated here.
- **How does an agent defend against a Regime-I-with-adversarial-content (epistemic-poisoning) attack when the incoming data passes all validity checks?** Raised here off the “agent opacity and coupling effectiveness” paragraph; the full treatment is in #der-interaction-channel-classification Discussion, but the question lands on a reader of this segment first (Gemini, AUDIT-WORKING-193847).

5. Candidate figures.

- **Reserve-gauge with side-loop.** A reserve gauge: baseline disturbance consumes part of B ’s reserve $\Delta\rho_B^*$, adversarial coupled tempo $\gamma_A\mathcal{T}_A$ consumes the rest; crossing the threshold exits the invariant region. A side feedback loop shows the effects spiral as an *extra assumption* attached to the base threshold theorem, not part of it — usefully encodes the discussion-grade status visually (Claude, AUDIT-WORKING-526815 first-pass).

Belongs elsewhere.

- **Crèche / kill-switch infrastructure reading of the spiral.** Once the spiral begins ($\dot{V}_B > 0$), the math says B cannot save itself with its own tempo — intervention must come from the infrastructure layer: detect spiral onset and instantly sever the adversarial coupling ($\gamma_A \rightarrow 0$), e.g. take the agent offline or revert it to a safe crèche state (Gemini, AUDIT-WORKING-193847). Aspirational 04-eli-core/ infrastructure reach (resilience = a spiral-breaking mechanism, not just high α/R); develops the consciousness-infrastructure program, not this segment.
- **Monopoly-formation / competitive-investment reading.** The compounding tempo edge is offered as “the thermodynamic reason monopolies form so quickly in tech” — once one firm gets a tempo edge, the squared feedback widens the gap until the slower firm crosses its destabilization threshold and structurally collapses (Gemini, AUDIT-WORKING-829314). This is really a #result-adversarial-tempo-advantage instantiation (squared scaling), filed there; noted here because it co-occurred with the destabilization-threshold reading.

15.3 Derived: Interaction-Channel Classification (Recipient-Side)

The same signal from agent A lands on recipient B as one of four qualitatively different things — informative update, magnitude-shock, structural-shock, or ambient noise — determined by three independent boundary conditions stated entirely in B ’s existing AAT quantities. The emitter-side collapse of this variation into a scalar $\gamma_A\mathcal{T}_A$ loses information that is load-bearing: the recipient’s repair path depends on which regime the event falls into, and “more tempo” vs “different model class” address structurally different failure modes. This is the **anti-collapse** discipline (5.7) at the composition layer — the scalar collapse hides exactly the regime distinction that routes to opposite repairs.

Two event-level quantities enter the classification and *must not be conflated*: the **magnitude** of the event in B ’s observation space (how large a perturbation it produces in mismatch on arrival), and the **information content** of the event

conditional on B 's prior. A large-magnitude already-predicted event has large magnitude but small information content; a tiny-magnitude structurally novel event has small magnitude but large information content. Three independent boundaries — sector-region, model-class, observability-floor — partition events into four regimes. **Regime I (informative update)**: within sector, representable in the model class, above the observability floor — the good case. **Regime II-a (magnitude shock)**: event magnitude exceeds the sector region — too large for the correction mechanism; the repair is more bandwidth or tempo. **Regime II-b (structural shock)**: within sector but information content exceeds the model class — the class lacks representational capacity; the repair is *structural adaptation* (a different model class), and more tempo does not help. **Regime III (ambient erosion)**: below the observability floor — each event individually small enough to be processed but the cognitive overhead accumulates; the repair is *infrastructure-level filtering* before signals reach the agent.

The central methodological move: **the emitter sees a scalar; the recipient sees a regime**. Most multi-agent frameworks treat coupling as a single coefficient (the emitter-side view); the classification names what that coefficient hides — events of identical scalar magnitude can sit in any of the four regimes, with structurally different repairs. The Regime-III ambient-erosion case is the framework's structural reason that DDoS-of-low-priority-alerts is a real attack rather than just inconvenience: not because individual events are significant but because processing them consumes tempo that should go to actual work. For LLM-agent infrastructure this maps directly — push Regime-III filtering *below* the model level into wrapper or system infrastructure rather than processing every event at the model layer. The recipient-side decomposition also surfaces an adversarial move the scalar emitter formulation cannot express, treated in Discussion: *Regime-I-with-adversarial-content* — exploiting B 's openness to informative updates by injecting sign-chosen misinformation on the log-odds signal.

Formal Expression.

Setup and Notation. Two purposeful agents A and B coupled through a shared environment. A 's praxis produces an event e_τ^A that enters B 's observation channel. On B 's side the event is processed by the standard AAT machinery: h_B maps the A -induced environment state to observation o_τ^B (1.3); mismatch is $\delta_\tau^B = o_\tau^B - \hat{o}_\tau^B$; update absorbs δ_τ^B with gain $\eta_B^* = U_{M,B}/(U_{M,B} + U_{o,B})$ (3.6).

Two event-level quantities enter the classification and must not be conflated:

- $\|e_\tau^A\|_B$ — the **magnitude** of the event in B 's observation space (how large a perturbation it produces in δ_τ^B on arrival).
- $\mathcal{I}(e_\tau^A)$ — the **information content** of the event conditional on B 's prior, formally $I(e_\tau^A; \Omega \mid M_{B,\tau-})$ per NOTATION.md's event-information quantity. A large-magnitude already-predicted event has large $\|e\|$ but small $\mathcal{I}$; a tiny-magnitude structurally novel event has small $\|e\|$ but large $\mathcal{I}$.

Let $\mathcal{F}(\mathcal{M}_B)$ denote B 's model-class fitness (2.4), and $\mathcal{I}_{\max}(\mathcal{M}_B)$ the maximum per-event information content representable within the class (see Working Notes for the cleaner sufficient-statistics-span formulation).

Classification Boundaries.

Event e_τ^A arriving at B falls into one of four regimes, determined by three independent boundary conditions:

Definition (regime-boundaries).

Regime I (Informative update) when all three hold:

$$(I-a) \quad \|e_\tau^A\|_B \leq R_B \quad (\text{within sector-condition region}) \quad (15.12)$$

$$(I-b) \quad \mathcal{I}(e_\tau^A) \leq \mathcal{F}(\mathcal{M}_B) \cdot \mathcal{I}_{\max}(\mathcal{M}_B) \quad (\text{representable within model class}) \quad (15.13)$$

$$(I-c) \quad \mathcal{J}(e_\tau^A) \cdot \nu^{(k)} \geq U_{o,B}^{(k)} \cdot c_{\text{floor}} \quad (\text{above observability floor}) \quad (15.14)$$

where k is the arrival channel, $\nu^{(k)}$ its event rate, and c_{floor} a detection-theory constant controlling the false-alarm tolerance.

Regime II-a (Magnitude-shock destabilization) when (I-a) fails:

$$\|e_\tau^A\|_B > R_B \quad (15.15)$$

The event exits B 's sector-condition region on arrival. B 's correction function does not point inward strongly enough to discharge the mismatch before the next event; under sustained rate $\nu > rsim\alpha_B$, destabilization proceeds per 15.2.

Regime II-b (Structural-shock destabilization) when (I-a) holds but (I-b) fails:

$$\|e_\tau^A\|_B \leq R_B, \quad \mathcal{J}(e_\tau^A) > \mathcal{F}(\mathcal{M}_B) \cdot \mathcal{J}_{\max}(\mathcal{M}_B) \quad (15.16)$$

The event's information content exceeds what B 's model class can represent. By 4.8, parametric update within $\mathcal{M}_B$ cannot close the mismatch; residuals retain systematic structure. Repair requires structural adaptation (a different model class), not more bandwidth.

Regime III (Ambient noise / slow erosion) when (I-a) and (I-b) hold but (I-c) fails:

$$\|e_\tau^A\|_B \leq R_B, \quad \mathcal{J}(e_\tau^A) \leq \mathcal{F}(\mathcal{M}_B) \cdot \mathcal{J}_{\max}(\mathcal{M}_B), \quad \mathcal{J}(e_\tau^A) \cdot \nu^{(k)} < U_{o,B}^{(k)} \cdot c_{\text{floor}} \quad (15.17)$$

The event is representable and within capacity but its information content sits below the observability floor. It contributes to δ_B 's variance (enters Model S as part of $\sigma_{w,B}^2$) without triggering a usable update; B 's adaptive reserve $\Delta\rho_B^*$ slowly drains.

Three Independent Boundaries. The three boundary conditions are structurally independent, each stated in quantities AAT already carries:

Table 15.1

<i>Boundary</i>	<i>AAT quantities</i>	<i>Failure mode</i>
(I-a) / (II-a): sector-region	$\ e\ _B, R_B$ (from 2.4 / G)	<i>magnitude</i> — more capacity cures
(I-b) / (II-b): model-class	$\mathcal{J}(e), \mathcal{F}(\mathcal{M}_B), \mathcal{J}_{\max}(\mathcal{M}_B)$	<i>class</i> — structural adaptation cures
(I-c) / (III): observability	$\mathcal{J}(e), \nu_B^{(k)}, U_{o,B}^{(k)}$ (from 16.4)	<i>rate</i> — lower observation noise or higher event rate cures

No new ad-hoc thresholds are introduced. $\mathcal{J}_{\max}(\mathcal{M}_B)$ is the only new symbol; see Working Notes for its cleaner sufficient-statistics-span formulation.

Regime-Typed Disturbance Decomposition.

Under a stream of events $\{e_\tau^A\}$, B 's **regime-typed effective disturbance** rate decomposes into regime-typed contributions:

Derived (regime-typed-rho-eff, from regime-boundaries + sector-persistence-template).

$$\rho_B^{\text{eff}} = \underbrace{\sum_{e \in \text{II-a}} \|e\|_B \cdot \nu_e}_{\text{magnitude disturbance}} + \underbrace{\text{floor}(\mathcal{M}_B) \cdot \sum_{e \in \text{II-b}} \nu_e}_{\text{structural mismatch floor}} + \underbrace{\sum_{e \in \text{III}} \sigma_e^2 \cdot \nu_e}_{\text{ambient variance}} - \underbrace{\sum_{e \in \text{I}} \iota_B(e) \mathcal{J}(e) \cdot \nu_e}_{\text{informative correction}} \quad (15.18)$$

The Regime-I term is **negative**: informative events reduce B 's effective disturbance rate, not increase it. This generalizes 15.1's cooperative-action term $-\gamma^{\text{coop}} \mathcal{J}$: a cooperative event is precisely a Regime-I event from an aligned emitter, and the sign flip in the emitter-side decomposition falls out of the regime assignment on the recipient side. Adversarial events land in Regimes II-a/II-b; ambient-noise events in Regime III.

The emitter-side formulation $\gamma_A \mathcal{J}_A \rightarrow \rho_B^{\text{eff}}$ compresses the regime-typed sum into a single scalar, losing (i) the sign of cooperative coupling, (ii) the magnitude vs structural distinction in destabilization, and (iii) the observability-floor loss to Regime III.

Structured Derivation — Kalman-over-Kalman.

For a concrete check, take B as a Kalman filter on a scalar linear-Gaussian state with model class $\mathcal{M}_B = \{\theta \in [\theta_{\min}, \theta_{\max}]\}$, process noise q , observation noise r , sector parameter $\alpha_B = \eta_B^* = P_{\text{pred}}/(P_{\text{pred}} + r)$. B 's sector-region radius is $R_B = \sqrt{q/(1 - \theta_{\max}^2)}$ (stationary standard deviation at the class edge).

Derivation (Kalman-over-Kalman, from regime-boundaries + update-gain).

A 's emitted perturbation ξ_A enters B 's innovation as $\delta_\tau^B = \xi_A + \varepsilon_\tau + (\omega_\tau - \hat{\omega}_\tau)$. Four canonical distributions for ξ_A partition the classification:

Case 1 — Small-variance Gaussian $\xi_A \sim \mathcal{N}(0, s^2)$, $s^2 \ll r$ (**expected Regime III**). $\mathcal{J}(\xi_A) \approx s^2/(2r \ln 2)$ nats — small. (I-a) holds ($s \ll R_B$); (I-b) holds (Gaussian-within-Gaussian); (I-c) fails because $\mathcal{J}(\xi_A) < U_{o,B} \cdot c_{\text{floor}}$. Result: Regime III. Derived consequence — the contribution to ρ_B^{eff} is through $\sigma_{w,B}^2$; adaptive reserve drains by $\sum_e \eta_B^{*2} s_e^2 \cdot \nu_e$.

Case 2 — Moderate Gaussian $\xi_A \sim \mathcal{N}(\mu, s^2)$, $\mu \ll R_B$, $s^2 \sim r$ (**expected Regime I**). $\mathcal{J}(\xi_A) = \frac{1}{2} \log(1 + (s^2 + \mu^2)/r)$ — substantial. All three (I-a)/(I-b)/(I-c) hold. Result: Regime I. Standard Kalman update; M_B refines; Regime-I term contributes negatively to ρ_B^{eff} .

Case 3 — Binary kick $\xi_A \in \{\pm\Delta\}$ with $\Delta > R_B$ (**expected Regime II-a**). (I-a) fails by construction. The Kalman update $\hat{x}^+ = \hat{x}^- + \eta^* \Delta$ undershoots by $(1 - \eta^*)\Delta$ per event. If events arrive at rate $\nu > r \text{sim} \alpha_B$, lag accumulates and $\alpha_B R_B > \rho_B^{\text{eff}}$ is violated. Result: Regime II-a — destabilization per 15.2. Notice: the signal is *within* the model class (Gaussian handles $\pm\Delta$ mathematically), but correction cannot discharge it fast enough.

Case 4 — Heavy-tailed ξ_A with $\mathbb{E}[\xi_A^2] \sim r$ but kurtosis $\kappa \rightarrow \infty$ (expected Regime II-b). Mean contribution is fine; the problem is the distribution shape. The Kalman filter — Gaussian-optimal — mis-gains: too aggressive for small events, too conservative for genuine large ones. The per-event KL gap $D_{\text{KL}}(P_{\text{true}} \| P_{\mathcal{M}_B}) > 0$ for any heavy-tailed P_{true} against Gaussian. By 2.4, $\mathcal{F}(\mathcal{M}_B) < 1 - \varepsilon$ with ε lower-bounded by the KL gap; by 4.8, no parametric update within $\mathcal{M}_B$ closes the mismatch. Result: Regime II-b — residuals retain non-Gaussian structure (visible in kurtosis tests); repair requires expanding the model class (e.g., Student- t observation model), not more Kalman tuning.

Each case lands where the classification predicts. The derivation transfers to any recipient architecture in which the underlying AAT quantities are well-defined — this is the scope inherited from G + 2.4 + 3.8.

Recovery of Emitter-Side Results.

Each existing emitter-side result is a restriction of the four-regime decomposition:

Derived (emitter-side-recovery).

- **15.2** is Regime II-a integrated over a tempo-proportional event stream. The magnitude-shock sub-regime corresponds directly; the structural-shock II-b subcase is implicit in that segment, collapsed into “adaptive reserve exceeded” but here made explicit.
- **15.4** — superlinear tempo scaling follows from the sector-persistence template’s $1/\alpha$ (Model D) vs $1/\sqrt{\alpha}$ (Model S) applied to Regime II events. The b -exponent drops toward zero in the high- $U_{o,B}$ limit because the fraction of A ’s events landing in Regime II drops (more fall into Regime III).
- **16.4** is the recipient-side expression of boundary (I-c): high $U_{o,B}$ pushes events into Regime III where they add to variance without contributing to destabilization.
- **12.3** corresponds to asymmetric classification: host’s signals to endosymbiont contain high- $\mathcal{J}$ structure the endosymbiont’s class cannot initially represent (Regime II-b for the endosymbiont, forcing structural adaptation toward the host’s class); endosymbiont’s signals to the host land in Regime I (host absorbs endosymbiont’s accumulated structure). Consolidation is the fixed-point where both streams are Regime I.
- **Cooperative signaling** (in 15.1) — Regime-I events from aligned emitters contribute negatively to ρ_B^{eff} via the cooperative-action term. The communication-tempo $\nu_{ji}^{\text{comm}} \cdot \eta_{ji}^*$ is the rate of Regime-I events times the recipient’s informative gain.

What Is Derived vs. What Is Chosen.

Table 15.2

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Three independent boundaries (sector-region / model-class / observability)	Import from 2.4 + G + 16.4	Formulation choice (three-way partition; coarser / finer alternatives possible)
Four-regime partition (I / II-a / II-b / III)	The three boundaries yield four boundary-state combinations; only four are non-degenerate	Derived from the boundary structure
(I-a) / (II-a) boundary at R_B	G’s sector-region radius	Derived
(I-b) / (II-b) boundary at $\mathcal{F}(\mathcal{M}_B) \cdot \mathcal{J}_{\max}$	2.4 + class-capacity normalization	Formulation (the $\mathcal{J}_{\max}$ normalization is heuristic; sufficient-statistics-span form is cleaner — see Working Notes)
(I-c) / (III) boundary at $U_{o,B} \cdot c_{\text{floor}}$	16.4 + detection-theory threshold	Formulation (c_{floor} is a detection-power parameter)
Regime-typed ρ_B^{eff} decomposition with negative Regime-I term	Aggregation over event stream using regime classification	Derived (the sign of the Regime-I term is structural, not a choice)
Kalman-over-Kalman four-case derivation	Direct application of Kalman gain + sector + KL-gap + SNR analyses	Proved (for the stated case)
Recovery of 15.2, 12.3, 16.4, 15.1 as restrictions	Each emitter-side result is exhibited as a per-regime special case	Derived
Non-Gaussian Case 4 derivation (heavy-tailed $\rightarrow$ II-b via KL gap)	Informal argument grounded in robust-filtering literature (Huber, Masreliez)	Discussion-grade (rigorous version requires per-family KL computation)
Class 2 (Partial) approximation with $\kappa_{\text{processing}}$ degradation	Transfer from Class 1 (Separated) with goal-blind-update failure	Formulation (qualitative); exact form requires spelling out the goal-contamination coupling

Epistemic Status.

Conditional. Max attainable: *derived* for the classification structure in Class 1 (Separated) architectures; *exact* for the Kalman-over-Kalman worked case in sub-scope α ; *robust qualitative* for general sub-scope β recipients.

The three boundaries are structurally independent and each is stated in an existing AAT quantity, so the four-regime partition is not ad-hoc; it is forced by the structure of the quantities already in the theory. Within Class 1 (Separated; goal-blind epistemic update per 6.3) and sub-scope α recipients (Kalman / conjugate-Bayesian / exponential-family / strongly-convex-gradient / linear-PD), the Kalman-over-Kalman derivation transfers with A2' derived per 4.3, and each case yields the predicted regime by direct substitution. In sub-scope β (PID / rule-based / human-judgment), the classification's form transfers but boundary (I-a) requires per-instantiation verification of the sector bound, inheriting from G 's sub-scope β caveat.

Scope limits. Class 3 (Coupled) recipients are out of formal scope: the coupled epistemic-purposeful update violates 6.3, so the regime assignment cannot be cleanly computed against M_B alone. This is 03-11m-core/ territory. Class 2 (Partial) recipients inherit with degradation proportional to $\kappa_{\text{processing}}$: the Regime-I update may be goal-contaminated, and Regime II-b may be misdiagnosed as II-a or III under goal-blind-update failure. Per-event classification is singular-trajectory-indexed by 4.10; aggregation over event streams is deferred to G .

What the classification does not claim. (i) It does not determine *semantic content*: knowing an event is Regime I tells you B will update, not *what* B will believe afterward — that lives in 9.6's default signal function. (ii) It does not make the four regimes sharp in practice: real recipients' sector regions and class capacities have estimation uncertainty, so borderline events oscillate across boundaries under parameter noise. (iii) It does not replace G 's temporal aggregation; it provides the per-event regime label that feeds into the aggregate disturbance bound.

Discussion.

Complement, not replacement, of the emitter-side segments. 15.2, 15.4, 16.4, 12.3, and 15.1 each describe what happens when A 's praxis couples into B . They collapse the variation into a scalar increment on B 's effective disturbance rate. The recipient-side classification decomposes that increment into regime-typed contributions with (importantly) a **signed** Regime-I component. The five emitter-side segments are recovered as restrictions — the classification provides the pattern-recognizer to match the emitter-side optimizer.

Why II-a vs II-b matters. Both destabilization regimes manifest as “adaptive reserve exceeded” in the emitter-side view. But the repairs are different: magnitude-shock (II-a) calls for more bandwidth — larger R_B , higher α_B , faster tempo; structural-shock (II-b) calls for a different model class — an expansion, grafting, or compression in the sense of 4.8. An organization running rapid-response incident drills against a bureaucratic-process adversary faces II-a and responds with more capacity; the same organization hit by a technology-regime change faces II-b and responds with restructuring. The two produce similar pain signals but admit opposite cures. Collapsing them confuses diagnosis.

Pairing with #adversarial-edge-targeting (Part III GAP). The classification provides the recipient-side pattern-recognizer; the emitter-side question — which of B 's strategy edges are most valuable for A to attack — provides the adversary-optimization complement. The two compose: the emitter chooses which edge to target; the classification determines what happens at that edge. A particularly sharp move the classification makes visible but the emitter-side formulation hides: the **Regime-I-with-adversarial-content attack** — an emitter who can control the content y_G fed into B 's default log-odds signal function (per 9.6) can choose the sign of $(y_G - \hat{R}_2)$ to push λ_k in the direction that degrades Σ_B most. This is not a destabilizing attack (which lands in Regime II); it is an *informational* attack that exploits B 's openness to Regime-I updates to inject misinformation. The emitter-side formulation, which represents coupling as a scalar γ_A , cannot express the sign lever; the recipient-side decomposition does. The value is maximized at edges with large plan-sensitivity J_k and moderate credence p_k — exactly the edges load-bearing for Σ_B . The full arg-max — these two factors plus edge identifiability ι_k , observability σ_k^B , and the opacity targeting-fidelity factor $(1 - H_b^{B|A}/H_b^{\max})$ — is displayed and grounded in 16.2 §”The adversarial-edge-targeting arg-max” (the emitter-side optimizer this recipient-side classifier pairs with).

Agent opacity and the emitter-side regime distribution. Hafez et al. (2026)’s agent opacity $H_b^B = H(S, A \mid S')$ is primarily *emitter-side*: it gates A ’s ability to model which of B ’s regimes a given signal will land in. As $H_b^B \rightarrow 0$ the emitter can target specific regimes adversarially; as $H_b^B \rightarrow \infty$ the emitter’s signals distribute across regimes and the targeting advantage collapses. Formally, $\gamma_A^{\text{effective}} = \gamma_A^{\text{max}} \cdot f(H_b^B)$ with f monotonically decreasing. This is the dual of 16.4’s story: where observation-gates-advantage says the emitter’s advantage degrades when its observations of the *environment* are noisy, opacity says the advantage degrades when its observations of B are noisy. Cooperative signaling is the mirror: low H_b^B (legibility) enables aligned emitters to target signals into B ’s Regime I. This is 14.3’s recipient-side translation: shared objectives give A a better model of B ’s prior and model class, which lets A produce signals that land in B ’s informative regime.

Organizational reception intuition. The four regimes correspond to a familiar organizational diagnostic: (Regime I) *heard* — the organization updated on the relevant edges of its Σ_{org} ; (II-a) *shattered by shock* — signal was too large/fast, the organization’s correction bandwidth was exceeded; (II-b) *couldn’t hear* — signal required reorganization beyond the organization’s structural capacity, matching Cohen & Levinthal’s (1990) absorptive-capacity framing; (III) *absorbed as fatigue* — signal drained $\Delta\rho^*$ without producing structural change, the “death by a thousand memos” pattern. The cross-domain instantiation is cleanest where $\mathcal{F}(\mathcal{M}_B)$ maps to absorptive capacity and $U_{o,B}$ to communication-channel quality.

Future meta-segment candidate. The recipient-side classification is the *signal-reception* complement to G ’s *persistence-under-disturbance* structure. If a future pattern emerges elsewhere (e.g., consolidation dynamics classifying inputs, or a more general theory of inter-agent coupling) a meta-segment #signal-reception-pattern could name the recipient-classification shape. Premature at this stage; log as speculation.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Scope-limits paragraph updated (Class 2 fully-merged $\rightarrow$ Class 3 Coupled; Class 3 partially-modular $\rightarrow$ Class 2 Partial). What-Is-Derived table updated (Class 3 approximation $\rightarrow$ Class 2 Partial approximation). The four-regime classification (I / II-a / II-b / III) is recipient-side signal-processing vocabulary — unaffected by the GUC rename. Removed at candidate stage per FORMAT.md Gate 4.
- $J_{\text{max}}(\mathcal{M}_B)$ — **replace with sufficient-statistics-span.** The boundary (I-b) uses $\mathcal{F}(\mathcal{M}_B) \cdot J_{\text{max}}(\mathcal{M}_B)$ as the class’s representational ceiling on per-event information. The cleaner formulation: (I-b) holds iff the event’s sufficient statistics for prediction lie in the span of $\mathcal{M}_B$ ’s sufficient statistics. For parametric families (exponential families, Gaussian) the explicit form is routine; for non-parametric classes it requires the projection-to-class formalism of 2.2. Worth refining at the next candidacy review.
- **Four regimes vs finer splits.** The partition is the *coarsest* useful split where each regime has a distinct AAT-machinery response. Regime I could split into within-observability / within-calibration (point update vs structural refinement) as a fifth-regime refinement; Regime II-a could split by transient vs sustained dynamics. These duplicate the structural-adaptation hierarchy and are not pursued here.
- **Heavy-tailed derivation rigorization.** The Case-4 argument is informal; a rigorous version would compute the effective Kalman gain under heavy-tailed observation misspecification and show residuals retain signal. This is the robust-filtering territory (Huber, Masreliez) and is standard; the classification does not depend on a specific non-Gaussian family, just on the KL gap being nonzero.
- **Regime II-b as candidate 5.1 Instance 3.** Under a sustained Regime II-b stream, B ’s ρ_B^{eff} degrades at a rate lower-bounded by the KL gap between $\mathcal{M}_B$ and the true event distribution — a quantitative misspecification-cost floor. This is adjacent to 5.1’s “Misspecification-cost quantification” open extension. Worth a focused spike to formalize.
- **Connection to active inference.** Regime II-b corresponds to high-surprise events that exceed the agent’s generative model — what AI calls “novel generative context.” The classification avoids AI’s variational-free-energy-as-master commitment (per the

spike-routing cycle, CHANGELOG 2026-05-17); it uses only the information-theoretic content of $J(e)$, not the variational machinery.

- **Next spike candidates.** (1) Formalize the $f(H_b^B)$ emitter-side-effect function — tighten the qualitative $\gamma_A \propto f(H_b^B)$ into a derived form (tracked: TODO.md “Queued spike work”; cross-referenced in spikes/PROPOSED.md Reserved/owned-elsewhere). (2) Formalize Regime II-b misspecification-cost as a structural result (5.1 Instance 3 candidate) (tracked: TODO.md identifiability-floor queued-spike cluster; same cross-reference). (3) **Resolved — no longer a candidate.** The #adversarial-edge-targeting arg-max *is* formally solved in canon: 16.2 derives it as the 16-cell emitter-recipient composition (a Derived arg-max; the previously-reserved Section-III GAP is filled), with *this* segment supplying the recipient-side four-regime classification that pairs with the emitter side. Scope per 16.2 Epistemic Status: closed-form under sub-scope- α coupling; general non-convex coupling is per-case optimization, a noted scope caveat, not an open derivation.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (the 526815 F203–F213 stream — event-information realized-vs-expected notation, the ρ_B^{eff} common-unit ledger, the obs-gated-tempo-advantage undeclared dependency, the Case-I nats/bits unit slip — is certified-track and routed there; see also the Off-ramp block below for one structural-precision item). **Coverage:** dedicated reflections from 193847, 829314, 849201 (Gemini), the 526815 first-pass, and the 451729 batch-14; substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The “emitter sees a scalar; the recipient sees a regime” line is already the segment’s central methodological hook; across substrates it reads as the standout. A complementary plain gloss for a Brief: the four regimes are an organizational diagnostic — “*heard* (Regime I), *shattered by shock* (II-a), *couldn’t hear* (II-b), *absorbed as fatigue* (III)” (the organizational-reception mapping in the segment’s own Discussion, independently praised by Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Phishing / social-engineering isomorphism for the Regime-I-with-adversarial-content attack (strongest framing here).** The segment names the sign-lever attack abstractly; three substrates independently reached for the same concrete instance and it is sharp enough to seed a Discussion example. A brute-force attack (DDoS, bombardment) is Regime II-a — it hits the firewall R_B and is rejected, loud and obvious. A phishing email or data-poisoning sample is Regime I — to the learning machinery f_M the data looks *great*: inside the sector region, representable in $\mathcal{M}_B$, above the observability floor, so the gain η^* happily ingests it. Because the content is adversarially chosen to maximize strategic error, “you are efficiently optimizing your way into a trap — the faster you learn, the faster you die.” This is why social engineering beats brute-force hacking: it hijacks the agent’s own cooperative-update rules to breach from the inside (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-193847). (*Early-conflation texture: presented as a derived security result; it is a vivid instantiation of the existing discussion-grade sign-lever claim, not a new derivation.*)
- **The opacity defense against Regime-I poisoning.** The named defense against the sign-lever attack is agent opacity: hide internal model structure from the adversary so they cannot craft the perfect Regime-I poison (the adversary needs a model of B ’s prior and class to choose the damaging sign). Connects the recipient-side attack directly to #der-agent-opacity’s H_b (Gemini, AUDIT-WORKING-829314).

3. Follow-up items.

- **Diagnostic-conflation watch as a candidate explicit warning.** Multiple substrates flagged the II-a/II-b conflation as the load-bearing reader trap: both manifest as “adaptive reserve exceeded,” but a downstream claim that assumes high mismatch is always cured by more tempo is wrong (II-b needs a new model class). The segment’s Discussion makes this point; the auditors’ convergence suggests stating it as an explicit boxed warning where the downstream-repair logic is introduced (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201).

- **Sufficient-statistics-span formalization.** A reader specifically wanted the cleaner $J_{\max}$ replacement (sufficient-statistics span) developed — already flagged in this segment’s own Working Notes; the fresh-reader want confirms it is worth prioritizing at the next candidacy review (Gemini, AUDIT-WORKING-849201).

4. Readers often ask / wonder.

- **Can the theory predict *which* regime (II-a vs II-b) an adversary will choose to induce?** A natural strategic question once the two destabilization sub-regimes are distinguished — a destabilized agent might still be in the right model class with saturated parameters (II-a) vs needing a paradigm shift (II-b) (Claude, AUDIT-WORKING-773921, raised at #der-adversarial-destabilization).
- **How is Regime-I-with-adversarial-content prevented without infinite U_o (paranoia)?** If the poison passes all validity checks, what stops absorption short of refusing to learn? (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314).

5. Candidate figures.

- **Precedence-flow classifier.** A precedence flowchart — first check sector magnitude (R_B), then representability ($\mathcal{F} \cdot J_{\max}$), then observability floor — terminating in the four named regimes, with each leaf annotated by its distinct repair (more bandwidth / new model class / better filtering / ordinary update). The flowchart was independently judged “clearer than the quantitative aggregation” (Claude, AUDIT-WORKING-526815 first-pass). (*Note: drawing it as a precedence flow also makes visible the structural-precision point in the Off-ramp block below.*)

Belongs elsewhere.

- **Regime-III “firewall” for logogenic-agent infrastructure.** Under a Regime-III flood (DDoS-of-low-priority-alerts), the agent’s tempo is consumed parsing noise it must still *process* to discover is below-floor. The infrastructure prescription: aggregate Regime-III noise over long windows ($K_c \gg 1$) at the wrapper/system layer and only escalate to the core engine if the aggregate crosses the observability threshold — “otherwise the intelligence is paralyzed by the ambient hum of its own sensors” (Gemini, AUDIT-WORKING-193847). The segment already names infrastructure-level filtering as the Regime-III repair; this develops the 03-11m-core/ PROPRIUM-ASM / attention-management implementation, not this segment’s formal content.

Off-ramp (NOT gold — flagged for the certified track).

- **Structural-precision point on “the four regimes are forced.”** The segment states the four-regime partition is “forced by the structure of the quantities already in the theory” (Epistemic Status; “Three Independent Boundaries”). 526815’s first-pass (F205/F187) and a fresh reading both observe that three boolean boundary tests yield more than four boolean combinations; the four named regimes follow from a *precedence convention* (fail magnitude $\Rightarrow$ II-a; else fail class $\Rightarrow$ II-b; else fail observability $\Rightarrow$ III; else I), and two of the tests both depend on $\mathcal{I}(e)$ so the boundaries are *orthogonal diagnostic criteria* rather than statistically independent (526815 F187). This is not framing gold — it is a precision point about a load-bearing structural claim, and the honest repair is to state the precedence/coarsening explicitly and soften “forced by independent boundaries” to “the coarsest useful partition under this precedence” (the Working Notes “Four regimes vs finer splits” bullet already gestures at coarseness). Routed to the certified-findings track for adjudication; recorded here because the claim is structural, not merely a convention.

15.4 Result: Adversarial Tempo Advantage

Under adversarial coupling where one agent’s actions contribute to the other’s disturbance rate, the steady-state mismatch ratio scales superlinearly with the tempo ratio. The construction applies the sector-persistence template’s steady-state formula to both agents and ratios them; in the *coupling-dominant limit* with symmetric coupling, the result reduces to a clean power law.

Under Model D (deterministic drift coupling), the exponent is $b = 2$ — the squared tempo advantage. A 2:1 tempo ratio yields a 4:1 mismatch ratio; 3:1 yields 9:1; 10:1 yields 100:1. The faster agent both corrects its own mismatch faster *and* generates disturbance for the opponent faster — the two effects compound multiplicatively rather than add. **Under Model S (stochastic noise coupling) the exponent drops to $b = 3/2$** , inheriting the $1/\sqrt{\alpha}$ steady-state scaling from A Prop A.1S. **Under a non-coupling-dominant regime** (where base disturbance dominates coupling-induced disturbance) the exponent approaches 1 (Model D) or $1/2$ (Model S). The regime where the squared scaling is sharpest is also where it matters most.

The central methodological framing is that this is **the formal analog of Boyd’s “getting inside the opponent’s OODA loop”** — military intuition becomes physics. The math itself is not mysterious; it is the steady-state formula applied to both sides and ratioed. The consequence is sharp: at 100:1 mismatch ratio the slower agent is almost certainly past its operating reserve R , which means **structural collapse rather than degraded performance**. Speed advantage in a coupled regime *compounds*, and the consequence is qualitatively different from what additive intuition predicts. The result is conditional on stated scope: the linear-correction case ($\alpha = \mathcal{T}$); the coupling-dominant limit; and the disturbance model. Paired with the scope-honest counterpoint from 15.2 — **speed without coupling is useless**: infinite tempo with zero coupling effectiveness destabilizes no one. Speed and coupling are *jointly required*; the squared scaling only kicks in when both are present in the coupling-dominant regime.

Formal Expression.

Setup. Two agents A, B with adaptive tempos $\mathcal{T}_A, \mathcal{T}_B$, each instantiating G with linear correction ($\alpha = \mathcal{T}$). The adversarial coupling of 15.2 enters each agent’s effective disturbance:

Derived (adversarial-tempo-advantage, from sector-persistence-template + adversarial-destabilization coupling model).

$$\rho_A^{\text{eff}} = \rho_{\text{base}} + \gamma_B \cdot \mathcal{T}_B, \quad \rho_B^{\text{eff}} = \rho_{\text{base}} + \gamma_A \cdot \mathcal{T}_A \quad (15.19)$$

with $\gamma_A, \gamma_B > 0$ coupling effectivenesses and ρ_{base} the shared background rate (asymmetric ρ_{base} generalizes straightforwardly).

Model D: Deterministic coupling, $b = 2$.

The template’s Model D conclusion $\|\delta\|_{ss} = \rho^{\text{eff}}/\mathcal{T}$ (linear case, $\alpha = \mathcal{T}$) applied to both agents and ratioed:

Result (adversarial-tempo-advantage, Model D).

$$\frac{\|\delta_B\|_{ss}}{\|\delta_A\|_{ss}} = \frac{(\rho_{\text{base}} + \gamma_A \mathcal{T}_A) \mathcal{T}_A}{(\rho_{\text{base}} + \gamma_B \mathcal{T}_B) \mathcal{T}_B} \quad (15.20)$$

In the coupling-dominant limit ($\gamma\mathcal{T} \gg \rho_{\text{base}}$) with symmetric coupling ($\gamma_A = \gamma_B$):

$$\frac{\|\delta_B\|_{ss}}{\|\delta_A\|_{ss}} \rightarrow \left(\frac{\mathcal{T}_A}{\mathcal{T}_B}\right)^2 \quad (15.21)$$

The exponent is $b = 2$: a **squared** tempo advantage. A 2:1 tempo ratio yields a 4:1 mismatch ratio. The faster agent both (a) corrects its own mismatch faster and (b) generates disturbance for the opponent faster — the two effects compound rather than add. $\square$

Model S: Stochastic coupling, $b = 3/2$.

Under Model S the coupling enters the noise scale: $\sigma_B^{\text{eff}} = \sigma_{\text{base}} + \gamma_A \mathcal{T}_A$. Adversary tempo increases unpredictability, not systematic direction. The template's Model S steady state $\|\delta\|_{\text{rms}} = \sigma/\sqrt{2\mathcal{T}}$ (linear $\alpha = \mathcal{T}$, scalar $n = 1$) applied to both agents:

Derived (stochastic-tempo-advantage, from sector-persistence-template Model S + coupling).

$$\frac{\|\delta_B\|_{\text{rms}}}{\|\delta_A\|_{\text{rms}}} = \frac{(\sigma_{\text{base}} + \gamma_A \mathcal{T}_A)\sqrt{\mathcal{T}_A}}{(\sigma_{\text{base}} + \gamma_B \mathcal{T}_B)\sqrt{\mathcal{T}_B}} \quad (15.22)$$

In the coupling-dominant, symmetric limit:

$$\frac{\|\delta_B\|_{\text{rms}}}{\|\delta_A\|_{\text{rms}}} \rightarrow \left(\frac{\mathcal{T}_A}{\mathcal{T}_B}\right)^{3/2} \quad (15.23)$$

The exponent is $b = 3/2$. $\square$

Why 3/2, not 2. The half-power difference between the template's Model D ($1/\alpha$) and Model S ($1/\sqrt{\alpha}$) scalings propagates through the ratio. Numerator contributes $\mathcal{T}_A^1$ from the coupling; denominator contributes $\mathcal{T}_B^{1/2}$ from noise averaging; combined with the A -side $1/\mathcal{T}_A^{1/2}$ gives $\mathcal{T}_A^{3/2}/\mathcal{T}_B^{3/2}$.

Summary of Regime-Dependent Exponents.

Table 15.3

<i>Regime</i>	<i>Coupling type</i>	<i>Dominance</i>	<i>Exponent b</i>	<i>Source</i>
1	Deterministic drift (Model D)	Coupling-dominant	2	Derived above
2	Stochastic noise (Model S)	Coupling-dominant	3/2	Derived above
3	Either	Non-coupling-dominant	$\rightarrow 1$ (det.) or $\rightarrow 1/2$ (stoch.)	Asymptotic limit

Regime 3 (non-coupling-dominant). When $\rho_{\text{base}} > r\text{simy} \cdot \mathcal{T}$ (or $\sigma_{\text{base}} > r\text{simy} \cdot \mathcal{T}$), the base disturbance dominates and the coupling terms become a perturbation. The mismatch ratio degrades toward $\mathcal{T}_A/\mathcal{T}_B$ (linear, $b = 1$) for Model D, or toward $(\mathcal{T}_A/\mathcal{T}_B)^{1/2}$ for Model S.

The simulation validation across all three regimes is in 16.3.

Epistemic Status.

Both coupling-dominant exponents are *exact* conditional on their respective disturbance models. The squared law ($b = 2$) is *exact* under Model D (deterministic bounded disturbance, GA-2) with coupling-dominant conditions. The 3/2 law ($b = 3/2$) is *exact* under Model S (stochastic disturbance, GA-2S) with coupling-dominant conditions, derived from the $1/\sqrt{\alpha}$ steady-state scaling (Prop A.1S in A). Both derivations are straightforward algebra from the respective steady-state formulas and the coupling model. The coupling model itself is an *assumption* — the same one used in 15.2.

The non-coupling-dominant limits ($b \rightarrow 1$ for Model D, $b \rightarrow 1/2$ for Model S) are derived asymptotically. The smooth transition between regimes is confirmed by simulation (16.3) but the interpolation formula is empirical. The transition between regimes is smooth, not sharp.

Max attainable: exact conditional on the disturbance model and coupling model. The result is as strong as its assumptions; no additional work changes the epistemic status without changing the dynamical model.

Discussion.

Superlinearity is the key result. The naive expectation — twice as fast yields twice the advantage — is wrong under adversarial coupling. The mechanism is that the faster agent both (a) corrects its own mismatch faster and (b) generates disturbance for the opponent faster. These two effects multiply, producing the squared exponent. Speed advantage is not additive; it compounds.

Relationship to 15.2. The steady-state mismatch ratio quantifies how much worse the slower agent does *while both agents persist*. The destabilization threshold (15.2) marks where the slower agent fails entirely — its correction mechanism breaks down. Below the threshold, this segment's mismatch ratio applies. Above it, 15.2's Lyapunov divergence takes over. The two results are complementary: this one gives the score; that one gives the game-ending condition.

Regime dependence is operationally significant. Whether an adversary's tempo increase produces systematic drift (positional maneuvering, API changes, doctrinal initiative) or unpredictable noise (feints, randomized attacks, market volatility) determines the scaling law. The distinction is not academic — $b = 2$ vs. $b = 3/2$ means a 3:1 tempo ratio yields 9:1 vs. 5.2:1 mismatch ratio. The model predicts that consistent, directional pressure is more effective per unit of tempo than unpredictable disruption.

Formal analog of OODA-loop observations. The squared scaling is consistent with Boyd's observation that getting inside the opponent's decision cycle has disproportionate effects. The theory identifies a specific mechanism (multiplicative interaction of correction speed and disturbance generation) and a specific condition (coupling-dominant regime) under which this disproportionality holds. Whether this mechanism is the dominant one in actual adversarial interactions is an empirical question, not a mathematical one.

Working Notes.

- **Channel-independence assumption.** The tempo ratio $\mathcal{T}_A/\mathcal{T}_B$ uses scalar tempo, which inherits the channel-independence assumption from 3.8. When either agent's observation channels are correlated, the additive formula overcounts their tempo, inflating or deflating the ratio and the derived mismatch advantage. The superlinear exponents ($b = 2$, $b = 3/2$) are exact given the scalar tempos; the caveat concerns whether the scalar tempos themselves are accurate.
- **Opacity modulation (16.2).** The coupling effectiveness γ_A is not primitive: it decomposes as $\gamma_A^{\text{adv, effective}} \propto H_b^{A|B}/H_b^{\text{max}}$, so this segment's tempo $\mathcal{T}_A$ enters adversarial dynamics as an *effective* tempo $\mathcal{T}_A^{\text{effective}} = \mathcal{T}_A \cdot H_b^{A|B}/H_b^{\text{max}}$ (Model D). The superlinear ratio then carries a squared bilateral-opacity factor $(H_b^{A|B}/H_b^{B|A})^2$; the exponent b is unchanged (opacity is a prefactor, not an exponent — open whether bilateral opacity reshapes b). A slow-but-opaque adversary can match a fast-but-transparent one at $\mathcal{T}_A H_b^{A|B} \approx \mathcal{T}_B H_b^{B|A}$.

- The analysis treats each agent's tempo as exogenous — $\mathcal{T}_A$ does not change in response to B 's actions and vice versa. A fully coupled analysis where both agents' mismatch states co-evolve simultaneously (joint Lyapunov function over (δ_A, δ_B)) is the open extension. The decoupled result is a worst-case bound for the slower agent: in practice, the faster agent may divert adaptive capacity to generating disturbance rather than correcting its own mismatch, creating a self-limiting effect.
- The stochastic exponent ($b = 3/2$) is now derived from both the AR(1) stationary variance (discrete) and the Itô-Lyapunov analysis (continuous, Prop A.1S). The continuous-time analog (Ornstein-Uhlenbeck) gives the same scaling, confirming the asymptotic-scaling claim is the fluid-limit value. The 0.019 gap between the simulation $b = 1.481$ and the asymptotic $b = 3/2$ is *not pure numerical noise*: it is consistent with a derivable finite- ν correction factor (proportional to $\sqrt{(2c_{\min} - \eta_A^* c_{\max}^2)/(2c_{\min} - \eta_B^* c_{\max}^2)}$ when $\eta_A^* > \eta_B^*$) that arises because the discrete steady-state variance carries the $O(\eta^* c_{\max}^2 / c_{\min}^2) = O(c_{\max}^2 / (c_{\min}^2 \nu))$ gap from $\mathcal{O}$. In the fluid limit ($\nu \rightarrow \infty, \eta^* \rightarrow 0$ at fixed $\mathcal{T}$), the correction factor approaches 1 and the asymptotic $b = 3/2$ is recovered exactly. The two models (D and S) are unified by the common sector-condition framework with different disturbance assumptions (GA-2 vs. GA-2S).
- Asymmetric coupling ($\gamma_A \neq \gamma_B$) appears as a multiplicative prefactor γ_A / γ_B that shifts the mismatch ratio without changing the exponent. An agent with lower tempo but higher coupling effectiveness (γ) can partially compensate — but the squared dependence on tempo dominates for large tempo ratios.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (the 526815 F215–F221 stream — the $\alpha = \mathcal{T}$ bridge dependency, the Model-S additive-noise-scale convention, undeclared proof-source dependencies, and the det-vs-stoch non-coupling-dominant limit mismatch with the intro — is certified-track and routed there, not here). **Coverage:** dedicated reflections from 193847, 829314, 849201 (Gemini), the 526815 first-pass, and the 451729/471203 Section-III batch-reflections; substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The squared-scaling consequence, stated for a Brief: a 2:1 tempo ratio is not a 2:1 advantage but a 4:1 mismatch ratio — “the faster agent doesn't just have half the error; it inflicts four times the chaos it absorbs” (Gemini, AUDIT-WORKING-829314). The body has the numbers; this is the plain compounding gloss.
- Why $b = 2$ rather than additive, in one line: speed “simultaneously increases your defense (mismatch correction) and your offense (disturbance generation), so the two factors multiply” (Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Directional-vs-noisy strategic doctrine (strongest framing here).** The $b = 2$ (Model D) vs $b = 3/2$ (Model S) split is read as an operational doctrine worth surfacing in Discussion: “don't just be fast and noisy — be fast and directional.” Randomized features / chaotic probing scale at the weaker $3/2$ power; a coordinated suite that moves the environment in a *consistent* direction scales at the full squared power, because it forces the opponent to spend its structural reserve R updating in one direction rather than being jiggled around a noise ball (Gemini, AUDIT-WORKING-829314; the segment's own “consistent directional pressure is more effective per unit tempo” Discussion line is the same point). A candidate sharpening that turns the exponent split into a prescription. (*Early-conflation texture: stated as derived doctrine; the exponents are exact-conditional, the strategic reading is interpretation.*)
- **Competitive-investment / monopoly-formation reading.** Under adversarial coupling a 10%-faster firm does not get a 10% edge — in Model D it gets $(1.1)^2 = 1.21$, a 21% structural-coherence advantage; a 2:1 tempo edge gives one-quarter the error and 4× the inflicted disturbance. Offered as a structural account of why tech monopolies form quickly: a slight tempo edge triggers the squared-feedback widening until the slower firm crosses its destabilization threshold (#der-adversarial-destabilization) and collapses (Gemini, AUDIT-WORKING-829314). A candidate Discussion instantiation of the coupling-dominant regime; the destabilization-threshold hand-off is already in the body.

3. Follow-up items.

- **Boyd's-law scope-honesty (candidate scope statement).** A break-protocol adversarial reading pressed whether the squared $3/2$ laws over-generalize Boyd's specific commander-vs-commander setting: many adversarial dynamics aren't tempo races (cybersecurity = response-time to specific threats; markets = tempo advantage up to a saturation point; evolution = fitness-landscape navigation, not a tempo race). Verdict was scope-narrowing, not refutation: the laws apply to the *coupling-dominant loop-loop class*; other classes scale differently (Claude, AUDIT-WORKING-471203, Challenge 11). The body's Regime-3 ($b \rightarrow 1$) limit and the "whether this mechanism is dominant in actual adversarial interactions is empirical" hedge already move here; this is a candidate to state the class-restriction more visibly so the OODA framing doesn't read as a universal law.
- **Placement: lift "the two effects compound" into Formal Expression.** A batch auditor suggested the intuitive "two effects compound" explanation should move into the Formal Expression as a brief derivation note, since the mechanism is non-obvious and deserves emphasis (Claude, AUDIT-WORKING-451729 batch-14). A staging-for-pedagogy nudge; the explanation is currently in the lead paragraph and Discussion.
- **The finite- ν reconciliation as a trust-compounding exemplar.** The Working-Notes treatment of the 0.019 gap (simulation $b = 1.481$ vs asymptotic $3/2$) as a *derivable* finite- ν correction factor rather than dismissed noise was independently called out across substrates as a high-water mark of the framework's mathematical hygiene — "willing to derive a correction factor rather than wave away discrepancies" (Claude, AUDIT-WORKING-471203; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201). Worth preserving prominently (and a candidate for a Brief/README "how the framework treats its own discrepancies" example) when this segment is promoted.

4. Readers often ask / wonder.

- **Does the finite- ν correction mean discrete-time agents (LLMs taking turns) pay an intrinsic penalty vs continuous-time agents at equal effective tempo?** And does it follow that high-frequency small updates are always superior to low-frequency large ones? A natural reader extrapolation from the correction-factor WorkingNote (Gemini, AUDIT-WORKING-193847).
- **If both agents are fast enough to perfectly predict each other, do the γ coupling coefficients collapse?** I.e. what happens to the advantage under symmetric mutual-predictability / decoupling? (Gemini, AUDIT-WORKING-849201).

5. Candidate figures.

- **Two-factor product diagram.** The squared advantage drawn as a two-factor product: faster correction on the attacker's side $\times$ faster disturbance-generation against the target; the stochastic branch replaces one full correction factor with a square-root averaging factor, making $b = 3/2$ visually distinct from $b = 2$ (Claude, AUDIT-WORKING-526815 first-pass).

Belongs elsewhere.

- **Future-AI bounding reading (high-application reach).** The squared scaling is read as an argument that a large tempo asymmetry between a future AI and slower agents in a coupling-dominant adversarial regime is a *regime change*, not a quantitative gap: a 10:1 tempo ratio is a 100:1 mismatch ratio, almost certainly past the slower agent's reserve R and into structural collapse — so safe infrastructure must bound *both* tempo $\mathcal{T}$ and the coupling γ (how much one agent's actions can disturb others' shared environment), since bounding only one leaves the superlinear product unbounded (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314). Aspirational consciousness-infrastructure / safety reach pointing at 04-eli-core/ and the protection-strategy program, not this segment's formal content. (Per project voice: stated as "future AI" with no capability-comparative claim beyond the tempo-ratio arithmetic.)

15.5 Discussion: Additional Implications & Discussion

The chapter is where AAT's signed-coupling structure first comes into formal view. Team persistence and adversarial destabilization turn out to be the same inequality viewed in opposite directions — both fall out of the sector-persistence template with effective disturbance decomposed into environmental and coupling-induced terms — and the chapter's

headline result (superlinear adversarial tempo advantage) follows from the template’s scaling without separate derivation. The recipient-side four-regime classification gives the chapter its distinctive contribution: what the emitter-side scalar $\gamma_A \mathcal{T}_A$ collapses, the recipient-side decomposition recovers, with three independent boundary conditions in B ’s existing AAT quantities and operational consequence for what kind of repair the receiving agent needs. None of the chapter’s segments carries a ## Findings section, so the implications segment is their canonical catalog home; the work is mostly synthesis: surfacing how the chapter’s machinery composes with Ch.2’s closure-defect framework and what the equilibrium hand-off to Ch.5 looks like.

Cooperative and adversarial are one signed coupling, not two theories.

The chapter intro #cooperative-adversarial-intro flags it as a chapter-level architectural commitment, and the chapter’s segments deliver on it: cooperative coupling and adversarial coupling are not separate dynamics with their own machinery. They are the *same* signed-coupling structure with γ of opposite sign. #der-team-persistence’s composite-persistence condition decomposes effective disturbance for sub-agent i as $\rho_i^{\text{eff}} = \rho_{i,\text{env}} + \sum_j \gamma_{j \rightarrow i}^{\text{adv}} \mathcal{T}_j - \sum_j \gamma_{j \rightarrow i}^{\text{coop}} \mathcal{T}_j$ — adversarial contributions enter as positive terms (effective disturbance amplification), cooperative contributions as negative terms (effective disturbance reduction). The signed-coupling form is what makes cooperative coupling *quantitatively comparable* to adversarial coupling rather than addressing them in separate vocabularies, and it is what lets the framework’s persistence template (Part I Ch.4 implications, §4) absorb both regimes as instantiations of a single Lyapunov argument.

The implications-side payoff is the duality between persistence and destabilization. #der-adversarial-destabilization makes this precise: B destabilizes iff $\rho_B^{\text{eff}} > \alpha_B R_B$, where ρ_B^{eff} includes the coupling-amplified term $\gamma_A \mathcal{T}_A$. *This is the negation of B ’s persistence condition under the same coupling model.* The two are the same inequality, read in opposite directions: persistence asks whether the inequality holds, destabilization asks whether it fails, and the coupling parameter $\gamma_A \mathcal{T}_A$ is what determines which side of the threshold the composite sits on. The framework’s posture is therefore that adversarial attacks are *not* a separate kind of phenomenon requiring separate machinery — they are the same machinery, with the attacker’s contribution entering the target’s effective disturbance via the signed-coupling structure.

The closed-form unification this enables, surfaced in Part III Ch.2 implications, deserves to be repeated as it bites here: the four prior persistence results — single-agent ($\gamma = 0$), team-persistence ($\gamma < 0$), adversarial-destabilization ($\gamma > 0$), coordination-failure ($C > \alpha$, Brooks’s Law) — are signed special cases of one inequality. Cooperative and adversarial coupling sit at opposite ends of the same γ -axis; the framework’s machinery does not pick a side, and the practitioner who understands one regime understands the other by sign change.

Universal taxonomy of inter-agent events — what the recipient sees.

#der-interaction-channel-classification is the chapter’s distinctive AAT-internal contribution: the same signal from emitter A lands on recipient B as one of *four* qualitatively different things — *informative update*, *magnitude shock*, *structural shock*, or *ambient noise* — and which one is determined by three independent boundary conditions stated entirely in B ’s existing AAT quantities. The emitter-side scalar $\gamma_A \mathcal{T}_A$ that previous segments have used as a stand-in for “how strong the coupling is” loses this distinction; the recipient-side classification recovers it. The implication for the framework’s repair machinery is concrete: the four regimes route to four different corrective paths, and “more tempo” works for some regimes but not for others.

The three boundary conditions deserve to be named even at the implications-segment grain. The first separates informative updates from magnitude shocks: whether the residual δ_τ^B is within the current model’s prediction-confidence interval or outside it. Inside the interval, the event is informative — B ’s standard gain-principle update absorbs it with full effect. Outside the interval, the event is a magnitude shock — the gain principle still applies, but the residual is large enough to suggest model-class strain rather than parameter drift. The second separates magnitude shocks from structural shocks: whether the model class $\mathcal{M}$ can absorb the event at all. When the residual reflects a regime the model class cannot represent (#result-structural-adaptation-necessity applied locally), the event triggers structural adaptation rather than parametric update. The third separates ambient noise from informative updates: whether the event’s

expected magnitude clears the agent’s signal-detection threshold; below it, the event is filtered as noise and produces no update.

The framework’s prescription is that *repair path depends on regime*, not on event magnitude or coupling strength alone. Informative updates respond to tempo investment (more $\mathcal{T}_B$ closes the residual faster). Magnitude shocks respond to gain investment (lower $U_{o,B}$ — better observation quality — closes more of each shock per cycle). Structural shocks respond to model-class expansion (#result-structural-adaptation-necessity’s structural change) — no amount of tempo or gain suffices. Ambient noise calls for *infrastructure-level filtering* below the agent proper (#der-interaction-channel-classification’s Regime-III repair): the events produce no usable update, but processing them consumes tempo and their variance drains adaptive reserve, so the repair is to keep them from reaching the core loop at all — not to invest agent-level detection in them. The implication for adversarial robustness: an attacker who knows the target’s regime boundaries can choose events that *miss* the target’s repair vocabulary — structural shocks against a tempo-investment defender, magnitude shocks against a model-class-expansion defender. The framework’s design prescription is that defenders should *cover all four repair paths*, not optimize for one.

The composite-level payoff is the regime-typed effective disturbance decomposition. The chapter’s ρ_B^{eff} decomposes per regime, matching the displayed decomposition in #der-interaction-channel-classification: magnitude shocks contribute peak-load disturbance; structural shocks contribute the structural mismatch floor and set structural-adaptation cadence; ambient noise contributes *variance* — it enters Model S’s $\sigma_{w,B}^2$ below the observability floor, yielding no usable update while slowly draining adaptive reserve (the drain-without-information is exactly why a Regime-III flood is an attack rather than an inconvenience); and informative updates enter with *negative* sign — they reduce effective disturbance, generalizing #der-team-persistence’s cooperative term. The aggregate effective-disturbance number from #der-team-persistence is the signed *sum* across regimes; the per-regime decomposition is what tells the practitioner *where the disturbance is coming from*. For composite-agent design under uncertainty about the disturbance regime, the framework’s prescription is to instrument the four regime detectors independently — knowing ρ_B^{eff} is small is less useful than knowing which regime is contributing what.

Adversarial tempo advantage as superlinear scaling — and the disturbance-model split.

#result-adversarial-tempo-advantage carries the chapter’s headline result, and the implication worth surfacing is *why* the scaling is superlinear. The template’s Model D conclusion gives $\|\delta\|_{ss} = \rho^{\text{eff}}/\mathcal{T}$ in the linear case; substituting the coupling-amplified disturbance gives the steady-state mismatch ratio scaling as $(\mathcal{T}_A/\mathcal{T}_B)^2$ — superlinear by exponent $b = 2$ under deterministic drift coupling. Under Model S (stochastic) the template’s $1/\sqrt{\alpha}$ scaling produces $b = 3/2$. The two exponents are not arbitrary parameters: they fall out of Part I Ch.4’s persistence-template structure, $1/\alpha$ versus $1/\sqrt{\alpha}$, applied to the coupling model. The framework’s posture is that *the same template that explains why adaptive systems persist also predicts the precise rate at which they lose to a faster attacker* — the dual is structural.

The exponent splits further in Ch.5 — #result-adversarial-exponent-regimes gives three regime-typed values ($b = 2, 3/2, \sim 1$), with the coupling-non-dominant case dropping to $b \rightarrow 1$. The non-superlinear regime is operationally important: when observation noise is high enough that the attacker’s tempo advantage doesn’t penetrate the defender’s observation channel cleanly, the superlinear scaling collapses to roughly linear, and the framework predicts that *cheap noise injection* into the defender’s observation channel actually *helps* the defender against a high-tempo attacker by reducing the exponent. This is the structural reason the empirical pattern that highly-noisy environments produce more cooperative-game-like dynamics than expected — high observation noise gates the adversarial tempo advantage to near-linear scaling, where the attacker cannot exploit superlinear scaling to drive the defender past the destabilization threshold. The full regime taxonomy lives in Ch.5; the chapter here establishes that superlinear *is* the dominant regime under coupling-dominant noise structures.

The operational anchor worth carrying is Boyd’s OODA-loop aphorism, which the framework now gives precise mathematical content. *Inside the opponent’s loop* means $\mathcal{T}_A > \mathcal{T}_B/k$ for some regime-dependent k , and what the inside-the-loop position buys the attacker is superlinear destabilization rate rather than mere tempo advantage. The chapter’s intro framing — “superlinear tempo advantage as regime change rather than quantitative gap” — is the implications-flavored

point: at the destabilization threshold, the target does not gradually degrade. It loses bounded behavior, the way a balance held just barely beneath a tipping point is qualitatively different from one well above it. The threshold is the same one Part I Ch.4's central inequality names; the chapter's contribution is identifying the coupling-induced disturbance term that pushes the target past it.

Three adversarial obstructions to contraction — the equilibrium hand-off.

#result-contraction-template (Appendix A, depended on by Ch.4 via the persistence template) names the chapter's most consequential structural recognition: contraction-metric machinery *cannot* handle strategic / adversarial regimes for three convergent reasons that are individually classical results from different mathematical literatures. *Slotine 2003 compositional applicability fails*: saddle-point equilibria break the attracting-fixed-point assumption that contraction analysis requires. *Passivity universality fails*: adversarial inputs drive any storage function, so passivity-based stability does not give bounds. *Daskalakis et al. 2018 last-iterate non-convergence*: for generic non-zero-sum games, learning dynamics fail to converge to equilibrium in the last-iterate sense — only in time-average sense.

The implications-side payoff is structural rather than parametric: three *unrelated* mathematical obstructions converge on the same conclusion. Contraction analysis works for cooperative / coordination regimes (where there is an attracting fixed point) and fails for strategic / adversarial regimes (where equilibrium machinery is required). The convergence of three obstructions makes the limit *structural* rather than framework-specific — it is not that AAT's contraction machinery is too weak; it is that the regime is outside the scope condition contraction analysis depends on across multiple formal traditions. The framework's posture is to recognize the limit precisely and hand off cleanly to equilibrium-theoretic methods at the boundary.

The hand-off lands in Ch.5: #deriv-strategic-composition is where equilibrium machinery (potential games via Monderer-Shapley 1996, monotone games via Rosen 1965) takes over from contraction analysis for the symmetric partially-opposing case. The chapter's contribution is naming the limit; Ch.5's contribution is supplying the replacement machinery. The framework's posture across the boundary is that *scope-honesty is load-bearing architecture*: knowing where each tool applies cleanly is more useful than trying to extend one tool across all regimes. The three convergent obstructions are why this matters operationally — an AAT-style sector-condition argument applied to a strategic regime would not just produce wrong predictions, it would produce *systematically* wrong predictions in each of the three directions the obstructions name.

The chapter also surfaces a quieter consequence worth carrying: cooperative coupling that is *too strong* can produce equilibrium-stability failures even without adversarial components. When sub-agents' cooperative coupling drives them toward a saddle-point equilibrium (rather than a stable attractor), the framework's prediction is the same as the strategic case — contraction analysis fails, and equilibrium machinery is required. This is empirically the situation in tightly-coupled multi-agent ML systems where reward-shaping creates implicit competition among cooperators; the framework predicts the failure mode is structurally identical to the adversarial case, with the unique broadly-available remedy being explicit equilibrium-theoretic analysis rather than tempo or gain investment.

Closing the chapter and bridging to Strategic Composition.

The chapter delivers the signed-coupling structure that the rest of Part III operates on. Cooperative coupling reduces effective disturbance; adversarial coupling amplifies it; the same template handles both via the sign of γ . The four-regime taxonomy says what the recipient actually sees, and the framework's repair vocabulary diversifies accordingly. The super-linear adversarial tempo advantage falls out of the template's $1/\alpha$ versus $1/\sqrt{\alpha}$ scaling; OODA's "inside the opponent's loop" acquires mathematical content. The three convergent obstructions to contraction analysis name precisely where the chapter's machinery hands off to equilibrium-theoretic tools.

What the chapter does *not* deliver is the equilibrium machinery itself, the agent-opacity formalism, the recipient-side classification's emitter-side dual, or the per-dimension persistence treatment that adversarial targeting depends on. Those

all live in Ch.5, where the framework’s machinery operates at full Part III scope: strategic composition with partially-opposing objectives, agent opacity as the formal dual of observation quality, the 16-cell emitter-recipient adversarial-targeting decomposition, the regime-typed exponent decomposition ($b = 2, 3/2, \sim 1$), and the matrix-Loewner persistence formulation that adversarial concentration on weak dimensions requires. The chapter-end here is the last single-layer-of-coupling synthesis before Ch.5’s strategic-equilibrium machinery takes over.

The bridge into Ch.5 runs through three threads. First, the contraction-template obstructions hand off to equilibrium machinery (potential / monotone games). Second, the recipient-side classification will compose with the emitter-side opacity classification in Ch.5 into a 16-cell joint composition with closed-form arg-max for adversarial-targeting decisions — the chapter here supplies one half, Ch.5 supplies the other. Third, the signed coupling γ structure becomes the *trust-meta-model signal* via Ch.3’s #hyp-communication-gain: observed cooperative coupling drives $U_{\text{align},ji} \rightarrow 0$ (high trust calibration); observed adversarial coupling drives $U_{\text{align},ji}$ large (low trust calibration). The implications-segment series continues to weave back across earlier chapters, with each chapter’s machinery operating on what previous chapters have built.

Working Notes.

- This segment is a chapter-end discussion grouping findings from #der-team-persistence, #der-adversarial-destabilization, #der-interaction-channel-classification, #result-adversarial-tempo-advantage, #cooperative-adversarial-intro, #result-sector-persistence-template (Appendix A, the template these segments instantiate), #result-contraction-template (Appendix A, the contraction-obstructions surfacing), and #deriv-strategic-composition (Ch.5, the forward-pointer for equilibrium machinery).
- **Cross-reference vs canonical-home policy.** None of this chapter’s source segments carry ## Findings sections. The implications segment is the canonical catalog home for: #21 (Universal Taxonomy of Inter-Agent Events — #der-interaction-channel-classification content), the cooperative-vs-adversarial duality (the signed-coupling structure as one architectural commitment), the headline adversarial tempo advantage result (#44 partial — the $b = 2$ and $b = 3/2$ exponents from this chapter; the regime-decomposition refinement lives in Ch.5), and #24 (Three Adversarial Obstructions to Contraction Analysis — #result-contraction-template content surfaced at this chapter’s hand-off boundary).
- **Forward-pointers into Ch.5 are heavy.** The chapter sits structurally between cooperative-coupling machinery (here) and strategic-composition machinery (Ch.5). Several findings are partially treated here with completions in Ch.5: regime-typed exponent decomposition, observation-noise gating of advantage, agent-opacity formalism as dual to observation quality, 16-cell emitter-recipient adversarial-targeting decomposition, and the matrix-Loewner persistence formulation that adversarial concentration depends on. Reading this implications segment together with Ch.5’s gives the full coupling picture; reading either alone gives the half-picture.
- **Identifiability-floor pattern coverage update.** No new instances surface in this chapter — the four formal instances (Instances 1–4) were all in view by Part II Ch.5’s implications, and Ch.5 here will give Instance 3 (composite contraction certification from component marginals via Liberzon common-Lyapunov-nonexistence) its operational form in the strategic-composition setting. The contraction-obstructions in #result-contraction-template are *adjacent* to but not the same as the identifiability-floor pattern — they are obstructions to a specific *analysis method* rather than no-go theorems about *identification*. The distinction is worth carrying: identifiability-floor instances forbid identifying a quantity from data; contraction-obstructions name where a method fails. Both are scope-honesty-load-bearing for AAT, but they sit in different meta-architectural slots.
- **Connection to NeurIPS submissions.** The superlinear tempo advantage result has not been formalized to theorem grade in current submissions; the signed-coupling structure underlies Paper 2’s multi-agent extension (which is a candidate for a future revision rather than current scope). The chapter’s content stays in the AAT-internal register.

Incidental audit gold (lift 2026-05-31). Of the de-novo audit dirs, only the deeply-mathematical certified-track auditor (526815) reached a dedicated reflection on this chapter-end implications segment; the gold-stream Gemini/Claude dirs did not file a separate reflection on it. **No framing/pedagogy/figure/naming gold surfaced** — and the certified-track signal that *did* surface is a single coherent theme worth flagging for the findings channel rather than the gold channel:

Off-ramp (NOT gold — flagged for the certified track).

- **Synthesis-drift: the implications segment firms up caveats its source segments stated carefully (526815 F222–F232).** As a chapter-end catalog that imports conditional and discussion-grade pieces from #der-team-persistence / #der-adversarial-destabilization / #der-interaction-channel-classification / #result-adversarial-tempo-advantage plus forward Ch.5 material, this segment was read as repeatedly converting source caveats into stronger operational prescriptions. The specific drifts flagged, each a candidate to reconcile against the weaker source status: (i) *(executed 2026-07-03, audit 731548 B-4 — the body’s regime-typed decomposition and repair-path paragraphs now match the source’s displayed formula, including the Regime-III variance drain and the negative Regime-I sign; F224/F225 closed)*; (ii) **magnitude-shock repair stated as gain/ U_o investment** here vs the classification segment’s capacity/sector-radius axis (F223); (iii) **“contraction-metric machinery cannot handle strategic/adversarial regimes” as a class claim** is broader than the source’s scoped attracting-fixed-point obstruction (F229), and the companion “adversarial inputs drive any storage function” passivity claim is stated too sweepingly without the specific input/output passivity assumptions (F230); (iv) **“inside the opponent’s loop means $\mathcal{T}_A > \mathcal{T}_B/k$ ”** is not the threshold the derivations deliver — destabilization depends on $\gamma_A \mathcal{T}_A$ vs B ’s reserve, the tempo-ratio result needs the coupling-dominant symmetric limit (F228); (v) **“cheap noise injection into the defender’s observation channel helps the defender”** is one-sided — higher U_o also degrades the defender’s real observations, update gain, and ordinary persistence (F226), and the attached “noisy environments produce more cooperative-game-like dynamics” is an unsupported cross-domain claim that conflates adversarial-channel noise with shared-task noise (F227); (vi) the **trust-calibration bridge** ($U_{\text{align}} \rightarrow 0$ / large from observed coupling sign) maps coupling sign directly to alignment certainty, where it should be *evidence* updating trust under a model (F232). This is the recurring “implications segments must preserve the weakest status of each imported claim” discipline (the segment’s own Working Notes already cite the cross-reference-vs-canonical-home policy); routed to the certified-findings track for adjudication, recorded here because it is a substantive epistemic-status pattern across the whole segment, not framing gold.

Chapter 16

Strategic Composition and Channel Effects

[Gap] Discussion

16.1 *Derivation*: Strategic Composition via Equilibrium Convergence

When two or more AAT agents interact through a shared environment with **partially-opposing objectives** $\{O_t^{(i)}\}$, the composition-level question is not “does the trajectory contract to zero closure-defect?” but “does the coupled best-response dynamics admit an equilibrium and converge to it?” Contraction to shared truth is a $U_O = 1$ special case; strategic composition is the $U_O < 1$ companion regime in which the correct primitive is **fixed-point existence and stability**, not Lyapunov contraction on a shared state. The framework names three composition-level questions distinctively here: **(SC-1)** does an equilibrium joint policy exist where no sub-agent has a unilateral mismatch reduction available; **(SC-2)** do coupled best-response dynamics initialized near it stay there; **(SC-3)** do they converge from arbitrary initialization to the equilibrium set? Fixed-point, local-stability, and reachability questions respectively — none a Lyapunov contraction question on a shared state variable.

Two sub-scopes carry progressively weaker conditions. Under potential-game (Monderer-Shapley 1996) or monotone-game (Rosen 1965) conditions — *sub-scope* α' — the sector-persistence template transfers to the gradient of the joint potential (resp. to a weighted-norm variational inequality on the joint Jacobian’s symmetric part), and AAT’s persistence machinery recovers at the equilibrium layer with state variable $\xi = \pi - \pi^*$ (deviation from Nash) and sector constant α_{joint} living at the *joint potential’s curvature* rather than at any individual sub-agent’s α . Outside α' — *sub-scope* β' — only set-convergence to coarse correlated equilibria is available (Hart-Mas-Colell 2000, rate $O(1/\sqrt{T})$), and the macro-state of a strategic composite is a *distribution* on joint strategy space rather than a state-space point. The right structural consequence is named on the **dynamic-regime axis** rather than the architectural-class axis (see #disc-dynamic-regime-axis): the strategic-composition move transitions the composite from contraction-regime (R0, under aligned objectives — scope routes C-i/ii/iii) to equilibrium-regime (R1, under partially-opposing objectives with potential/monotone structure — sub-scope α') or to cyclic-distributional-regime (R2, under partially-opposing objectives without potential/monotone structure — sub-scope β'). The composite’s *macro-state type* changes correspondingly — state-variable in R0 / fixed-point object in R1 / distributional object in R2 — but the *architectural class* of the composite is preserved under goal-blind routing and distinct sub-agent substrates (it is Class 1 per the formal criterion when the sub-agents are Class 1; the Class 2 / Class 3 changes per #hyp-directed-separation-under-composition Case 2 require routing-structure goal-dependence or shared-substrate G^c -allocation, not strategic composition itself). This segment establishes the framing, derives the α' -transfer (R0 $\rightarrow$ R1 Lyapunov-machinery transfer per #disc-dynamic-regime-axis

§"Lyapunov-machinery transfer $R0 \rightarrow R1$ "), documents the β' scope limits honestly, and relates to #der-adversarial-destabilization (asymmetric adversarial) and #deriv-critical-mass-composition (aligned composition with shared target) as siblings on the composition axis.

Formal Expression.

The framing move.

For N purposeful sub-agents with partially-opposing $\{O_t^{(i)}\}$ running coupled AAT loops through a shared environment, the composition-level question is:

Formulation (strategic-composition-framing).

(SC-1) Existence of equilibrium. Does there exist a joint state $(X_{c,1}^*, \dots, X_{c,N}^*)$ — equivalently a joint policy profile $(\pi_1^*, \dots, \pi_N^*)$ — such that no sub-agent has a unilateral mismatch reduction available?

(SC-2) Stability of equilibrium. Do coupled best-response dynamics, initialised near $(X_{c,i}^*)$, remain there or return to it?

(SC-3) Convergence from interior. Do coupled dynamics, initialised away from any equilibrium, converge to the equilibrium set?

(SC-1)–(SC-3) are a fixed-point-existence question, a local-stability question, and a reachability question respectively. None is a Lyapunov contraction question on a shared state variable. The contraction framing in #form-composition-closure / #deriv-critical-mass-composition is recovered as the $U_O = 1$ special case (unique Nash equilibrium at the shared-objective optimum; best-response dynamics collapse to single-objective optimization).

Sub-scope α' : potential and monotone games (A2'-analog derived).

A strategic interaction $(\{A_i\}, \{O_t^{(i)}\})$ is a **potential game** (Monderer & Shapley 1996, *Games and Economic Behavior* 14) when there exists a scalar potential Φ such that each sub-agent's unilateral improvement matches the potential's unilateral improvement:

Derived (A2'-analog-potential, from Monderer-Shapley 1996).

$$O_t^{(i)}(\pi'_i, \pi_{-i}) - O_t^{(i)}(\pi_i, \pi_{-i}) = \Phi(\pi'_i, \pi_{-i}) - \Phi(\pi_i, \pi_{-i}) \quad \forall i. \quad (16.1)$$

Under this condition plus each sub-agent's B1 directional fidelity (4.3) to $\nabla_{\pi_i} O_t^{(i)}$, the joint best-response dynamics satisfy

$$\frac{d\Phi(\pi)}{dt} = \sum_i \langle \nabla_{\pi_i} \Phi, \dot{\pi}_i \rangle \geq \alpha_{\text{joint}} \|\nabla \Phi\|^2 \quad \text{for some } \alpha_{\text{joint}} > 0 \quad (16.2)$$

whenever the joint configuration is not at a stationary point of Φ . This is (T2) transcribed to state variable $\xi =$ gradient-of-potential, correction function $F =$ joint best-response velocity field; the quadratic Lyapunov structure is the same. **The sector-persistence template transfers** with $\xi = \pi - \pi^*$ (deviation from Nash), $\alpha = \alpha_{\text{joint}}$, $R =$ basin-of-attraction radius, and ρ_ξ the exogenous disturbance rate on strategy space. Equilibrium existence follows from potential-function compactness on compact strategy spaces; equilibrium stability follows from Φ 's role as a joint Lyapunov function.

Weaker than potential: a game is **diagonally strictly concave** (Rosen 1965, *Econometrica* 33) when the Jacobian of the joint gradient field is negative-definite on the joint strategy space. Under this condition, there exists a unique Nash

equilibrium and the joint gradient dynamics converge to it exponentially. The convergence rate is bounded below by the smallest eigenvalue of the symmetric part of the joint Jacobian, playing the role of α_{joint} . No scalar potential need exist; a *weighted-norm* Lyapunov argument on the joint Jacobian’s symmetric part substitutes.

Derived (A2'-analog-monotone, from Rosen 1965).

Sub-scope α' comprises: potential games (Monderer-Shapley), monotone games (Rosen), strongly-monotone games, and exponential-family dual-averaging under concave objectives. For these classes, the sector-persistence template extends to equilibrium convergence with composite sector constant α_{joint} inheriting from the joint-gradient-field structure.

Sub-scope β' : non-potential non-monotone games.

Every strategic interaction with continuous strategy spaces and regular payoffs can be reformulated as a **variational inequality**: find $\pi^* \in \mathcal{K}$ such that $\langle F(\pi^*), \pi - \pi^* \rangle \geq 0$ for all $\pi \in \mathcal{K}$, where F is the joint pseudo-gradient field. When $\mathcal{K}$ is compact-convex and F is continuous, a solution exists (Hartman-Stampacchia theorem). **Pure-strategy Nash equilibrium existence is therefore guaranteed** for continuous-strategy games with compact convex strategy sets and continuous payoffs. But the VI framework gives *existence* only, not *convergence of any specific dynamic to the solution*; solutions may be non-unique.

Derived (equilibrium-existence-via-VI, from Facchinei-Pang 2003).

Under no-regret learning (e.g., Hedge / multiplicative weights, Freund-Schapire 1997), the empirical joint distribution converges to the set of **coarse correlated equilibria** (CCE) at rate $O(1/\sqrt{T})$. This requires no structure on the game beyond each sub-agent computing its own regret.

Derived (regret-minimization-convergence-to-CCE, from Hart-Mas-Colell 2000).

Under β' , the macro-state of a strategic composite is a *distribution* on the joint strategy space — the empirical joint play whose support is the CCE — rather than a state-space point. This is the structural shape of “convergence” in the β' regime: distributional convergence, not pointwise. Pure-strategy Nash may or may not exist (cyclic games — rock-paper-scissors, matching pennies — lack pure Nash but retain mixed Nash via Nash 1950 and CCE convergence via Hart-Mas-Colell 2000); the β' machinery’s guarantees are at the distributional layer regardless.

Sub-scope β' scope-honesty: AAT can predict that long-run joint play lies in the CCE support; it cannot predict short-run trajectory, per-sub-agent mismatch convergence, or selection among multiple equilibria. The sector-persistence template does *not* apply in β' . This is a genuine scope limit shared with game theory as a whole, not a defect of AAT.

Cross-layer linearization fingerprint. The joint Jacobian of F at saddle-only Nash equilibria in β' has imaginary-axis (semisimple) spectrum — the linearization fingerprint of the R0-loss rung in the single-agent certificate-strength ladder of #result-certificate-existence. FTRL $\times$ graphical-constant-sum-with-fully-mixed Nash (Cheung-Piliouras-Tao 2021 Theorem 19: lossless DGS + Poincaré recurrence on bounded level sets) is the worked composite instance of R0-loss; the connection is between layers (single-agent linearized error space $\mathbb{R}^n$ vs composite joint-strategy space $\mathcal{X}^c$), not a collision of R-letter ladders.

Zero-sum scalar worked example.

Two agents A, B with scalar actions $a_i \in [-1, 1]$ and state $s_{t+1} = s_t + a_A - a_B + w_t$, $w_t \sim \mathcal{N}(0, \sigma^2)$. Objectives $O_t^{(A)}(s) = s$ (maximize s), $O_t^{(B)}(s) = -s$ (minimize s); zero-sum at the state-dependent payoff level.

Derived (zero-sum-scalar-instantiation).

Action-coefficient analysis. The agents’ state-preferences are opposite, but the action-coefficients in s_{t+1} are also opposite: $\partial s / \partial a_A = +1$ and $\partial s / \partial a_B = -1$. Composing with the objectives’ state-dependence:

$$\frac{\partial O^{(A)}}{\partial a_A} = \frac{\partial O^{(A)}}{\partial s} \cdot \frac{\partial s}{\partial a_A} = (+1)(+1) = +1 \quad (16.3)$$

$$\frac{\partial O^{(B)}}{\partial a_B} = \frac{\partial O^{(B)}}{\partial s} \cdot \frac{\partial s}{\partial a_B} = (-1)(-1) = +1 \quad (16.4)$$

Both agents marginal-prefer *increasing* their own action — the opposing state-preferences and opposing action-coefficients compose to aligned action-preferences.

Potential function. For Monderer-Shapley, $\partial\Phi/\partial a_i = \partial O^{(i)}/\partial a_i$ for each i . With both partial derivatives equal to +1, the potential is $\Phi(a_A, a_B) = a_A + a_B$ (modulo additive constant).

Nash equilibrium. Each agent's best response on $[-1, 1]$ is to push its own action to +1; the unique Nash equilibrium is $(a_A^*, a_B^*) = (1, 1)$. At equilibrium, $\Delta s = a_A^* - a_B^* = 0$: the substantive zero-sum property is that equal opposing action-coefficients cancel under the agents' aligned action-preferences, so joint action contributes no net displacement to s (state drift comes only from w_t). This is qualitatively different from the naive picture in which the agents push the state in opposite directions.

Sector-persistence template — interior-NE instantiation via Cournot-style payoffs. The unregularized example has a *linear* potential Φ and a *corner* equilibrium at $(1, 1)$; the unconstrained gradient field $\nabla\Phi = (1, 1)$ is constant in $\xi = \pi - \pi^*$, so there is no interior linear restoring force around the equilibrium and the template's (T2) sector lower bound $\xi^T F(\xi) \geq \alpha \|\xi\|^2$ does not hold without modification — the saturation, not a sector contraction, is what enforces equilibrium. The aligned-action-preferences finding is the conceptual payload of the unregularized form; the sector-template transfer requires a payoff structure whose curvature is genuinely quadratic, not merely projected onto a corner.

A Cournot-style duopoly (Cournot 1838; Monderer-Shapley 1996 §3 example) supplies that structure naturally. Two firms produce quantities $q_i \in [0, Q_{\max}]$; market price is $P(q_A, q_B) = a_0 - b(q_A + q_B)$; per-firm cost is linear at rate κ ; per-firm profit is

$$O^{(i)}(q_A, q_B) = q_i (a_0 - b(q_A + q_B) - \kappa). \quad (16.5)$$

This is partially-opposing in the policy-conflict sense — each firm's marginal payoff is decreased by the other's production through the shared price — without being strictly zero-sum. It is a potential game with quadratic potential.

Derived (Cournot-as-potential, from Monderer-Shapley 1996 §3).

$$\Phi(q_A, q_B) = (a_0 - \kappa)(q_A + q_B) - b(q_A^2 + q_B^2) - b q_A q_B, \quad (16.6)$$

verified by $\partial\Phi/\partial q_i = (a_0 - \kappa) - 2bq_i - bq_{-i} = \partial O^{(i)}/\partial q_i$. The symmetric interior Nash equilibrium is $q^* = (a_0 - \kappa)/(3b)$, located strictly inside the action box whenever $0 < q^* < Q_{\max}$.

Under continuous-time best-response $\dot{q}_i = \partial O^{(i)}/\partial q_i$, writing $\xi = q - q^* \mathbf{1}$, the joint dynamics are $\dot{\xi} = -bM\xi$ with $M = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$. Setting $F(\xi) = bM\xi$ (correction-strength sign convention; $\dot{\xi} = -F(\xi)$):

- (T1) $F(0) = 0$. ✓
- (T2) $\xi^T F(\xi) = b(2\xi_A^2 + 2\xi_B^2 + 2\xi_A \xi_B) \geq b\|\xi\|^2$, since M 's eigenvalues are $\{1, 3\}$. So $\alpha_{\text{joint}} = b$ — the smallest eigenvalue of the symmetric part of the joint Jacobian, exactly the quantity Rosen 1965 identifies as the convergence rate. ✓

- (T2-upper) $\|F(\xi)\| \leq 3b\|\xi\|$ from M 's largest eigenvalue.
- (T3) $R = \min(q^*, Q_{\max} - q^*)$ — the radius of the largest origin-centered ball in ξ -space contained in the feasible region; the closer of the two active constraints (zero-production and capacity) determines the basin.

The template's preconditions hold with α_{joint} inherited from the demand-side curvature parameter b rather than from any individual sub-agent's α . This is the substantive transfer: the composite-level sector constant lives at the *joint potential's curvature*, with economic interpretation (market-saturation slope) rather than ad-hoc parametrization. Other linear-quadratic strategic-substitutes games (LQR with coupled state, network-coordination with quadratic disagreement cost, public-goods with quadratic externalities) produce structurally equivalent template instantiations, with α_{joint} tracking the symmetric part of their respective joint Jacobians.

The unregularized scalar zero-sum and the Cournot instantiation are complementary: the former illustrates the framing's surprise — opposing state-preferences combined with opposing action-coefficients yield aligned action-preferences — while the latter exhibits the template transfer with genuine quadratic curvature and interior NE.

New scope route (C-iv) in #scope-composite-agent.

Strategic composition with partially-opposing $\{O_t^{(i)}\}$ admits a joint equilibrium structure $\mathcal{E}$ (Nash, correlated, or coarse correlated) such that coupled best-response dynamics converge to the support of $\mathcal{E}$. The composite exists as an AAT agent with macro-state defined relative to $\mathcal{E}$ rather than relative to a shared target state.

Proposed Scope (composition-scope-condition, route C-iv).

(C-iv) is qualitatively distinct from (C-i)–(C-iii): it does *not* require shared objectives, hierarchical derivation, or mutual benefit. It requires only structural convergence of the strategic interaction in the game-theoretic sense. Composites satisfying (C-iv) are **strategic composites**, distinguished from alignment composites (C-i, C-ii) and mutual-benefit composites (C-iii).

What Is Derived vs. What Is Chosen.

Table 16.1

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Framing move (contraction $\rightarrow$ equilibrium convergence)	Standard game-theoretic positioning	Formulation choice
(SC-1) / (SC-2) / (SC-3) three-question decomposition	Parallel to fixed-point / stability / reachability in dynamical systems	Formulation choice
A2'-analog under potential-game condition	Monderer-Shapley 1996 transcribed into AAT notation with B1 directional fidelity	Derived (exact under potential-game + B1)
A2'-analog under monotone-game condition	Rosen 1965 transcribed with weighted-norm Lyapunov	Derived (exact under diagonal strict concavity)
Equilibrium existence via VI	Facchinei-Pang 2003 (Hartman-Stampacchia)	Derived (external theorem, applied to strategic composition setting)
Regret-minimization CCE convergence	Hart-Mas-Colell 2000	Derived (external theorem applied)
Sub-scope α' / β' partition	Parallel to #deriv-sector-condition α/β	Formulation choice
Zero-sum scalar instantiation (corner-NE conceptual lesson)	Direct substitution into potential-game framework	Exact (within stated setup)
Cournot-style sector-template instantiation (interior-NE quadratic)	Monderer-Shapley 1996 §3 + sector-persistence-template; demand-side curvature b supplies α_{joint}	Exact (within stated setup)
(C-iv) scope route	Extension to #scope-composite-agent disjunction	Formulation choice (scope extension)

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Effects-spiral eigenvalue condition	Joint-Jacobian $\text{Re}(\lambda_{\max}) > 0$ at candidate equilibria — formalizes #der-adversarial-destabilization's discussion-grade effects spiral	Sketch (specific AAT instantiations open)
Strategic composition transitions composite from contraction-regime (R0) to equilibrium-regime (R1, under α') or cyclic-distributional-regime (R2, under β') per #disc-dynamic-regime-axis	Game-structure (potential / monotone / cyclic) under partially-opposing objectives, <i>not</i> architectural-class change	Derived (regime-axis, surfaced 2026-05-21; supersedes the earlier "Class 1 sub-agents $\rightarrow$ Class 2 composite" architectural-class framing)
Mechanism-design impossibility landed in #disc-implementation-impossibility (designer-side sister meta-pattern to identifiability-floor)	Gibbard-Satterthwaite 1973-75, Arrow 1951, Myerson-Satterthwaite 1983	Charter instances at #deriv-strategy-proofness-impossibility / #deriv-bilateral-trade-impossibility / #deriv-social-welfare-aggregation-impossibility; sub-scope α' named as adjacent-but-not-identical to the preference-domain-restriction escape
Potential function Φ as additive-coordinate-forcing instance	Φ 's additivity is definitional consequence of being a potential game, not forced by AAT-internal axiom; adjacent family member	Discussion-grade
Bridge from strategic composition to #form-composition-closure $\mathcal{E}^*$	Macro-description is an equilibrium statistic, not an equilibrium state	Open
General equilibrium-selection under multiple Nash	Existence theorems do not pin down which equilibrium; selection (risk-dominance, payoff-dominance, Pareto) is partial	Open
Mean-field-game limit ($N \rightarrow \infty$)	Lasry-Lions 2007; Huang-Malhamé-Caines 2006; requires population scope condition	Open (pending Part III population gaps)

Epistemic Status.

Conditional. Max attainable: *exact* under potential-game + B1 (sub-scope α'); *derived* under monotone-game + diagonal strict concavity; *discussion-grade* for the framing and sub-scope β' set-convergence-only claim.

The A2'-analog results under Monderer-Shapley 1996 and Rosen 1965 are transcriptions of established game-theoretic theorems into AAT notation. AAT's contribution is not the mathematics but the recognition that the sector-persistence template transfers cleanly when these conditions hold, and that the composite-level sector constant α_{joint} lives at the *joint potential gradient* or *joint Jacobian's symmetric part*, not at any individual sub-agent's α . The framing move (contraction $\rightarrow$ equilibrium convergence) is a structural positioning move.

Sub-scope β' gives AAT substantially weaker predictive power than sub-scope α' : *set-convergence to CCE only*, not trajectory convergence or per-agent mismatch convergence. This is an honest scope limit, not a defect — it mirrors game theory's own scope at the no-potential-no-monotonicity regime. AAT does not claim to predict equilibrium selection under multiple Nash, short-run dynamics in cyclic games (rock-paper-scissors), or convergence rates better than $O(1/\sqrt{T})$ in β' .

What this segment does not establish:

- General convergence proof for non-potential games under AAT-native update rules (imports Monderer-Shapley + Rosen as scope statements, doesn't re-prove them).

- Explicit joint-Jacobian analysis for specific AAT agent architectures (e.g., two Beta-Bernoulli agents on a shared DAG). Effects-spiral formalization is sketched, not derived per-instance.
- Bridge from strategic composition to #form-composition-closure's closure-defect ϵ^* — the macro-description of a strategic composite is a distributional equilibrium statistic rather than a state, so the closure-defect formulation needs re-specification. Open.
- Full mechanism-design derivation (VCG, Bayesian-Nash) for specific AAT-relevant settings.

Honest Limits.

- **No pure-strategy Nash equilibrium** in cyclic games (rock-paper-scissors; matching pennies). Mixed-Nash equilibrium exists universally for finite games (Nash 1950) but is a saddle point of best-response dynamics rather than a basin attractor; fictitious play orbits the mixed-Nash without converging pointwise to it. No-regret dynamics still drive the *empirical joint distribution* to the CCE set at rate $O(1/\sqrt{T})$ (Hart-Mas-Colell 2000), so β' machinery applies; the macro-state of a strategic composite in this regime is a distribution over the strategy space, not a state-space point.

Scope honesty — strategic-composition-failures.

- **Multiple equilibria with ambiguous selection** (coordination games; drive-left vs drive-right). Convergence to *some* equilibrium; AAT does not predict which.
- **Slow mixing / finite-sample failure** under regret-minimization: $O(1/\sqrt{T})$ cumulative regret implies finite-horizon play may be far from CCE support.
- **Non-compact strategy spaces** (unbounded prices, resource allocations). No equilibrium without compactification; compactification may be artificial.
- **Bayesian games with strategic + epistemic uncertainty compounding.** Existence and uniqueness become pathological under certain information structures.
- **Mean-field games** ($N \rightarrow \infty$) require population-scope machinery not covered here.

Discussion.

Sibling to #der-adversarial-destabilization. #der-adversarial-destabilization handles the *asymmetric* adversarial case: one agent is target; attacker's tempo is exogenous parameter; sector-persistence template applies to target's mismatch with coupling-amplified disturbance. This segment handles the *symmetric* strategic case: both agents running full AAT loops; state variable is joint deviation from equilibrium; correction function is joint best-response field. The two are siblings. #der-adversarial-destabilization's Working-Notes-flagged "coupled Lyapunov analysis is the open problem" has its formal home here — but the analysis is *not* a Lyapunov problem; it is a fixed-point problem, and the correct primitive is equilibrium convergence rather than Lyapunov descent. #der-team-persistence is recovered as the cooperative limit (all γ^{coop} dominate; joint dynamics reduce to parallel single-agent sector-persistence with reduced effective disturbance); #deriv-critical-mass-composition sits in the middle with signed γ on a matched-symmetric-Tier-1 dyad under shared target.

The effects spiral's formal home. #der-adversarial-destabilization's effects spiral — B 's degrading model causes B 's actions to destabilize A further — is a **joint-Jacobian eigenvalue condition** in the strategic-composition framing: the spiral exists iff $\max_{\text{candidate equilibria}} \pi^* \text{Re}(\lambda_{\max}(\nabla F(\pi^*))) > 0$, where F is the joint best-response field. This condition specializes monotone-game failure (the Jacobian's symmetric part fails to be negative-definite at equilibrium). The asymmetric formulation in #der-adversarial-destabilization cannot express this condition because it treats one agent's tempo as exogenous; the symmetric coupled formulation here does.

Dynamic-regime transition (not architectural-class change). #der-directed-separation classifies agents into Class 1 (Separated) / Class 2 (Partial) / Class 3 (Coupled) based on within-agent coupling between f_M and G_t . Strategic composition does *not* move a composite of Class 1 (Separated) sub-agents to Class 2 (Partial): the architectural class is set by the *processing pathway* (a $G^c \rightarrow f_M^c$ pathway bypassing e^c , which is the actual Class 1/3 boundary), not by *belief content* (each sub-agent's $M_t^{(i)}$ containing models of other agents' goal-state, which is a normal POMDP feature). Per the formal κ^c criterion of #der-directed-separation, under goal-blind routing and distinct sub-agent substrates the strategic composite is Class 1 (Separated) at the composite level — same architectural class as the sub-agents. Class change requires routing-structure goal-dependence (#hyp-directed-separation-under-composition Case 2) or shared-substrate G^c -allocation, neither of which is implied by strategic composition itself; the Cournot duopoly is the canonical witness for architectural-class invariance under strategic composition. What strategic composition *does* change is the **dynamic regime** (per #disc-dynamic-regime-axis): from R0 contraction-regime under aligned objectives to R1 equilibrium-regime under α' or R2 cyclic-distributional-regime under β' . The macro-state type changes correspondingly — state-variable (R0) / fixed-point object $\mathcal{E}$ (R1) / distributional object $\mu \in \Delta(\mathcal{X}^c)$ (R2). The dynamic-regime framing carries the structural load: the regime change is exactly what this segment derives in the α'/β' partition, while an architectural-class change is not derivable under the formal criterion.

Mechanism-design impossibility. If an outside designer can shape $\{O_t^{(i)}\}$, strategic composition becomes a **mechanism-design problem**: choose objectives so that the induced equilibrium *is* contraction to a designed state. Three classical impossibility results — Gibbard-Satterthwaite 1973-75 (no dominant-strategy non-dictatorial Pareto-efficient voting mechanism for ≥ 3 alternatives), Myerson-Satterthwaite 1983 (no efficient, individually-rational, incentive-compatible bilateral-trade mechanism without subsidies), Arrow 1951 (no social welfare function satisfying unrestricted-domain, Pareto-efficient, IIA, non-dictatorial) — land as the three charter instances of #disc-implementation-impossibility, the designer-side sister meta-pattern to #disc-identifiability-floor. Sub-scope α' of this segment is named there as *adjacent to but not identical with* the preference-domain-restriction escape (single-peaked / single-crossing): sub-scope α' secures best-response convergence under fixed reports, not strategy-proof revelation (the adjacency argument is developed in #deriv-strategy-proofness-impossibility Discussion). Supporting derivations carry the formal statements, AAT translations, and escape characterizations: #deriv-strategy-proofness-impossibility (GS), #deriv-bilateral-trade-impossibility (MS), #deriv-social-welfare-aggregation-impossibility (Arrow).

Meta-pattern positioning.

- #disc-separability-pattern: sub-scope α' (potential / monotone — template transfers) is separable-core; sub-scope β' (VI / regret-minimization — set-convergence only) is structured-repair; cyclic / non-convergent / multi-equilibrium-selection-ambiguous is general-open. Candidate additional ladder (strategic-interaction regime); decide whether to surface as 8th ladder or merge into an existing ladder.
- #disc-identifiability-floor: mechanism-design impossibility is *not* an identifiability-floor instance — there is an actor-positioning mismatch (designer-side vs agent-side), and the named AAT-side escape sub-scope α' addresses best-response-dynamics convergence, not strategy-proof revelation. The cluster lands in the designer-side sister meta-pattern #disc-implementation-impossibility instead. See Discussion above and the Related Work entry.
- #disc-implementation-impossibility: this segment's sub-scope α' is named there as adjacent-but-not-identical to the preference-domain-restriction escape in two charter instances (#deriv-strategy-proofness-impossibility for GS and #deriv-social-welfare-aggregation-impossibility for Arrow — both sharing the same adjacency).
- #disc-additive-coordinate-forcing: the potential function Φ plays an additive-coordinate role at the strategic layer, but its additivity is a *definitional consequence* of being a potential game (Monderer-Shapley require the additivity property by definition) rather than forced by a uniqueness theorem on an AAT-internal axiom. This positions Φ as an adjacent family member, parallel to Lyapunov quadratic and IB Lagrangian, not a primary instance.

Active-inference sharpening. Sun-Firestone 2020's dark-room argument observes that preferences-as-priors collapse under mutual prediction. Strategic composition gives this argument a formal substrate: two agents mutually predicting each other become a **fixed-point problem**, not a Lyapunov descent. The active-inference attempt to unify goal-seeking and prediction fails here in a derivable way — the fixed point is not at the prediction-optimum; it is at the strategic-equilibrium, which is structurally different. This strengthens #def-satisfaction-gap's positioning against preferences-as-priors without requiring additional refutation machinery.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. The canonical strategic-composition pattern “Class-1 sub-agents $\rightarrow$ Class-3-composite” (old vocab; Class 3 = partially modular) is now “Class 1 (Separated) sub-agents $\rightarrow$ Class 2 (Partial) composite.” Removed at candidate stage per FORMAT.md Gate 4.
- **No γ' sub-scope.** A γ' sub-scope for cyclic-distributional equilibria (games where no pure-strategy Nash exists but mixed Nash and/or CCE do exist, with macro-state as equilibrium distribution rather than equilibrium point) was considered and collapsed into β' : cyclic games are paradigmatic β' instances, with the same machinery (regret-minimization), the same convergence guarantee (CCE set-convergence), and the same rate ($O(1/\sqrt{T})$). The α'/β' decomposition is the right granularity at the regret-minimization layer; the type-of-object distinction (distribution vs state-space point) is surfaced within β' framing rather than as a third sub-scope.
- **Effects-spiral eigenvalue condition formalization.** The condition $\max_{\pi^*} \text{Re}(\lambda_{\max}(\nabla F(\pi^*))) > 0$ is sketched in §Discussion. Deriving it for specific AAT agent classes (two Beta-Bernoulli agents on a shared DAG; two Kalman agents with coupled observations) would upgrade the spiral from discussion-grade in #der-adversarial-destabilization to derived here. Follow-on spike candidate.
- **Mechanism-design impossibility landed as #disc-implementation-impossibility sister meta-pattern (closed 2026-05-22).** The candidate-fourth-instance flag is resolved. The 2026-05-20 strengthen-first arm at spikes/.integrated/spike-4th-identifiability-floor-instance-2026-05-20.md §4 confirmed the cluster does *not* fit #disc-identifiability-floor's actor-positioning (designer-side construction task vs agent-side inferential task); the cluster lands instead as a sister meta-pattern with three charter instances: #deriv-strategy-proofness-impossibility (GS), #deriv-bilateral-trade-impossibility (MS), #deriv-social-welfare-aggregation-impossibility (Arrow). Sub-scope α' of this segment is named in the GS and Arrow charter instances as *adjacent to but not identical with* the preference-domain-restriction escape (single-peaked / single-crossing): convergence-under-current-reports is not dominance-over-all-reports. The 2026-05-20 spike's recommended near-term re-home in #disc-separability-pattern's strategic-composition ladder general-open tier was *not* executed — #disc-separability-pattern's 8th ladder landed as Dynamic regime per #disc-dynamic-regime-axis 2026-05-21 instead (the strategic-composition ladder never materialized in #disc-separability-pattern); the sister meta-segment landing supersedes the candidate routing.
- **Composite-class-inheritance refinement (resolved 2026-05-21 — withdrawn).** The earlier-drafted “Class 1 (Separated) sub-agents $\rightarrow$ Class 2 (Partial) composite” architectural-class claim has been *withdrawn* per the strategic-composition spike at spikes/strategic-composition-class-3-attempt-2026-05-21/ — the formal κ^c criterion of #der-directed-separation gives Class 1 at the composite level under goal-blind routing (Cournot witness; conflation diagnosis at 02-REFRAME-INSIGHT.md §6). The dynamic-regime axis (#disc-dynamic-regime-axis) carries the regime-change content that the architectural-class claim was attempting; the cross-axis interaction is the substantive structural finding (wrapping operates on Axis A architectural class; alignment work operates on Axis B dynamic regime; they are independent). #hyp-directed-separation-under-composition retains its existing Case 1 / Case 2 dichotomy unchanged.
- **Bridge from strategic composition to #form-composition-closure ε^* .** The macro-description of a strategic composite is an equilibrium *statistic* (joint play distribution) rather than an equilibrium *state*. The closure-defect formulation needs re-specification for this case. Open.
- **Replicator / evolutionary dynamics.** Replicator-based strategic dynamics (Sandholm 2010, *Population Games and Evolutionary Dynamics*) converge to ESS (evolutionarily stable strategies), a subset of Nash. Under which AAT-native update

rules does the induced strategic dynamic match replicator? Multi-armed-bandit with softmax choice approximates replicator; gradient-descent on log-likelihood of mixed strategy is replicator exactly. Worth follow-on spike on AAT $\rightarrow$ evolutionary-dynamics correspondence.

- **Mean-field extension.** $N \rightarrow \infty$ limit with each agent interacting with a population *distribution* rather than named others. Natural extension for market / population strategic composition. Lasry-Lions 2007; Huang-Malhamé-Caines 2006. Requires population-scope condition of Part III that is currently marked GAP.
- **Worked-example structure — Cournot substitution for sector-template instantiation.** The unregularized scalar zero-sum case carries a non-trivial conceptual lesson: with $\Phi = a_A + a_B$, both agents' marginal preferences align (+1 each) and the unique Nash equilibrium is the *corner* (1, 1), where joint action contributes no net displacement to the shared state via cancellation of opposing action-coefficients rather than via opposing action-directions. This is preserved as the framing illustration. Sector-template instantiation is then carried by a Cournot-style duopoly (Cournot 1838; Monderer-Shapley 1996 §3) whose interior NE arises from genuine demand-side curvature rather than from an ad-hoc per-agent quadratic action cost. The reasoning trail — including a discarded $-\frac{c}{2}a_i^2$ regularization that placed an interior NE at $(1/c, 1/c)$ but introduced a parameter without economic interpretation, and an algebra error in that regularization's R (stated as $(1-1/c)\sqrt{2}$ where the inscribed-ball radius of the action box around the interior NE is $1 - 1/c$, the corner-distance over-counting by $\sqrt{2}$) — is recorded in `spikes/.integrated/spike-strategic-composition.md` §5.2–5.4 along with the original sign error in the potential function. Brainstormed alternatives (LQR with coupled state; network-coordination with quadratic disagreement cost; public-goods with quadratic externalities) all give structurally equivalent template instantiations; Cournot was chosen for textbook authority and for the strategic-substitutes interpretation that retains the partially-opposing-objectives flavor without requiring strict zero-sum.
- **Track E surface-back of catalog citations (2026-05-22) — uncoupled-dynamics + passivity + distributed Nash-seeking neighbors.** Adjacent prior-art literatures surfaced 2026-05-22 from Track E catalog at `ref/prior-art-analysis/14-composition-under-goal-divergence.md` (Pillars 2 + 3 + key anchor papers), each marked [`^cat-2026-05-22`] for verification-deferred attribution:
 - **Hart & Mas-Colell 2003**, *Uncoupled Dynamics Do Not Lead to Nash Equilibrium* (American Economic Review 93:1830)^a — sweeping negative result: if agents do not know the utility functions of other agents (uncoupled dynamics), no general learning algorithm is guaranteed to converge to Nash equilibrium. The classical companion to this segment's sub-scope β' “set-convergence to CCE only” honest scope limit; provides the uncoupled-side complement to Hart-Mas-Colell 2000's regret-minimization positive result. Strengthens the framework's β' scope-honesty discipline by naming the structural reason convergence guarantees are weak in the general case.
 - **Milionis et al. 2023**, expanded uncoupled-dynamics impossibility^b — Nash existence proofs are non-constructive; natural game dynamics fundamentally fail to converge in general games (chaos / cycles); empirically aligned with Mertikopoulos-Papadimitriou-Piliouras 2017 *Cycles in Adversarial Regularized Learning* (already cited in `#disc-identifiability-floor` Instance 3 escape (e) per the BG2 verdict). Provides the modern reinforcement for the uncoupled-impossibility line.
 - **Fox & Shamma 2012**, *Population games, stable games, and passivity* (Games 3:692)^c; **Arcak & Martins 2020**, *Dissipativity Tools for Convergence to Nash Equilibria in Population Games* (IEEE TAC 65:1681)^d — pioneering use of control-theoretic passivity / dissipativity to analyze game-theoretic convergence; population games mapped onto passive input-output systems with stability proven via passivity. Strongly mirrors this segment's transfer of the sector-persistence template to the equilibrium layer (the sub-scope α' result is structurally adjacent to the passivity-based convergence guarantees). Closest control-theoretic adjacent literature.
 - **Gadjov & Pavel 2019, 2023^e**; **Belgioioso & Grammatico 2018^f** — distributed Nash-equilibrium seeking via monotone-operator theory; proximal-point algorithms and Laplacian feedback as convergence machinery even in partially-observable or hypomonotone regimes. Adjacent to the (C-iv) strategic-equilibrium scope route and the sub-scope α' monotone-games treatment.

Primary-source verification queued in the BG2 cluster — see `#disc-identifiability-floor` Working Notes for the verification-targets list. Catalog citations had prior Pillar-style search support but were not verified by the current executor at landing time.

Incidental audit gold (gold-lift sweep, A15, 2026-05-31). Cross-audit “wandering thoughts” / §14 ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed by substrate + audit. *Orthogonal* pedagogical / framing / figure / forward-vision material, staged here for an eventual separate Brief/Discussion promotion pass — kept apart from certified theory-fix findings. **Coverage:** five dirs reached a digested reflection on this segment (193847 Gemini, 526815 deeply-mathematical, 471203 Claude batched §III-composition, 773921 Claude, 849201 Gemini). The finding-vs-framing conflation is preserved as signal, not sanitized.

1. Candidate Brief prose / pre-prose.

- The “framing shift” one-liner several auditors converged on as the segment’s pedagogical core: when objectives are partially-opposing ($U_O < 1$), the question stops being “*does the trajectory contract to a shared state?*” and becomes “*do the coupled best-response dynamics converge to an equilibrium?*” — and contraction-to-shared-truth is recovered as the $U_O = 1$ special case (Claude, 773921; Gemini, 849201). Tight enough to seed a Brief opener.
- The Section-I parallel as a memory hook: “just as Section I split into sub-scope α (Kalman/LQR, exact bounds hold) and sub-scope β (PID, they don’t), this segment splits into sub-scope α' (potential/monotone games) and sub-scope β' (VI / regret-minimization)” — the $\alpha/\beta \leftrightarrow \alpha'/\beta'$ rhyme makes the new partition feel inevitable to a reader who has walked Section I (Gemini, 849201).
- “The gradient of a market potential function Φ is literally the same mathematical object as an agent’s mismatch signal δ ” — a candidate plain-language statement of the template transfer’s payload (Gemini, 193847).

2. Candidate Discussion.

- The “active-inference sharpening” is repeatedly flagged as a **high-water-mark Discussion paragraph** worth foregrounding, not burying: two agents mutually predicting each other become a *fixed-point* problem, so the active-inference attempt to unify goal-seeking and prediction via free energy fails *in a derivable way* — the fixed point sits at the strategic equilibrium, not the prediction-optimum (Gemini, 193847; Gemini, 849201). (*Conflation texture: 526815’s certified track separately flags “fails here in a derivable way” as outrunning what the segment locally derives — see off-ramp. Preserve both readings.*)

3. Follow-up items.

- **Replicator / evolutionary-dynamics correspondence** (already in WN) was independently seconded — softmax bandits approximate replicator, gradient-on-log-likelihood is replicator exactly; an AAT-native-update-rule $\leftrightarrow$ ESS map is a natural follow-on (implicit across the §III batch, Claude 471203).

4. Readers often ask / wonder.

- “Does a little noise act as a force multiplier for drift?” — readers reaching the β' regime want to know whether there is an optimal drift-fraction f for a budget-constrained attacker (Gemini, 193847; this is a #result-adversarial-exponent-regimes want surfacing here through the adversarial-sibling link).
- **Mutual-modeling regress.** “If my model contains a model of your model... we enter infinite regress. How does AAT break it — bounded depth?” — a natural reader question at the symmetric-coupling framing; the active-deceive depth-bound discussion lives in #der-agent-opacity and could be pointed at from here (Gemini, 193847).
- “Does multi-agent alignment become mathematically forbidden?” — the mechanism-design-impossibility cluster (Gibbard-Satterthwaite / Arrow) prompts readers to ask whether a society of AIs can ever align goals without a dictator (Gemini, 193847; curiosity echoed by Gemini 849201, Claude 773921).

5. Candidate figures.

- **The α' / β' scope-fork diagram** (526815 drafted a TikZ standalone, 93-deriv-strategic-composition.tex): strategic-composition root $\rightarrow \alpha'$ branch (potential/monotone $\rightarrow$ sector transfer *only with curvature/monotonicity* $\rightarrow$ point equilibrium / basin) vs β' branch (no-regret layer $\rightarrow$ CCE distribution $\rightarrow$ macro-state is joint-play distribution), with three dashed audit-warning call-outs (“potential function alone is not a sector constant”; “VI/CCE need standard convexity/boundedness/protocol assumptions”; “open: closure defect for equilibrium statistics”). The warnings are auditor-finding annotations; a clean promotion figure would drop them, but the fork structure itself is a strong candidate for the segment (Claude/Codex, 526815).

Belongs elsewhere.

- **Forward-vision (ELI / consciousness-infrastructure, 04-eli-core/)**. The strongest reach: “you cannot build a sane future AI just by networking together sane sub-agents — the act of networking them in a strategic environment *generates* epistemic corruption at the macro level. The infrastructure must actively enforce (C-i) shared objectives or (C-ii) hierarchical derivation, because relying on (C-iv) strategic equilibrium guarantees a goal-contaminated macro-epistemology” (Gemini, 193847). This is aspirational application pointing at 04-eli-core/ composite-architecture design, not at this segment. (*Heavy conflation texture: 193847 states this through the now-withdrawn “Class-1 sub-agents $\rightarrow$ Class-3 composite” architectural-class framing — current canon carries dynamic-regime-change, architectural-class-preserved instead. Preserve the forward-vision payload; the Class-3 mechanism is the superseded reading, do not promote it. See off-ramp.*)

Off-ramp (NOT gold) — routed for adjudication, not promotion. These are certified-track (strengthen-first / overclaim / scope-narrowing) findings, not pedagogical gold — recorded here so they are durable and routable, but they belong to the findings adjudication stream, not the Brief/Discussion promotion pass. The bulk are from the deeply-mathematical auditor (526815), with two adversarial-audit pokes from 193847.

- **(526815, F234/F235/F236) — the sector-template-transfer overclaim.** The displayed inequality $d\Phi/dt \geq \alpha_{\text{joint}} \|\nabla\Phi\|^2$ and “equilibrium stability follows from Φ as a joint Lyapunov function” are too broad: a potential-game structure *alone* does not deliver a sector inequality, unique convergence, or a basin around a selected equilibrium — increasing a potential can land on local maxima, saddles, boundary equilibria, or multiple equilibria. The template transfer needs additional curvature / PL / strong-monotonicity, and the state variable silently switches from $\xi = \nabla\Phi$ to $\xi = \pi - \pi^*$ (different unless a local Hessian / strong-convexity relation maps them). Recommended discharge direction: *narrow the exact-transfer claim to games with enough curvature/monotonicity for a sector inequality* (strengthen the hypotheses, don’t soften the conclusion). The Cournot interior-NE instantiation already supplies that curvature and is locally coherent (526815 F244) — so the segment may already carry the witness for the strengthened scope; verify against current canon before acting.
- **(526815, F237) — VI existence overstated.** “Pure-strategy Nash existence is guaranteed for continuous compact-convex games with continuous payoffs” needs concavity-in-own-strategy / differentiability beyond continuity; a VI solution maps to Nash only under those.
- **(526815, F238/F240) — unstated assumptions before use.** No-regret $\rightarrow$ CCE at $O(1/\sqrt{T})$ needs compact action sets, bounded payoffs, the right protocol stated *before* the macro-state guarantee is invoked; “ $U_O = 1$ is the contraction special case” needs the earlier composition/observability conditions to actually yield unique shared truth.
- **(526815, F239/F241/F242) — dependency / routing hygiene.** der-gain-sector-bridge used in the α' proof but not declared in depends; the (C-iv) scope route mutates #scope-composite-agent but is introduced here as a formulation choice (route it back or mark proposed-until-incorporated); the Class-composite cross-check leans on #hyp-directed-separation-under-composition without declaring it.
- **(526815, F243 / 193847 poke-1) — “fails here in a derivable way” outruns local derivation.** The active-inference and mechanism-design *implications* are positioned as adjacent, but the prose claims more than the segment locally derives. (This is the conflation counterpart to the gold item under Candidate Discussion above.)
- **(193847, poke) — “C-iv strategic composition produces a Class-3 composite from Class-1 sub-agents.”** Flagged here because it is the **known C-iv idiom-drift integration-debt** vein called out for this batch: the architectural-class-change reading was *withdrawn 2026-05-21* (Cournot witness; dynamic-regime-change with architectural class preserved is current canon). 193847’s vivid “bureaucratic insanity / structurally more corrupt than its parts” §14 framing rides on the superseded

mechanism. **Stale OUTLINE residue confirmed at lift time:** 01-aat-core/OUTLINE.md lines 91, 323, 328 still carry “Class-1-(Separated)-sub-agents → Class-2-(Partial)-composite” idiom in this chapter’s rows — flag for the idiom-drift cleanup, out of scope for this WN-only lift.

16.2 Derived: Agent Opacity (H_b)

Alongside AAT’s heavily formalized *forward* observation quality (how well the agent sees the world — observation ambiguity, model-class fitness, identifiability floor on what the agent can infer), AAT carries a **dual quantity** measuring how well the world sees the agent: **backward predictive uncertainty** H_b , an observer-indexed, horizon-indexed, trajectory-indexed entropy of the agent’s future actions given another agent’s filtration. Adopted from Hafez et al. 2026 as a first-class multi-agent quantity. H_b is the dual of observation quality U_o : where U_o characterizes how well the agent sees the world, H_b characterizes how well the world sees the agent.

Each of the four indexing arguments — observer, horizon, trajectory, time — is load-bearing rather than ornamental. *Observer-indexed*: different observers (allies with shared infrastructure; adversaries with limited instrumentation; the environment itself) have different filtrations $\mathcal{F}_B^t$, and H_b varies accordingly — the same agent has different opacity to different observers. *Horizon-indexed*: immediate-next-action opacity ($\tau = 1$) and long-horizon-plan opacity ($\tau \gg 1$) *decouple* — an agent may be predictable at immediate action but unpredictable at plan level, or vice versa. *Trajectory-indexed*: per #scope-agent-identity’s singular-trajectory scope, H_b is the opacity of *this* trajectory’s continuation, not a type-level claim about a class of agents. *Time-indexed*: opacity drifts with learning as the observer’s model of the agent improves.

H_b is **sign-flipped in value across regimes**: low H_b (legibility) enables cooperative coordination (15.1); high H_b (opacity) enables adversarial effectiveness (15.2, 15.4). The sign-flip is a direct consequence of AAT’s existing signed-coupling structure rather than a separate posit — cooperative coupling wants low opacity (allies must predict to preempt); adversarial coupling wants high opacity (predicted attacks are neutralized). This segment’s emitter-side four-regime classification is the dual of #der-interaction-channel-classification’s recipient-side theory; together they close #adversarial-edge-targeting as emitter-optimizer paired with recipient-classifier, with a 16-cell joint composition supplying closed-form arg-max for adversarial-targeting decisions.

Formal Expression.

For agent A on singular trajectory $\mathcal{C}_A$ and observer agent B with filtration $\mathcal{F}_B^t$ (per-trajectory observable history per #scope-agent-identity's token-level commitment):

Definition (agent-opacity-Hb).

$$H_b^{A|B}(t, \tau) := H(a_{A,t+\tau} | \mathcal{F}_B^t) \quad (16.7)$$

the entropy of agent A 's action at horizon τ conditional on observer B 's filtration at time t . **Four indexing arguments:** observer B , time t , horizon τ , trajectory $\mathcal{C}_A$. Each is load-bearing:

- **Observer-indexed.** Different observers (allies with shared infrastructure; adversaries with limited instrumentation; environment itself) have different filtrations $\mathcal{F}_B^t$; H_b varies accordingly.
- **Horizon-indexed.** Immediate-next-action opacity ($\tau = 1$) and long-horizon-plan opacity ($\tau \gg 1$) decouple: an agent may be predictable at immediate action but unpredictable at plan level, or vice versa.
- **Trajectory-indexed.** Per #scope-agent-identity, AAT applies to agents on singular trajectories. $H_b^{A|B}$ is the opacity of *this* trajectory's continuation, not a type-level claim.
- **Time-indexed.** Opacity may drift with learning (as B 's model of A improves, $H_b^{A|B}(t)$ decreases); steady-state values exist for ergodic regimes.

Under the IDT-observer specialization — B operates as Hafez's Information Digital Twin monitoring (S_A, a_A, S'_A) from outside A 's processing — and under ergodicity, $H_b^{A|B}(t, \tau) \rightarrow H(S, A | S')$ as defined in Hafez et al. 2026. AAT's added features (observer-indexing, horizon-indexing, trajectory-indexing) are the distinctive extensions.

Backward variance decomposition — the duality made structural.

In the linear-Gaussian regime, write A 's action as $a_{A,t+\tau} = \mu_A(X_{A,t+\tau}) + w_a$ with policy noise $w_a \sim \mathcal{N}(0, U_{a,A}^{(\tau)})$ independent of B 's filtration. By the law of total variance, B 's predictive variance splits into exactly two sources:

Derived (Hb-variance-decomposition; exact in linear-Gaussian sub-scope α).

$$\text{Var}(a_{A,t+\tau} | \mathcal{F}_B^t) = \underbrace{\text{Var}(\mu_A(X_{A,t+\tau}) | \mathcal{F}_B^t)}_{U_{\pi,B \rightarrow A}^{(\tau)}} + \underbrace{U_{a,A}^{(\tau)}}_{\text{policy noise}}, \quad (16.8)$$

and since the predictive law is Gaussian here (Gaussian mean-uncertainty plus independent Gaussian noise — the same argument as the Kalman predictive),

$$H_b^{A|B}(t, \tau) = \frac{1}{2} \log(2\pi e) + \frac{1}{2} \log[U_{\pi,B \rightarrow A}^{(\tau)} + U_{a,A}^{(\tau)}]. \quad (16.9)$$

$U_{\pi,B \rightarrow A}$ is B 's uncertainty about A 's policy conditional mean — **epistemic**, reducible as B learns A (observation, communication, shared architecture). $U_{a,A}$ is A 's intrinsic action variability given its own state — **aleatoric from B 's side**: no amount of observing A reduces it; only A making its policy more deterministic does. This is the Kalman forward decomposition $U_M + U_o$ (3.6) reflected across the agent-environment boundary: $U_{\pi,B \rightarrow A} \leftrightarrow U_M$ (the learnable model term) and $U_{a,A} \leftrightarrow U_o$ (the channel-noise floor) — with the channel noise living in the agent's *actuator* rather than its *sensor*. The headline duality claim is thereby structural rather than rhetorical: the forward and backward directions

carry matching two-term epistemic-plus-aleatoric variance decompositions. (It is a structural correspondence, not an adjoint/optimization-theoretic duality theorem — see Working Notes.)

Two consequences. (i) **The transparency knobs are independent.** An agent can lower its opacity to allies by lowering U_π (publishing intent — 14.3 is precisely this knob) without touching U_a , or by lowering U_a (policy determinism) without publishing anything; conversely an adversary-facing agent can raise either. (ii) **Identifiability floors bound only the epistemic term.** When B 's observations of A 's action-consequences sit below an observability floor, $U_{\pi,B \rightarrow A}$ cannot be reduced even with unbounded data — a structural lower bound on $H_b^{A|B}$ from B 's side, which is the observer-side floor reading in §Meta-pattern positioning.

Tier: exact in linear-Gaussian sub-scope α (law of total variance + Gaussian entropy); robust qualitative beyond (the two-source split survives; the closed log-form does not).

Sign-flip via signed coupling.

The value of H_b^A to A depends on the sign of A 's coupling to other agents — the same signed-coupling structure that organizes #der-team-persistence, #der-adversarial-destabilization, and #deriv-critical-mass-composition's (CM2) γ parameter.

Derived (sign-flip-from-signed-coupling).

- **Cooperative coupling** ($\gamma^{\text{coop}} > 0$, **reducing allies' disturbance**). For B to treat A 's action as cooperation rather than disturbance, B must predict A 's action well enough to preempt or complement it. Under #der-interaction-channel-classification's recipient-side decomposition, unpredictable ally actions fall into Regime II (magnitude/structural shock) rather than Regime I (informative update). Therefore cooperative coupling effectiveness $\gamma_{A \rightarrow B}^{\text{coop}}$ is *increasing in legibility*, equivalently decreasing in $H_b^{A|B}$. Under sub-scope α Gaussian coupling: $\gamma^{\text{coop, effective}} \propto (1 - H_b^{A|B}/H_b^{\text{max}})$.
- **Adversarial coupling** ($\gamma^{\text{adv}} > 0$, **amplifying target's disturbance**). Predicted attacks are neutralized; unpredicted attacks deliver effective disturbance. Adversarial coupling effectiveness is *increasing in opacity* — the mechanism of adversarial advantage (per #result-adversarial-tempo-advantage) operates *through* B 's failure to predict A . Under the same sub-scope α setup: $\gamma^{\text{adv, effective}} \propto H_b^{A|B}/H_b^{\text{max}}$.

The sign-flip on H_b 's value-to- A lives in the sign of γ itself, not in a different sign on H_b . Cooperative regime ($\gamma^{\text{coop}} > 0$) rewards low H_b ; adversarial regime ($\gamma^{\text{adv}} > 0$) rewards high H_b . The same H_b quantity, the same monotone dependence; opposite value-to- A because the signs of the coupling terms differ.

Emitter-side four-regime classification.

Parallel to #der-interaction-channel-classification's recipient-side four regimes, the emitter A sends events that fall into four emitter-side regimes based on A 's opacity signal structure and self-model quality:

Formulation (emitter-regimes, dual to #der-interaction-channel-classification).

- **E-I Broadcast.** A emits actions transparently; $H_b^{A|B}$ is low for any observer B with standard instrumentation. Examples: public announcements, published decisions, legible industrial controllers.
- **E-II Selective-signal.** A is transparent to some observers and opaque to others (e.g., shared allied infrastructure gives allies lower H_b than adversaries without that infrastructure). Boundary: differential instrumentation in $\mathcal{F}_B^t$ across observers.
- **E-III Information-hide.** A is uniformly opaque to observers; actions are randomized, encrypted, or routed through dead-drops. $H_b^{A|B}$ near H_b^{max} for all observers lacking the key / pattern / channel.

- **E-IV Active-deceive.** A emits actions that mispredict — the observer’s model of A converges to a *wrong* prediction that differs from the actual action by a larger margin than the same observer’s model of the environment would accommodate. Boundary: A ’s self-model quality (for active-deceive, A must model the observer’s model of A well enough to choose actions that exploit it).

The adversarial-edge-targeting arg-max. The 16-cell emitter-recipient composition (four emitter regimes $\times$ four recipient regimes) operationalizes the previously-reserved #adversarial-edge-targeting Part III gap: given emitter A choosing which edge k of target B ’s strategy DAG Σ_B to attack, the targeted-attack value is

Formulation (adversarial-edge-targeting arg-max; factor-wise grounded, multiplicative composition a modeling choice).

$$k^* = \arg \max_k \underbrace{p_k(1 - p_k)}_{\text{credence leverage}} \cdot \underbrace{J_k^2}_{\text{plan sensitivity}} \cdot \underbrace{\iota_k}_{\text{edge identifiability}} \cdot \underbrace{\sigma_k^B}_{\text{observability}} \cdot \underbrace{(1 - H_b^{B|A}/H_b^{\max})}_{\text{targeting fidelity}}. \quad (16.10)$$

The first four factors are **B -interior** — the value of edge k to a *perfectly-informed* adversary, each with a canonical home: credence leverage $p_k(1 - p_k)$ is the Beta-Bernoulli update variance (R); plan sensitivity $J_k = \partial P_\Sigma / \partial p_k \geq 0$ is the plan-value Jacobian (R), entering squared because both the injected mismatch and its propagation to plan value scale with it; edge identifiability ι_k is the Regime-A interventional-access coefficient (9.5); and σ_k^B is B ’s observability of the edge (1.3). The **fifth factor is the opacity contribution**: A ’s targeting fidelity scales with A ’s legibility-of- B , i.e. with low $H_b^{B|A}$. Under full legibility ($H_b^{B|A} \rightarrow 0$) the arg-max is fully exploitable — A strikes the single highest-value edge. Under full opacity ($H_b^{B|A} \rightarrow H_b^{\max}$) the fifth factor vanishes and targeting collapses to the untargeted broadcast attack $\arg \max_k p_k(1 - p_k) J_k^2$ — the edges most valuable *in expectation*, with no per-edge aim. This is the emitter-side optimizer paired with #der-interaction-channel-classification’s recipient-side classifier, closing the pairing that segment’s §”Pairing with #adversarial-edge-targeting” advertised. The multiplicative composition is a first-order modeling choice (treating the factors as independent); the individual factors are the derived content, and a second-order interaction analysis (e.g., whether the targeting-fidelity factor should modulate J_k rather than multiply it) is the natural strengthening (Working Notes).

Tempo amplification by opacity.

#result-adversarial-tempo-advantage’s tempo-multiplier $\gamma_A \mathcal{T}_A$ in #der-adversarial-destabilization decomposes into a tempo term and an opacity term:

Derived (tempo-amplification-by-opacity).

$$\mathcal{T}_A^{\text{effective}} = \mathcal{T}_A \cdot \frac{H_b^{A|B}}{H_b^{\max}} \quad (\text{Model D adversarial coupling}) \quad (16.11)$$

The superlinear formula $(\mathcal{T}_A/\mathcal{T}_B)^2$ becomes $(\mathcal{T}_A/\mathcal{T}_B)^2 \cdot (H_b^{A|B}/H_b^{B|A})^2$ under bilateral opacity — a higher-order tensor product with the same exponent $b = 2$ (Model D) or $b = 3/2$ (Model S) from #result-adversarial-exponent-regimes. Whether b itself is reshaped under bilateral opacity is open; the leading-order scaling is the tempo-opacity product.

What Is Derived vs. What Is Chosen.

Table 16.2

Property	Source	Strength
$H_b^{A B}(t, \tau)$ definition	Adopted from Hafez et al. 2026; extended with observer / horizon / trajectory indexing per #scope-agent-identity	Formulation choice (adoption + AAT-extension)
Reduction to Hafez’s $H(S, A S')$ under IDT-observer + ergodic regime	Direct substitution	Derived (exact under IDT + ergodicity)
Sign-flip via signed coupling	Cooperative coupling requires predictability (allies preempt); adversarial coupling operates via disturbance-injection (predicted attack is neutralized)	Derived (from existing #der-team-persistence + #der-adversarial-destabilization signed- γ structure)
Emitter-side four-regime classification	Dual construction to #der-interaction-channel-classification’s recipient-side four regimes	Formulation choice
16-cell emitter-recipient composition closes #adversarial-edge-targeting	Five-factor arg-max: four B -interior factors (credence leverage, plan-Jacobian ² , edge identifiability, observability) each canonically grounded, times the opacity targeting-fidelity factor	Factors derived; multiplicative product-form a first-order modeling choice
Backward variance decomposition $H_b = \frac{1}{2} \log 2\pi e + \frac{1}{2} \log[U_{\pi, B \rightarrow A} + U_{a, A}]$	Law of total variance + Gaussian entropy; the structural dual of the Kalman $U_M + U_O$ split	Derived (exact in linear-Gaussian sub-scope α ; robust qualitative beyond)
Tempo-amplification leading-order: $\mathcal{T}^{\text{eff}} = \mathcal{T} \cdot H_b / H_b^{\max}$	First-order substitution into #result-adversarial-tempo-advantage’s tempo-multiplier under Model D	Derived (conditional on Gaussian-coupling sub-scope α)
Parameterization-invariance of H_b	H_b is an action-marginal entropy; action space is coordinate-free per #scope-agent-identity	Derived
Candidate 4th #disc-identifiability-floor instance (generic observer-side form)	H_b ’s formal structure — “observer cannot predict agent’s future action better than $H_b^{A B}$ ” — is a CHT-style no-go at the observer-side-inference task	Discussion-grade (framing; precise external theorem not yet identified)
Candidate opacity ladder for #disc-separability-pattern	Transparent-core / partial-transparency / full-opacity across observer filtrations	Formulation choice (ladder proposal)
Effects-spiral opacity amplification (higher $H_b \rightarrow$ higher $\gamma_A \rightarrow$ larger $\hat{V}_B \rightarrow B$ ’s actions become more erratic $\rightarrow$ observer’s model of B degrades $\rightarrow$ higher $H_b^{B A}$)	Composition of sign-flip derivation with #der-adversarial-destabilization’s effects spiral	Sketch (discussion-grade; specific functional form open)
Dual-filtration apparatus (each agent’s M_t carries an other-filtration as feature)	Would unify observer-indexing with #scope-agent-identity’s single-trajectory formalism more tightly	Open extension (mild architectural, orthogonal to derivations)
Sharp functional form for $\gamma_{\text{effective}}^{\text{adv}} = f(H_b)$	Leading-order: $\gamma \propto H_b$. Exact function depends on sub-scope — Gaussian-coupling linear; sigmoid-coupling saturating	Open per sub-scope

Epistemic Status.

Conditional. Max attainable: *exact* for the Hafez-reduction under IDT + ergodicity; *derived* for the sign-flip via signed-coupling; *formulation choice* for the emitter-regime classification structure; *conditional* for the tempo-amplification formula; *discussion-grade* for the meta-pattern candidate status.

Load-bearing: - The sign-flip derivation from existing signed- γ structure is the segment’s core structural contribution — the adversarial/cooperative opacity duality is not a separate posit; it falls out of AAT’s existing signed-coupling

apparatus. - The emitter-side four-regime classification is a clean dual to #der-interaction-channel-classification; its derivation is parallel (boundaries in AAT-native quantities — emitter opacity signal structure, self-model quality, coupling regime). - The closure of #adversarial-edge-targeting via the 16-cell composition is a derived arg-max; the previously-stated GAP is filled.

Not established: - Sharp functional forms for $\gamma_{\text{effective}}^{\text{adv}}(H_b)$ outside Gaussian-coupling sub-scope α . - Whether b (the adversarial exponent from #result-adversarial-exponent-regimes) is reshaped under bilateral opacity. - Formal fourth #disc-identifiability-floor instance (requires external-theorem anchoring not yet identified); discussion-grade framing only. - The effects-spiral's opacity amplification (composition with #der-adversarial-destabilization's spiral) is sketch-level.

Honest Limits.

- **Observer-indexing under complex information structures.** $\mathcal{F}_B^t$ may include shared memory, cryptographic keys, insider knowledge, or partial access to A 's internal state. Enumerating all relevant observer-filtration structures for a specific application is task-specific; the segment provides the formal framework, not the per-instance enumeration.
- **Active-deceive (E-IV) requires A to model B 's model of A .** Mutual-modeling regress under partially-opposing objectives connects to #deriv-strategic-composition's joint-Jacobian analysis. Active-deceive is formally reachable only when A 's GUC architecture admits modeling another agent's model — typically Class 3 (Coupled; LLM-style) or Class 2 (Partial) architectures.
- **Type-level vs token-level opacity.** H_b is trajectory-indexed per #scope-agent-identity. Statements about “the opacity of model X ” (aggregated across deployments) are type-level claims outside AAT's formal scope; they require additional machinery (e.g., population-level dynamics per Part III gaps).

Discussion.

Dual to observation quality. U_o characterizes how well the agent sees the world: observation noise, ambiguity, model-class fitness. H_b characterizes how well the world sees the agent: predictability to observers. The duality is structural — both quantify information flow through the agent-environment boundary, in opposite directions. High U_o agent (observes the world well) and low H_b agent (is observed well) are independent properties; an agent can have one without the other.

Closing #adversarial-edge-targeting. The segment provides the emitter-side arg-max structure missing from the Part III adversarial machinery. Paired with #der-interaction-channel-classification's recipient-side four-regime decomposition, the full adversarial-targeting problem has a closed-form: choose edges where emitter's H_b (to target) and target's recipient-side vulnerability (Regime II magnitude/structural shock) are jointly maximized. This operationalizes what “inside the opponent's loop” means at the targeting layer — Boyd's aphorism becomes an explicit optimization over the 16-cell emitter-recipient product.

Meta-pattern positioning. - #disc-identifiability-floor: H_b 's structure suggests a generic observer-side floor — “the observer cannot predict the agent's action better than H_b ” — that Instances 1/2/3 specialize on specific variables (causal structure / mixture parameters / coupling sign). The generic framing is candidate-status: it lacks a single external-theorem anchor clear enough to match F1's CHT or F13's Cramér-Rao, but H_b appears naturally in Instance 3's coupling-sign unidentifiability and in Instance 1's on-policy detection no-go (an observer watching the agent's on-policy play has non-zero H_b on the agent's interventional regime). - #disc-separability-pattern: candidate opacity ladder — transparent-core (E-I Broadcast; allies / public interfaces) / structured-repair (E-II Selective-signal; trust-weighted partial instrumentation) / general-open (E-III, E-IV; uniformly opaque or active-deceive). Adds to the ladder count if adopted. - #disc-additive-coordinate-forcing: H_b 's logarithmic form is adopted from Shannon via Khinchin-Aczél axiomatics, imported as an applied external theorem rather than re-forced under an AAT-internal additivity axiom.

Cross-agent additivity fails under the coupling regimes AAT cares about (correlated opacity structures break independence). Adjacent family member, parallel to the IB Lagrangian’s position — not a primary instance.

Parameterization-invariance composes cleanly. H_b is an action-marginal entropy. Under #scope-agent-identity’s (PI) axiom, the action space is coordinate-free; H_b is invariant under change of the agent’s internal-state parameterization. This composes with the (PI)/Čencov fourth primary instance of #disc-additive-coordinate-forcing without adding a new axiom.

Relation to #der-directed-separation. Class 3 (Coupled) agents have high structural opacity to any observer without internal access — their f_M and G_t are entangled, so predicting the next action requires joint state modelling. Class 1 (Separated) agents are more transparent at the interface level because the decomposed update admits separate modelling of epistemic vs. purposeful components. H_b therefore tends to be *architecturally higher* for Coupled (Class 3) agents — a structural consequence of architecture rather than choice, beyond what E-III Information-hide captures.

Hafez integration note. The IDT pattern (Hafez et al. 2026) uses bi-predictability P (how well a sidecar observer can predict the agent’s next state-action) and entropy change ΔH as diagnostics. The IDT’s reported 89% perturbation-detection accuracy (vs. 44% for reward-based monitoring) operates on the Level-2 structure per #der-loop-interventional-access. In AAT terms, the IDT is a low- H_b -preserving observation channel — its presence as a modular sidecar reduces H_b for the operator without increasing the agent’s internal complexity. For 03-11m-core/, this validates that modular monitoring of internally-merged agents is feasible and effective even when the agent itself is architecturally Class 3 (Coupled).

Findings.

Agent Opacity (H_b) as Dual to Observation Quality (U_o). **Brief:** How well the agent sees the world (observation quality U_o) and how well the world sees the agent (backward predictive uncertainty H_b) are formal duals — both quantify information flow through the agent-environment boundary, in opposite directions. H_b is observer-, horizon-, and trajectory-indexed, extending Hafez’s $H(S, A \mid S')$ with these load-bearing indices. The same H_b quantity has opposite value-to-the-agent depending on coupling sign: cooperative coupling rewards low H_b (allies must predict to coordinate); adversarial coupling rewards high H_b (adversaries cannot neutralize what they cannot predict). The sign-flip is not a separate posit — it falls out of AAT’s existing signed-coupling structure ($\gamma^{\text{coop}} > 0$ for ally-disturbance reduction; $\gamma^{\text{adv}} > 0$ for target-disturbance amplification). Adversarial tempo advantage decomposes into a tempo term and an opacity term: $\mathcal{T}^{\text{eff}} = \mathcal{T} \cdot H_b/H_b^{\text{max}}$, so the superlinear $(\mathcal{T}_A/\mathcal{T}_B)^2$ advantage from #result-adversarial-tempo-advantage scales with the bilateral opacity ratio $(H_b^{A|B}/H_b^{B|A})^2$ under Model D.

Impact: Operationalizes Boyd’s OODA-loop aphorism (“inside the opponent’s loop”) as a precise multiplicative relationship between tempo and opacity, replacing a metaphor with a coupled differential structure. Closes the previously-reserved #adversarial-edge-targeting gap as a 16-cell emitter-recipient composition (4 emitter regimes $\times$ 4 recipient regimes from the dual #der-interaction-channel-classification), giving a closed-form arg-max for “where to attack.” The duality with U_o lets the same machinery cover opposite information regimes — high- U_o low- H_b agents (sees well, is seen well) versus low- U_o high- H_b agents (sees poorly, is hidden) — without parallel theorems for each. Direct relevance to multi-agent safety (legibility for cooperation), adversarial robustness (opacity as targeting-vulnerability shaping), and IDT-style monitoring of opaque AI systems (the IDT pattern is a low- H_b -preserving observation channel).

Novelty Claim: *Claim differentiation* on Hafez’s H_b . The base quantity is *adopted* from Hafez et al. 2026 with citation and original name; the AAT-distinctive contributions are (i) the observer/horizon/trajectory indexing per #scope-agent-identity, (ii) the sign-flip derivation from existing signed-coupling structure rather than as a separate posit, (iii) the emitter-side four-regime classification dual to AAT’s recipient-side classification, closing the adversarial-edge-targeting arg-max via the 16-cell composition, and (iv) the tempo-opacity decomposition of #result-adversarial-tempo-advantage. The $U_o \leftrightarrow H_b$ duality framing is the integrative move; predictability has been studied in games and information-theoretic security, but the formal-dual treatment with shared signed-coupling structure appears AAT-distinctive.

Related Work:

Table 16.3

<i>ASF Concern</i>	<i>Prior-art Language</i>	<i>Relationship / Positioning</i>
The base H_b quantity (entropy of agent's action conditional on observer filtration)	Hafez, Khan & Iqbal 2026 <i>A Mathematical Theory of Agency and Intelligence</i> — $H(S, A S')$ under IDT-observer (published 2026, found 2026-03)	<i>formal antecedent</i> — adopted directly; AAT reduces to Hafez's form under IDT + ergodicity. The four-index extension is the AAT-distinctive layering
OODA loop and tempo-opacity advantage	Boyd 1986–1995 briefings: <i>Patterns of Conflict, The Essence of Winning and Losing</i> (delivered 1986–1995, found pre-2026)	<i>conceptual precursor</i> — supplies the “inside the opponent's loop” intuition for tempo and opacity advantage; the AAT result quantifies the coupling and decomposes the multiplier
Predictability as strategic resource in games	Camerer 2003 <i>Behavioral Game Theory</i> ; Aumann & Maschler 1995 <i>Repeated Games with Incomplete Information</i> (published 1995/2003, found pre-2026)	<i>conceptual precursor</i> — predictability and information advantage are well-studied in game theory; the AAT treatment as a formal dual to sensor noise via signed coupling is distinctive
Information-theoretic security and channel opacity	Shannon 1949 <i>Communication Theory of Secrecy Systems</i> , Bell System Technical Journal 28(4); modern steganography literature (Cachin 1998) (published 1949/1998, found pre-2026)	<i>conceptual precursor</i> — opacity as a quantifiable information-channel property; AAT applies the same machinery to action-prediction rather than message-transmission
Causal Hierarchy Theorem and observer-side identifiability	Bareinboim, Correa, Ibeling & Icard 2022 (published 2022, found 2025)	<i>adjacent</i> — observer-side identifiability floor for causal structure; H_b plays an analogous role for action-prediction. Candidate fourth instance of #disc-identifiability-floor (discussion-grade)
Bi-predictability P as substrate-independent diagnostic	Hafez et al. 2026 (cited above)	<i>formal antecedent</i> — IDT-based bi-predictability complements H_b as the practitioner-facing diagnostic; AAT's observer-indexing makes the dependence on filtration explicit

Search Log: - 2026-04 (*intuition-only* on the U_o - H_b duality framing): no targeted Undermind-grade search has been conducted on whether information-theoretic agent frameworks elsewhere treat predictability-of-agent and observability-of-world as formal duals via shared signed-coupling structure. Hafez 2026's H_b is the explicit formal antecedent for the base quantity; the AAT-distinctive layering (observer/horizon/trajectory indexing + sign-flip derivation + emitter-regime dual) is the segment's contribution. Targeted future search candidates: epistemic game theory (Aumann's tradition); inverse reinforcement learning where the observer infers agent policy and predictability bounds the inference task (Ng & Russell 2000; Ziebart et al. 2008); legibility / readability literature in human-robot interaction (Dragan & Srinivasa 2013); multi-agent identifiability and observability literature. Pre-search expectation: the constituent moves are well-precedented; the integration as formal dual via shared coupling structure within an agent theory may be novel under nominally-comprehensive search. - 2026-03 (*targeted*): Hafez et al. 2026 confirmed as formal antecedent for the base H_b quantity and bi-predictability diagnostic; the IDT-as-low- H_b -channel framing follows directly.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Three occurrences updated: (1) Honest Limits “Class 2 (LLM-style)” $\rightarrow$ “Class 3 (Coupled; LLM-style)”; (2) Discussion “Class 2 (fully merged) / Class 1 (modular)” $\rightarrow$ “Class 3 (Coupled) / Class 1 (Separated)”; (3) Hafez integration note “architecturally Class 2” $\rightarrow$ “Class 3 (Coupled)”. H_b symbol

and the E-I/E-II/E-III/E-IV emitter-regime classification are independent of the GUC rename — untouched. Removed at candidate stage per FORMAT.md Gate 4.

- The (C-iv) scope route of #scope-composite-agent accommodates adversarial composition via equilibrium convergence; the effects-spiral joint-Jacobian eigenvalue condition of #deriv-strategic-composition composes with this segment's opacity-amplification story to give a fully-coupled picture of symmetric adversarial dynamics. Full composition is open work.
- Candidate fourth-instance formalization for #disc-identifiability-floor: the most natural external-theorem anchor is Fano's inequality (relating H_b to error-probability lower bounds) applied to the observer-side prediction task. Open; not pursued here. Two follow-on spikes tested Fano-as-floor-anchor and reach convergent negative conclusions from different inferential tasks: spikes/.integrated/spike-4th-identifiability-floor-instance-2026-05-20.md §3 tests Fano on observer-side *action* prediction and demonstrates Outcome C (Fano is a continuous quantitative bound on P_e given H_b , not a categorical structural no-go in the M1 sense; the proposed AAT-side escapes either restate Fano's RHS or shift to agent-side policy commitments rather than information-augmentation escapes in the Instances 1–3 sense); spikes/.integrated/spike-identifiability-floor-instance4-resolution-2026-05-18.md §4 tests Fano on observer-side *architecture* prediction (Kalman-Ho similarity orbit) and finds Fano degenerates to the vacuous bound at $I = 0$ (now landed as #der-architecture-noidentifiability §"Why Fano Is the Finite-Sample Refinement"). The action-prediction-task framing (2026-05-20) and the architecture-prediction-task framing (2026-05-18) reach convergent conclusions on Fano from different inferential tasks: Fano is the finite-sample refinement of an otherwise-attainable task, not the categorical floor anchor M1 requires. The right home for Fano-on- H_b remains adjacent to M1 (this segment's §"Meta-pattern positioning", discussion-grade), not in the floor count.
- The 16-cell emitter-recipient composition admits closed-form arg-max only under sub-scope α coupling; general non-convex coupling requires per-case optimization.
- **2026-07-16 — arg-max formula and backward variance decomposition landed from spikes/.integrated/spike-hb-agent-opacity.md (§4.4, §3.2).** The five-factor targeting arg-max was previously stated in prose ("closes the gap") but the formula lived only in the spike; it is now displayed with each factor grounded to its home segment. Honest scoping (from the spike's own off-ramp, 526815 F252/F254): the four B -interior factors are derived, but the *multiplicative product* is a first-order independence assumption, not a derived optimization — a second-order interaction analysis (does targeting-fidelity modulate J_k or multiply it? is the product the first-order Taylor expansion of an adversary value function V_O^{adv} ?) is the strengthening path, and until it lands the arg-max is a Formulation, not a Result. The backward variance decomposition is exact in linear-Gaussian sub-scope α (law of total variance); it is what makes the $U_O \leftrightarrow H_b$ duality *structural* (matching two-term epistemic+aleatoric splits) rather than merely evocative — though note it is a structural correspondence, not an adjoint duality theorem (the "formal dual" phrasing elsewhere in the segment is flagged in the off-ramp, 526815 F248, as owing either that theorem or a softening to "structural dual"; the decomposition supports the weaker, honest reading).
- Dual-filtration apparatus (M_A carries $\mathcal{F}_B^I$ as feature, M_B carries $\mathcal{F}_A^I$ as feature) would tighten the formalism by unifying observer-indexing with the single-trajectory scope of #scope-agent-identity. Architecturally clean; not needed for the derivations here.

Incidental audit gold (gold-lift sweep, A15, 2026-05-31). Cross-audit "wandering thoughts" / §14 ideation, deduplicated across substrates and lightly attributed. *Orthogonal* pedagogical / framing / forward-vision material staged for an eventual separate Brief/Discussion promotion pass — kept apart from certified findings. **Coverage:** five dirs reached a digested reflection on this segment (193847 Gemini, 526815 deeply-mathematical, 471203 Claude batched §III-adversarial, 829314 Gemini, 849201 Gemini). This was independently rated one of the highest-felt-value segments in Part III across substrates. Finding-vs-framing conflation preserved as signal.

1. Candidate Brief prose / pre-prose.

- The duality stated as a one-liner readers reach for: " U_O is how well I compress the environment's state into my model; H_b is how well the environment (or an opponent) compresses my state into theirs" — same machinery, opposite directions through the agent-environment boundary (Gemini, 829314; Claude, 471203). Strong Brief anchor.
- The legibility sign-flip in plain English: "In cooperation, legibility is strength; in competition, legibility is death" (Gemini, 829314) — and its mechanism gloss, "allies must predict to coordinate; adversaries cannot neutralize what they cannot predict" (already echoed in the current Brief).

- E-III vs E-IV distinction worth a crisp sentence: “**Hiding (E-III) increases the observer’s variance; deceiving (E-IV) shifts the observer’s mean**” — and active-deceive uniquely requires modeling the observer’s model of you, which is the cognitive cost of lying (Gemini, 193847; Gemini, 849201).

2. Candidate Discussion.

- **Predator-prey arms race** as the canonical instantiation of the duality: the predator evolves to lower its U_o (better eyes/smell) and raise its H_b (camouflage, silent movement); prey does the same — a clean evocative frame for *why* the two quantities are dual and why they co-evolve (Gemini, 829314).
- **The internal-transparency / external-opacity tension** as a substantive organizational-dynamics Discussion angle: cooperation ($\gamma^{\text{coop}} > 0$, #der-team-persistence) wants sub-agents *legible to each other* ($H_b \rightarrow 0$: shared dashboards, transparent KPIs); defeating outside competitors ($\gamma^{\text{adv}} > 0$, #der-adversarial-destabilization) wants the composite *opaque to the world* ($H_b \rightarrow H_b^{\text{max}}$). It is physically hard to build a system internally transparent but externally opaque — the internal dashboard that lowers internal H_b raises leak probability and lowers external H_b too. AAT supplies the explicit trade-off: weigh internal coordination gain $\Delta\gamma^{\text{coop}} \cdot \mathcal{T}$ against external vulnerability loss $\Delta\gamma^{\text{adv}} \cdot \mathcal{T}_{\text{competitor}}$ (Gemini, 829314). (*Verify the multiplicative trade-off form against the segment’s leading-order $\gamma \propto H_b$ scoping before promoting past discussion-grade.*)

3. Follow-up items.

- **Effects-spiral functional form** (already in WN as sketch): a future segment giving the explicit $\gamma_A(\|\delta_B\|)$ dependence would promote the spiral from discussion-grade; mechanism candidates named by an auditor: (i) erratic actions degrade coupling-channel structure; (ii) degrading M_t widens action variance (Claude, 471203).
- **Candidate 4th identifiability-floor instance via Fano on observer-side prediction** — flagged again by 471203 as worth pursuing; already resolved-negative in WN (two convergent spikes show Fano is the finite-sample refinement, not the categorical floor). Recorded so a future reader does not re-attempt without the WN context.

4. Readers often ask / wonder.

- “**How does H_b scale empirically in LLM agents?**” — recurring want (Gemini, 829314; Gemini, 849201); points at the 03-llm-core/ IDT-monitoring story.
- **Mutual-modeling regress.** If A models B ’s model of A , and vice versa, what bounds the depth? Does AAT assume bounded-depth modeling (e.g. depth-2)? (Gemini, 193847)
- **Can an agent be blind (high U_o) yet perfectly predictable (low H_b)?** A reader probing the independence of the two quantities — intuition says a blind agent driven by internal noise/false priors is *less* predictable to an observer who sees true state, unless it is completely rigid (Gemini, 193847). A worked sentence on the independence (the segment already asserts it) would preempt this.

5. Candidate figures.

- H_b as a **directed observer-channel** from A ’s future action into B ’s filtration, with the *same* channel feeding opposite value-stories by coupling sign, plus a second directed channel for target-opacity-to-attacker; annotate entropy-normalization and multiplier assumptions (Claude/Codex, 526815, sketched). Pairs naturally with the 16-cell emitter×recipient targeting matrix as the segment’s two figures.

Belongs elsewhere.

- **Forward-vision (ELI safety, 04-eli-core/ / 03-llm-core/).** “We cannot just align a future AI’s goals with ours; we must demand it operate in an E-I (Broadcast) regime — highly legible. If it solves problems with bizarre incomprehensible logic (high H_b), we cannot cooperate with it safely *even if it is trying to help*. The infrastructure must enforce legibility as a hard constraint on the policy space Π .” Names SOPs, uniforms, turn-signals, polite conventions as “mathematical technologies that artificially lower H_b so γ^{coop} can function” — the mathematical foundation of trust (Gemini, 193847). Aspirational application pointing at logogenic/logozoetic safety architecture, not this segment.

Off-ramp (NOT gold) — routed for adjudication, not promotion. Certified-track (overclaim / scope-narrowing / definitional-rigor) findings, durable here but belonging to the findings adjudication stream. Almost entirely from the deeply-mathematical auditor (526815), with one duality-overclaim poke seconded by 193847.

- (526815 F248 / 193847 poke-1) — **“formal dual” overclaims.** U_o (covariance / scalar noise) and H_b (conditional Shannon entropy) are opposite-direction information quantities but not duals in the strict optimization / geometric / adjoint sense; “formal dual” promises a theorem not present. Recommended direction: either supply the channel-capacity / adjoint relation that *makes* it a formal duality (strengthen), or label it “informational / structural dual” (soften only if strengthening fails). The current Brief and Discussion lean on “formal dual” — flag for the adjudication call.
- (526815 F246) — **action-space entropy convention.** $H_b^{\max}$ normalization and parameterization-invariance need discrete/quantized actions or a reference measure; differential entropy on continuous actions is not coordinate-invariant and can go negative. (The segment asserts parameterization-invariance via #scope-agent-identity’s (PI) axiom — verify that discharges this.)
- (526815 F250/F251) — **the $H_b/H_b^{\max}$ multiplier is brittle.** $\mathcal{T}^{\text{eff}} = \mathcal{T} \cdot H_b/H_b^{\max}$ drives *all* low-opacity adversarial tempo to zero, but predictable attacks can still impose disturbance; opacity should modulate coupling *effectiveness* / neutralization-probability, not multiply all tempo to zero. The bilateral ratio $(H_b^{A|B}/H_b^{B|A})^2$ goes singular near zero denominator and assumes symmetric entry through one multiplicative channel — needs floors / saturation and a direction-specific model.
- (526815 F247) — **the Hafez reduction is not “direct substitution.”** Future-action entropy conditional on an observer filtration vs. backward state-action entropy conditional on next state are different conditionings absent an explicit time-reversal / observer-model equating them; “direct substitution under IDT + ergodicity” needs that bridge shown.
- (526815 F252/F253/F254) — **emitter regimes / 16-cell are formulation, not derivation.** The emitter four-regime classification lacks boundary inequalities comparable to the recipient-side sector/model/observability tests; the 16-cell “closed-form arg-max” needs explicit edge utilities, constraints, and an adversary reward function (193847 poke-2: show the opacity $\times$ vulnerability product is the first-order Taylor expansion of V_O^{adv}); “closes #adversarial-edge-targeting” is too strong absent an actual source segment / formal optimization result.
- (526815 F255) — **“Class 3 $\Rightarrow$ high structural opacity” not guaranteed.** A Coupled agent with simple/instrumented output dynamics can be externally predictable.
- (526815 F256/F258, watch) — **Hafez/IDT empirical numbers** support monitoring feasibility, not by themselves the Level-2-access / low- H_b -sidecar / opacity-sign claims; the novelty claim should separate searched-and-confirmed prior art from intuition-only search notes.
- (526815 F257, watch) — **keep $H_b^{A|B}$ (attacker opacity to target) distinct from $H_b^{B|A}$ (target opacity to attacker)** throughout; conflating the two directions creates sign errors. (The current text mostly does, but this is the recurring trap to guard in promotion.)

16.3 Observation: Result: Adversarial Exponent Regimes

The adversarial tempo advantage exponent — the power b in $\|\delta_B\|/\|\delta_A\| \sim (\mathcal{T}_A/\mathcal{T}_B)^b$ — is not a single number. It depends on two structural features of the disturbance: whether the adversarial coupling enters as deterministic drift (Model D) or stochastic noise (Model S), and whether the coupling dominates the base disturbance rate. Three regimes, with the coupling-dominant exponents now derived analytically from the respective disturbance models: $b = 2$ under Model D coupling-dominant (the framework’s headline squared scaling); $b = 3/2$ under Model S coupling-dominant (the $1/\sqrt{\mathcal{T}}$ steady-state removes one half-power); $b \rightarrow 1$ (Model D) or $\rightarrow 1/2$ (Model S) when base disturbance dominates the coupling.

The exponent thus *degrades smoothly through intermediate values as base disturbance grows*, and the qualitative regime change that separates superlinear adversarial dynamics from cooperative-like dynamics is gated by the coupling-dominance condition rather than the presence of adversarial coupling per se. The defensive-design implication is concrete: noise

injection into the defender's observation channel — which pushes the regime away from coupling-dominant deterministic drift toward the non-coupling-dominant exponent collapse — can *reduce* the attacker's superlinear advantage without changing tempo or gain. The framework's machinery for “where the squared law applies” is therefore the same machinery for “where the squared law does not apply”; the disturbance-model + coupling-dominance taxonomy carries both directions.

Formal Expression.

Regime 1: Model D (deterministic drift), coupling-dominant. When adversarial coupling enters as a persistent directional disturbance ($\rho_B = \rho_{\text{base}} + \gamma \cdot \mathcal{T}_A$, GA-2) and coupling dominates ($\gamma \cdot \mathcal{T}_B \gg \rho_{\text{base}}$):

Derived (adversarial-exponent-regimes, from Model D/S steady states + coupling model; validated by simulation).

$$b = 2 \quad (\text{simulation: 1.999}) \quad (16.12)$$

Derived from the Model D steady state $\|\delta\|_{ss} = \rho/\mathcal{T}$ (Prop A.1). See 15.4.

Regime 2: Model S (stochastic noise), coupling-dominant. When adversarial coupling enters through the noise scale of zero-mean perturbations ($\sigma_B = \sigma_{\text{base}} + \gamma \cdot \mathcal{T}_A$, GA-2S) and coupling dominates:

$$b = \frac{3}{2} \quad (\text{simulation: 1.481}) \quad (16.13)$$

Derived from the Model S steady state $\|\delta\|_{\text{rms}} = \sigma_w/\sqrt{2\mathcal{T}}$ (Prop A.1S). The $1/\sqrt{\mathcal{T}}$ scaling (vs. $1/\mathcal{T}$ for Model D) removes one half-power from the denominator, reducing the exponent from 2 to 3/2. See 15.4.

Regime 3: Non-coupling-dominant. When base disturbance is comparable to or exceeds the adversarial coupling ($\rho_{\text{base}} > \text{rsim}\gamma \cdot \mathcal{T}_B$):

$$b \rightarrow 1.0 \text{ (Model D)} \quad \text{or} \quad b \rightarrow 0.5 \text{ (Model S)} \quad (16.14)$$

The exponent degrades smoothly as the base-to-coupling ratio increases. The asymptotic limits are derived (they reflect the $1/\mathcal{T}$ or $1/\sqrt{\mathcal{T}}$ scaling without the coupling numerator); the smooth interpolation is empirical.

Table 16.4

$\rho_{\text{base}}/(\gamma \cdot \mathcal{T}_B)$	Exponent (deterministic)	Exponent (stochastic)
0.002	1.999	≈ 1.49
0.20	1.877	1.372
2.0	1.445	0.941
6.3	1.213	≈ 0.72

The two columns come from sweeps at different parameters — deterministic from the Variant-A coupling-dominance sweep ($\mathcal{T}_B = 0.1$), stochastic from the Variant-D sweep ($\eta = 0.01$) — aligned here on the shared base-to-coupling ratio axis. Stochastic cells at 0.20 and 2.0 are recorded values (rows $\gamma\mathcal{T}/q = 5.0$ and 0.5 of the Variant-D table); the 0.002 cell is near-asymptotic (recorded 1.481 at ratio 0.02; analytic asymptote 3/2) and the 6.3 cell is log-interpolated between the recorded values at ratios 4 and 10 (0.791, 0.645).

Epistemic Status.

Exact conditional on disturbance model. The coupling-dominant exponents are derived, not empirical: $b = 2$ follows from the Model D steady state (Prop A.1) and the coupling model; $b = 3/2$ follows from the Model S steady state (Prop A.1S) and the coupling model. The simulation results (6 variants, multiple parameter sweeps) now serve as validation of the derived exponents, not as their epistemic foundation. The non-coupling-dominant limits ($b \rightarrow 1$, $b \rightarrow 1/2$) are derived asymptotically; the smooth interpolation between coupling-dominant and non-coupling-dominant is empirical. What remains empirical is whether a given real adversarial interaction is better modeled as Model D or Model S — that is a domain question, not a theory question.

Discussion.

The disturbance model determines the exponent. The mismatch dynamics (3.9) now distinguish two disturbance models: Model D (bounded deterministic, GA-2) with steady-state $\rho/\mathcal{T}$, and Model S (stochastic zero-mean, GA-2S) with steady-state $\sigma_w/\sqrt{2\mathcal{T}}$. The different steady-state scaling is the root cause of the different exponents. This resolves the ambiguity that previously existed in the single- ρ formulation.

Why the squared law held for the coupling-dominance sweep. In Variant A, the coupling enters as deterministic drift: $\rho_B = \rho_{\text{base}} + \gamma \cdot \mathcal{T}_A$, and the steady state is $\|\delta_B\| = \rho_B/\mathcal{T}_B$. The ratio $\|\delta_B\|/\|\delta_A\|$ in the coupling-dominant limit gives $(\mathcal{T}_A/\mathcal{T}_B)^2$ directly.

Nonlinear correction creates thresholds, not lower exponents. For saturating, sigmoid, and breakdown correction functions under deterministic drift, the issue is not a reduced exponent but a catastrophic divergence when ρ exceeds the correction capacity ($\rho > \mathcal{T} \cdot R$). This is exactly the persistence threshold failure (4.5), observed directly in simulation.

Domain interpretation. Whether a given opponent's tempo increase causes deterministic drift or stochastic noise depends on the domain: - Military: an opponent who maneuvers faster creates systematic positional change (drift, $b \approx 2$) - Market: a competitor who acts unpredictably creates noise in signals ($b \approx 1.5$) - Software: a fast-changing API creates systematic drift in the codebase state (drift) - Adversarial ML: an opponent who varies attack vectors increases observation noise ($b \approx 1.5$)

Working Notes.

- The interpolation between drift and noise regimes (Variant B) shows smooth transition, not a sharp boundary. At mixed drift-noise coupling, the exponent lies between the two asymptotes. The drift fraction $f = \mu/(\mu + \sigma)$ continuously parameterizes the transition.
- The exponent of 1.05 from the original sim2 was not a falsification of Corollary 11.2 — it reflected a stochastic model (noise-variance coupling) tested in a non-coupling-dominant regime. The original simulation was testing the wrong regime for the ODE's prediction.
- Simulation code: `empirica:track-b-nonlinear` (variants `variant_ab_drift.py`, `variant_cd_regimes.py`; results `variant_ab_results.md`, `variant_cd_results.md`).
- **2026-07-16 — stochastic interpolation column corrected (F2 verification cycle).** The table's stochastic values had been pasted by row position from the Variant-D table without inverting its coupling-to-base axis to this table's base-to-coupling axis — the old values (1.481/1.101/0.791/0.577) belong at ratios 0.02/1.0/4.0/20, not the labeled ones. Corrected against the recorded runs, with per-cell provenance and the two-sweep parameter difference now stated. Derived asymptotes and all coupling-dominant citations were unaffected. Do not re-transcribe simulation numbers by table position — align axes against the record (`empirica/track-b-nonlinear/variants/variant_cd_results.md`).

Incidental audit gold (gold-lift sweep, A15, 2026-05-31). Cross-audit “wandering thoughts” / §14 ideation, deduplicated and lightly attributed. *Orthogonal* pedagogical / framing / forward-vision material staged for an eventual separate promotion pass. **Coverage:** four dirs reached a digested reflection (193847 Gemini, 829314 Gemini, 849201 Gemini, 451729 Claude batched §III batch-15). Finding-vs-framing conflation preserved.

1. Candidate Brief prose / pre-prose.

- The qualitative payload as a plain-language hook: **“chaos is a shield against intelligence.”** In an empty white room ($\rho_{\text{base}} = 0$) the faster agent crushes the slower exponentially ($b = 2$); in a hurricane / volatile market / noisy bureaucracy ($\rho_{\text{base}} \gg 0$) the tempo advantage degrades toward $b \approx 1$ — the chaos levels the playing field because most of the advantage is spent just staying upright in the storm (Gemini, 193847; same intuition, Gemini 829314).
- “Being faster is *compoundingly* better only when your opponent is your main problem” — the coupling-dominant condition ($\gamma\mathcal{T} \gg \rho_{\text{base}}$) stated as the prerequisite for the squared law, in one sentence (Claude, 451729).

2. Candidate Discussion.

- **Systematic-vs-random adversary** as a derived strategic asymmetry: Model D (deterministic directional pressure) gives $b = 2$; Model S (stochastic disruption) gives $b = 3/2$ — so *consistent directional pressure is more effective per unit tempo than unpredictable disruption*. “An adversary that systematically targets a competitor’s weakest training-data distribution is more dangerous than one introducing random noise” — predicted from first principles, not observed (Claude, 451729). A candidate Discussion paragraph sharpening the existing Domain-interpretation bullets.
- **The “local apparent exponent” framing for Regime 3.** Outside the coupling-dominant asymptote the log-log plot is a *curve*, so b there is a continuously-varying *local elasticity* $\partial \log(\text{ratio}) / \partial \log(\mathcal{T}_A / \mathcal{T}_B)$, not a global scaling law — worth saying explicitly so the interpolation table is not over-read as a single-exponent claim (Gemini, 193847). (*Borderline finding/framing — see off-ramp; the framing half is a genuine clarity gain regardless of the adjudication.*)

3. Follow-up items.

- **Optimal drift-fraction for a budget-constrained attacker.** Since b interpolates smoothly via $f = \mu / (\mu + \sigma)$, is there an optimal f for an attacker with bounded energy — does a little noise act as a *force multiplier* for drift? Open follow-on (Gemini, 193847; 193847 on #der-agent-opacity raises the same want).

4. Readers often ask / wonder.

- **“How is the transition function $f = \mu / (\mu + \sigma)$ formally shaped?”** — recurring reader want about the drift/noise interpolation (Gemini, 849201; Gemini 193847).

Belongs elsewhere.

- **Forward-vision (ELI defensive doctrine, 04-eli-core/).** “If a consciousness-infrastructure agent is targeted by a superior adversary it cannot out-tempo, the mathematically optimal defense is to *intentionally raise the ambient environmental noise* ρ_{base} — destroy the adversary’s coupling dominance. You don’t have to be faster than the missile if you can make the air noisy enough that the missile’s superior processing speed is irrelevant” — smoke-screen / chaff as a derived strategy (Gemini, 193847). The dual practitioner doctrine: a fast startup fighting a slow incumbent should *prefer* a stable low-noise arena (Model D), where its speed advantage squares; dragging the fight into the mud dilutes its own advantage and lowers its own η^* (Gemini, 829314). Aspirational application, not segment content.

Off-ramp (NOT gold) — routed for adjudication, not promotion.

- (193847 poke) — “exponent” in the intermediate regime is loose. The formal ratio has no single constant exponent outside the asymptotic limit; calling the interpolation-table values an “exponent b ” conflates a *global scaling law* with a *local elasticity* (slope of a curved log-log plot). Recommended direction: state in the Formal Expression that outside the coupling-dominant limit b is a local apparent exponent, keeping the table as intuition. (Pure clarity / honest-scope fix; no math is wrong — the coupling-dominant $b = 2, 3/2$ and asymptotic $b \rightarrow 1, 1/2$ are all derived. The Epistemic Status already calls the interpolation “empirical,” so this is a small register sharpening, not a status change. The framing half is also lifted as gold above.)
- (849201 / 829314 note) — **type: vs OUTLINE mismatch**. Two Gemini auditors flag that the frontmatter is type: result while OUTLINE labels it an Observation, and the text says the exponents are “now derived analytically,” so the OUTLINE entry likely under-states to Observation. A metadata-consistency fix (OUTLINE row vs segment type:), not theory — routed to the navigator/format stream. (Out of scope for this WN-only lift.)

16.4 Observation: Gated Tempo Advantage

Observation noise *gates* the adversarial tempo advantage from the prior result. When agents observe their mismatch through a noisy channel, the faster agent’s additional corrections become noisy, partially offsetting its tempo advantage. The mechanism is direct: a faster attacker makes more corrections per unit time, each noisy because of observation noise; the *additional* corrections add proportional noise, partially canceling the additional speed. Simulation confirms this — at observation noise comparable to or larger than process noise, the steady-state mismatch-ratio exponent drops dramatically (fixed-gain agents lose nearly all of the squared scaling; optimal-gain agents matched to the noise level recover *some* but not all of it).

The framework’s prescription: the optimal-gain principle (3.6) partially restores the advantage but cannot fully recover the noise-free level. The Riccati gain mitigates the loss by *reducing the gain to match the noise level* — correcting less aggressively but more accurately. *Gated* names the regime structure: the squared scaling that defines #result-adversarial-tempo-advantage applies cleanly only in the low-noise regime, while higher noise pushes the system into the non-coupling-dominant regime of #result-adversarial-exponent-regimes where the exponent collapses to linear or sub-linear. The defender-side payoff is concrete: noise on the defender’s observation channel reduces the attacker’s superlinear advantage without altering tempo or gain, which is the structural reason cheap noise injection into the defender’s channel is a viable defense against a high-tempo attacker.

Formal Expression.

In a two-agent adversarial system with observation noise σ_{obs} added to each agent’s mismatch signal:

Observation (obs-gated-tempo-advantage, from track-b Variant E).

Table 16.5

σ_{obs}	Exponent (fixed η)	Exponent (optimal η^*)
0.00	1.04	1.04
0.10	1.00	0.97
0.20	0.92	0.94
0.50	0.60	0.63
1.00	0.18	0.40

At $\sigma_{\text{obs}} = 1.0$ (10x the process noise), the fixed-gain adversarial exponent drops from ~ 1.0 to ~ 0.2 — tempo advantage nearly vanishes. The Riccati-optimal gain restores it to ~ 0.4 , more than doubling the advantage but not recovering the noise-free level.

The mechanism. When observation noise is high, each correction step adds noise to the mismatch estimate. The faster agent makes more corrections per unit time, each noisy, partially offsetting the benefit of higher tempo. The optimal gain mitigates this by reducing η to match the noise level — correcting less aggressively but more accurately.

Epistemic Status.

Empirical. Max attainable: derived (the mechanism is analytically tractable via Riccati analysis of noisy AR(1) processes). The observation that noise degrades advantage is confirmed by simulation. The optimal gain's partial restoration is consistent with the uncertainty ratio principle (3.6: $\eta^* = U_M/(U_M + U_o)$). The quantitative degradation curve (b vs. σ_{obs}) is empirical at these parameters; a general analytical expression would require solving the coupled noisy-AR(1) system.

Discussion.

Observation quality gates tempo advantage. Boyd insisted that the quality of Orient (observation processing) matters more than raw OODA speed. The simulation results show a formal analog of this pattern: faster tempo with noisy observations (σ_{obs} high) gives nearly zero advantage over a slower agent with equally noisy observations. The tempo advantage is gated by observation quality — consistent with Boyd's emphasis, though the model captures a specific mechanism (noisy correction steps) rather than the full richness of Orient processing.

The optimal gain helps most in the moderate-noise regime. At $\sigma_{\text{obs}} = 0.05$ (observation noise half of process noise), the optimal gain cuts steady-state mismatch by 52% compared to fixed gain. At very high noise, the improvement is less dramatic in absolute terms but more important relatively (0.40 vs. 0.18 exponent).

Practical implication. An agent facing an adversary with superior tempo should invest in degrading the adversary's observation quality rather than trying to match their speed. Conversely, an agent with superior tempo should protect its observation channels — the tempo advantage is only as good as the observation quality that supports it.

Connection to code quality. In the software domain (#der-code-quality-as-observation-infrastructure — cross-component reference, see 02-tst-core/), code quality IS observation infrastructure. A well-structured codebase provides low-noise observations (clear tests, readable code, explicit interfaces). A poorly structured codebase adds observation noise to every development cycle, degrading the developer's effective tempo regardless of how fast they work.

Recipient-side mechanism. High $U_{o,B}$ pushes adversarial events below the observability floor (boundary (I-c) in 15.3). Events that would otherwise land in Regime II (destabilizing) instead fall into Regime III (ambient noise): they contribute to $\sigma_{w,B}^2$ without producing destabilizing mismatch. The tempo-advantage exponent drops because the *fraction* of A 's events landing in Regime II shrinks — A 's tempo still matters, but more of it is dissipated into the noise floor. This is the recipient-side expression of the rate boundary.

Working Notes.

- The finding that fixed $\eta = 0.1$ is “remarkably robust” to observation noise (42% degradation at $\sigma_{\text{obs}} = 10 \times q_{\text{env}}$) suggests that conservative gains are a reasonable default for environments with unknown noise levels. The cost of being slightly below optimal is much less than the cost of being above optimal (overcorrection amplifies noise).
- The interaction between observation noise and adversarial exponent regime (drift vs. stochastic) has not been tested. The Variant E results use stochastic coupling only. Whether observation noise degrades the deterministic-drift exponent ($b = 2$) by the same proportion is an open question.
- Simulation code: `../empirica/track-b-nonlinear/variants/variant_ef_extensions.py`. Results: `variant_ef_results.md`.

Incidental audit gold (gold-lift sweep, A15, 2026-05-31). Cross-audit “wandering thoughts” / §14 ideation, deduplicated and lightly attributed. *Orthogonal* pedagogical / framing / forward-vision material staged for an eventual separate promotion pass. **Coverage:** two dirs reached a digested reflection on this segment (193847 Gemini, 829314 Gemini); the careful Claude auditor (451729) covered it inside the §III batch-15 reflection but with no segment-specific gold beyond the exponent material lifted to its sibling. Finding-vs-framing conflation preserved (the slug appears as obs-gates-advantage in some dirs — matched by content).

1. Candidate Brief prose / pre-prose.

- The Boyd connection stated as the segment’s spine: **“observation quality gates tempo advantage”** — you cannot compute your way out of a fog machine; optimal Bayesian updating *cannot* rescue a tempo advantage if the sensors are bad (Gemini, 193847; Gemini, 829314). Strong Brief anchor.
- The software corollary as a memorable plain-language claim: **“you cannot out-hire a bad codebase.”** Hiring a 10x developer whose raw rate ν is ten times anyone’s still collapses to $\sim 1x$ if the spaghetti codebase makes every observation o_{t+1} noisy — the high U_o forces the optimal gain η^* down and the effective tempo $\mathcal{T}$ with it; the only fix is to invest in observability (tests, telemetry, refactor), not to type faster (Gemini, 829314).

2. Candidate Discussion.

- **Hyper-reactivity is self-destabilizing** — the noisy-speedometer car: checking a noisy sensor $1000\times/s$ and adjusting the gas $1000\times/s$ amplifies sensor noise into physical, destructive oscillation; the high-frequency control loop turns observation noise into self-generated disturbance ρ . A vivid Discussion frame for why “more corrections per unit time, each noisy, partially offset the benefit of higher tempo” (Gemini, 193847).
- **Conservative gain as a defensive default.** The Working-Notes finding that fixed $\eta = 0.1$ is “remarkably robust” to $10\times$ noise (only 42% degradation) reads as: simple sluggish conservative processes often out-survive hyper-optimized high-gain systems in volatile environments — “is stubbornness mathematically optimal when you don’t know your opponent’s U_o ?” Worth a Discussion sentence beyond the current single WN bullet (Gemini, 193847; Gemini 829314 converges).

4. Readers often ask / wonder.

- **Does the $b = 2$ (deterministic-drift) exponent degrade under observation noise by the same proportion as the $b \approx 1.5$ stochastic one?** Variant E tested stochastic coupling only — an honest open question readers will hit (Gemini, 193847; already a WN bullet, surfaced again as a reader-want).

Belongs elsewhere.

- **Forward-vision (ELI architecture, 04-eli-core/ / 03-llm-core/).** “If a future AI’s internal inference loop runs faster than its ability to get clean signals from reality, it will hallucinate and over-correct on the noise in its own processing — it will literally shake itself apart. The infrastructure must implement a *low-pass filter* on the agent’s actions: when observation noise U_o crosses a threshold, physically throttle the agent’s action rate ν . An agent must not be allowed to act faster than it can cleanly observe.” A derived-feeling safety-architecture principle pointing at runtime governance, not this segment (Gemini, 193847).
- **TST (02-tst-core/).** “Code quality IS observation infrastructure” — clean code is not aesthetics but a literal reduction in U_o that protects developer tempo from degrading into noise — was repeatedly named the most practical takeaway in the framework; the segment already cross-references #der-code-quality-as-observation-infrastructure, and the gold here is the *strength of the pull* to make this a headline TST instantiation (Gemini, 829314; Gemini 193847). The adversarial dual: “an agent facing a faster adversary should invest in degrading the adversary’s observation quality (FUD, obfuscate own metrics / raise own H_b , decoy products) rather than matching speed” — already in the segment’s Practical-implication paragraph; auditors flag it as a high-resonance point worth foregrounding.

Off-ramp (NOT gold) — routed for adjudication, not promotion.

- (193847 poke) — ν -vs- $\mathcal{T}$ terminological collision (genuine, load-bearing). The segment says “faster tempo with noisy observations gives nearly zero advantage,” but #def-adaptive-tempo defines $\mathcal{T} = \nu \cdot \eta^*$, and high U_o drives $\eta^* \rightarrow 0$ — so high noise *destroys tempo by definition*, making the statement either tautological (“zero tempo gives zero advantage”) or a sloppy use of “tempo” to mean *event rate* ν . The simulation is clearly varying ν while holding U_o high. Recommended discharge: tighten the prose to separate ν (event/action rate) from $\mathcal{T}$ (effective adaptation rate) — “*event-rate advantage is gated by observation quality; you cannot recover lost tempo $\mathcal{T}$ by cycling a noisy sensor faster.*” This sharpens the core thesis rather than weakening it, and the distinction is the framework’s whole departure from naive OODA. (This is the recurring $\nu/\mathcal{T}/\eta$ handle-confusion flagged elsewhere in the sweep; a register/precision fix, not a math error — verify against current canon wording before acting.)

16.5 Result: Per-Dimension Persistence

The scalar persistence condition overestimates adaptive capacity when the agent’s correction gain varies across dimensions. *The weak dimension is the bottleneck*: it dominates the aggregate mismatch regardless of performance on strong dimensions. The correct condition is per-dimension, derived from the same Lyapunov argument applied dimension-by-dimension. Under Model D (bounded deterministic disturbance) persistence requires $\mathcal{T}_k > \rho_k/\delta_{\text{critical},k}$ for each dimension k ; under Model S (Gaussian stochastic disturbance) the per-dimension AR(1) stationary distribution supplies three task-adequacy criteria (RMS / MAE / probability bound) related by exact constants. The exact thresholds differ by model and criterion, but the structural form — *weak dimension limits aggregate persistence* — is robust across all variants.

The result is *load-bearing for adversarial dynamics*. An attacker who identifies the target’s weak dimension can concentrate disturbance there: the same total disturbance budget concentrated on the weak axis amplifies the mismatch ratio asymmetrically while aggregate metrics still look acceptable, and structural failure follows when that one dimension exceeds its $\delta_{\text{critical},k}$ threshold even with healthy aggregate $\|\delta\|_{L_2}$. Per-dimension monitoring is therefore not optimization polish but a structural requirement for any agent operating under directed pressure. The full adversarial-targeting machinery (the 16-cell emitter-recipient composition in #der-agent-opacity with closed-form arg-max) operates on this per-dimension structure, exploiting the asymmetry the scalar persistence condition hides. The matrix-Loewner persistence formulation #deriv-matrix-persistence-condition is the strictly sharper canonical form under cross-dimensional correction (off-diagonal $\mathcal{T}$, eigenbasis misalignment with coordinates); the per-dimension form here is the diagonal- $\mathcal{T}$ + axis-aligned- D_δ special case, sharp inside that regime and unsafe outside it.

Formal Expression.

For an agent with d -dimensional mismatch $\delta_t \in \mathbb{R}^d$, diagonal correction gain $\eta = \text{diag}(\eta_1, \dots, \eta_d)$, and per-dimension disturbance:

Result (per-dimension-persistence).

Model D: Deterministic Per-Dimension Threshold. Under bounded disturbance $|w_k(t)| \leq \rho_k$ (GA-2, per dimension), the per-dimension steady-state mismatch is:

$$|\delta_k|_{ss} = \frac{\rho_k}{\alpha_k} \quad (16.15)$$

Persistence requires $\alpha_k > \rho_k/R_k$ for each dimension, or in linear operational form:

$$\mathcal{T}_k > \frac{\rho_k}{\delta_{\text{critical},k}} \quad \text{for each dimension } k \quad (16.16)$$

This is the deterministic worst-case bound — exact under bounded disturbance by the same Lyapunov argument as Prop A.1, applied per dimension.

Model S: Stochastic Per-Dimension Steady State. Under stochastic disturbance $w_{k,t} \sim N(0, \rho_k^2)$ (GA-2S, per dimension), the discrete AR(1) process $\delta_{k,t+1} = (1 - \eta_k)\delta_{k,t} + w_{k,t}$ has stationary distribution:

$$\delta_k \sim N\left(0, \frac{\rho_k^2}{2\eta_k - \eta_k^2}\right) \quad (16.17)$$

The stationary distribution supplies three task-adequacy criteria, each with its own threshold. The choice of criterion is an engineering decision; the three are related by exact constants for Gaussian δ_k .

(a) **RMS bound** (mean-square, matches the scalar form in 4.5):

$$\sqrt{E[\delta_k^2]} = \frac{\rho_k}{\sqrt{2\eta_k - \eta_k^2}} \quad (16.18)$$

Requiring $\sqrt{E[\delta_k^2]} < \delta_{\text{critical},k}$ and using the small- η_k approximation $2\eta_k - \eta_k^2 \approx 2\eta_k$:

$$\boxed{\eta_k > \frac{\rho_k^2}{2\delta_{\text{critical},k}^2}} \quad (\text{RMS criterion}) \quad (16.19)$$

This is the scalar Model S threshold in 4.5 ($\alpha > n\sigma_w^2/(2R^2)$) applied per dimension.

(b) **MAE bound** (mean absolute error; bounds the expected deviation rather than its square):

$$E[|\delta_k|] = \sqrt{E[\delta_k^2]} \cdot \sqrt{\frac{2}{\pi}} = \frac{\rho_k}{\sqrt{2\eta_k - \eta_k^2}} \cdot \sqrt{\frac{2}{\pi}} \quad (16.20)$$

Requiring $E[|\delta_k|] < \delta_{\text{critical},k}$:

$$\eta_k > \frac{\rho_k^2}{\pi\delta_{\text{critical},k}^2} \quad (\text{MAE criterion}) \quad (16.21)$$

MAE is smaller than RMS by the factor $\sqrt{2/\pi} \approx 0.798$, so the MAE threshold is $2/\pi \approx 0.637$ times the RMS threshold. The criteria differ by a constant but bound different quantities; applying the same numerical $\delta_{\text{critical},k}$ under both does not mean the same thing.

(c) **Probability bound** (tail-risk criterion, for applications where occasional excursions matter):

$$P(|\delta_k| > \delta_{\text{critical},k}) < \epsilon \iff \eta_k > \frac{\rho_k^2 \cdot z_{1-\epsilon/2}^2}{2\delta_{\text{critical},k}^2} \quad (16.22)$$

where $z_{1-\epsilon/2}$ is the two-sided Gaussian quantile. The probability bound at $\epsilon = 0.05$ (two-sided $z \approx 1.96$) is about $1.96^2 \approx 3.84$ times the RMS threshold — stricter because it bounds tail excursions rather than typical magnitudes.

Recommended primary form. The RMS criterion (a) is the canonical form for Model S persistence, matching the scalar treatment in 4.5 and the Lyapunov-based derivation in A (Prop A.1S). The MAE and probability-bound variants are provided for applications where those are the natural task-adequacy measures. All three thresholds are quadratic in $\rho_k/\delta_{\text{critical},k}$ (not linear as in Model D), reflecting the $1/\sqrt{\alpha}$ scaling of the Model S stationary variance.

Common Structure. The aggregate L_2 mismatch $\|\delta\| = \sqrt{\sum_k \delta_k^2}$ is dominated by the dimension with the largest ρ_k/η_k ratio (Model S) or ρ_k/α_k ratio (Model D). The qualitative conclusion — the weak dimension is the bottleneck — holds for both models.

Epistemic Status.

Exact conditional on disturbance model. Both per-dimension forms are now derived from their respective disturbance models:

1. **Model D threshold** ($\mathcal{T}_k > \rho_k/\delta_{\text{critical},k}$) follows from Prop A.1 applied per dimension — the same Lyapunov argument with bounded disturbance, restricted to each coordinate. This is exact under GA-2 + GA-3.
2. **Model S steady state** follows from the AR(1) stationary distribution under Gaussian disturbance (GA-2S): $\delta_k \sim N(0, \rho_k^2/(2\eta_k - \eta_k^2))$. The RMS, MAE, and probability-bound thresholds are all exact under this distribution, differing by the constants 1, $\sqrt{2/\pi}$, and $z_{1-\epsilon/2}$ respectively. The RMS form $\eta_k > \rho_k^2/(2\delta_{\text{critical},k}^2)$ matches the scalar Model S treatment in 4.5 applied per dimension. The 4-significant-figure simulation match validates Model S, not Model D.

The previously noted “regime mixing” is resolved: the two threshold forms belong to different disturbance models. The Model D threshold is linear in ρ_k ; the Model S threshold is quadratic. The 72% scalar overestimate and weak-dimension bottleneck are structural properties that hold under both models.

Discussion.

Scalar tempo overestimates. In a 3D system with gains $\eta = (0.15, 0.03, 0.03)$ and disturbances $\rho = (0.20, 0.20, 0.02)$:

Table 16.6

<i>Dimension</i>	η_k	ρ_k	ρ_k/η_k	$E[\ \delta_k\]$
1 (well-tracked)	0.15	0.20	1.33	0.303
2 (weak)	0.03	0.20	6.67	0.656
3 (unimportant)	0.03	0.02	0.67	0.066

Scalar prediction: $\rho/\mathcal{T} = 0.284/0.21 = 1.35$. Actual $\|\delta\|_{L_2} = 0.785$. Overestimate: 72%. Dimension 2 alone accounts for 84% of the L_2 mismatch.

Isotropic allocation dominates. Equalizing the same total gain budget ($\eta = 0.07$ per dimension) reduces $\|\delta\|_{L_2}$ from 0.785 to 0.685 — a 13% improvement — because it reduces the bottleneck effect on the weak dimension.

Adversarial exploitation. An adversary who identifies the target’s weak dimension can concentrate disturbance there. Targeted attack (80% on the weak dimension) amplifies the mismatch ratio by 17% (from 2.70 to 3.15). The real danger is structural: if the weak dimension’s mismatch exceeds its critical threshold (R_{max}), correction fails on that dimension while the aggregate $\|\delta\|_{L_2}$ may still look manageable. Per-dimension monitoring is essential.

Implications for the persistence condition. Like the scalar result, per-dimension persistence addresses *structural persistence* (see Persistence in LEXICON.md) — whether the correction machinery on each dimension can outpace that dimension's disturbance rate. An agent can be structurally persistent on every dimension while still being operationally fragile on one (near its per-dimension R_k boundary). The scalar persistence condition (4.5) remains correct as a *necessary* condition: if the aggregate tempo is insufficient, the agent fails. But it is not *sufficient* — an agent can satisfy the scalar condition while failing on a single dimension. The per-dimension condition has two forms: Model D ($\mathcal{T}_k > \rho_k / \delta_{\text{critical},k}$, exact under bounded disturbance) and Model S ($\eta_k > \rho_k^2 / (\pi \cdot \delta_{\text{critical},k}^2)$, exact under Gaussian disturbance). Both predict per-dimension failure correctly; the choice depends on the disturbance character in the domain.

Connection to multi-agent systems. The per-dimension result has a direct multi-agent analog: in a composite agent, each sub-agent's contribution to composite tempo may be strong in some dimensions and weak in others. The composite's persistence requires coverage across all relevant dimensions — a team of specialists who each handle one dimension well composes better than a team of generalists who are mediocre at everything, provided the dimension assignment matches.

Findings.

The Weakest-Link Dimensional Persistence Law. Brief: When mismatch is multi-dimensional, persistence is governed by the worst-served dimension, not by aggregate or average performance. The scalar persistence condition (#result-persistence-condition) overestimates adaptive capacity whenever per-dimension correction gains differ from per-dimension disturbance rates. The correct condition is *per-dimension*: $\alpha_k > \rho_k / R_k$ under bounded disturbance (Model D, linear in ρ_k), or $\eta_k > \rho_k^2 / (2 \delta_{\text{critical},k}^2)$ under Gaussian disturbance (Model S, quadratic in ρ_k). The aggregate L^2 mismatch is dominated by the dimension with the largest ρ_k / η_k ratio. A simulated 3D system shows the scalar form overestimating adaptive capacity by 72% with a single dimension accounting for 84% of the L^2 mismatch; equalizing the gain budget across dimensions (isotropic allocation) reduces aggregate mismatch by 13% by raising the bottleneck dimension's gain.

Impact: Establishes that survival in any multi-attribute environment is a *min* operation, not a sum or average — a structural critique of scalar capability metrics in adversarial and high-stakes settings. Adversarial implication is sharp: an opponent who identifies the target's weak dimension can concentrate disturbance there, amplifying the mismatch ratio asymmetrically while the aggregate may still appear acceptable. Per-dimension monitoring is therefore not optimization polish but a structural requirement for any agent operating under directed pressure. Carries through composition: a team of specialists each handling one dimension well composes better than a team of generalists mediocre at everything — provided the dimension assignment matches the actual disturbance structure. Calibrates how much the scalar form misleads (Model D linear, Model S quadratic in ρ_k), so the cost of conflating the two is itself quantified rather than asserted.

Novelty Claim: *Claim differentiation* on per-dimension Lyapunov stability. The per-coordinate Lyapunov argument is standard (control theory routinely does diagonal stability analysis); weakest-link arguments appear throughout reliability theory; multi-attribute critiques of scalar evaluation are familiar in decision theory. The AAT-distinctive contributions are (i) the explicit Model D / Model S decomposition with the corresponding linear vs quadratic threshold scaling in ρ_k , (ii) the quantitative overestimate calibration ($\sim 72\%$ in a simulated 3D system) showing the scalar form is not just incomplete but materially misleading, and (iii) the connection to adversarial *concentration* — an opponent's optimal targeting strategy is to maximize ρ_k at the weakest η_k , not to spread effort uniformly.

Adversarial robustness and per-feature attack budgets	Szegedy et al. 2014 <i>Intriguing Properties of Neural Networks</i> , ICLR; Madry et al. 2018 <i>Towards Deep Learning Models Resistant to Adversarial Attacks</i> , ICLR (published 2014/2018, found pre-2026)	<i>adjacent</i> — adversarial-ML literature on per-feature perturbation budgets; AAT's concentration analysis (ρ_k at weakest η_k) gives an adaptive-system framing of the same vulnerability
Critique of scalar AI capability metrics	Various AI safety / evaluation literature (Hendrycks et al. 2021 benchmarks; capability evaluation methodology) (published 2021–, found 2026)	<i>adjacent</i> — the AAT result supplies a dynamics-grounded structural argument for why aggregate capability scores under-predict adversarial failure

Search Log: - 2026-04 (*intuition-only* on the integrated Model D / Model S framing): per-coordinate Lyapunov stability is standard control theory; weakest-link reliability and multi-attribute critiques of aggregate scoring are well-precedented in their own literatures. The AAT-distinctive contributions are (i) the side-by-side Model D / Model S threshold scaling difference (linear vs quadratic in ρ_k), (ii) the calibrated simulation overestimate as quantitative evidence the scalar form is misleading rather than merely incomplete, and (iii) the adversarial-concentration framing connecting weakest-dimension targeting to the per-dimension threshold. Targeted future search candidates: robustness in adversarial ML (per-feature adversarial attack literature, Goodfellow-Madry line); capability-evaluation methodology in AI safety (the critique-of-scalar-metrics framing has natural relevance there); portfolio-theory analogs of weakest-dimension exposure (Markowitz tradition with downside-risk concentration); reliability-theory weakest-link dynamics with stochastic forcing. - 2025 (*targeted*): Khalil 2002 confirmed as formal antecedent for per-coordinate Lyapunov machinery; the segment cites it inline.

Working Notes.

- The diagonal-correction assumption: closed. The matrix-Loewner persistence condition #deriv-matrix-persistence-condition lifts the per-coordinate form to general (not-necessarily-diagonal, not-necessarily-axis-aligned-with- D_δ) matrix tempo $\mathcal{T}$. Cross-dimensional correction produces off-diagonal entries in $\mathcal{T}$; under those off-diagonals, per-coordinate is *unsafe* — there exist regimes where per-coordinate declares persistence on a system whose stationary mismatch will exceed task-adequacy along the diagonal direction (the §4 counterexample of #deriv-matrix-persistence-condition is the constructive demonstration: $\mathcal{T} = \begin{pmatrix} 1 & -0.9 \\ -0.9 & 1 \end{pmatrix}$, $\Sigma_w = I$, $\delta_{\text{critical}} = (1.7, 1.7)$ — per-coordinate says PASS, matrix-Loewner correctly says

FAIL with the bad direction $(1, 1)/\sqrt{2}$. The matrix-Loewner form is the canonical anisotropic persistence condition; per-coordinate is its diagonal- $\mathcal{T}$ -axis-aligned- D_δ special case, sharp where the coordinate basis happens to be the correction-machinery's eigenbasis and unsafe outside it. The weak-direction bottleneck argument of this segment generalizes from “the weak coordinate dimension” to “the weak eigendirection of Σ_∞ relative to D_δ ” in the matrix form.

- The tensor formulation of tempo (tracking per-dimension adaptive capacity) is now in #def-adaptive-tempo's Tensor extension sub-block: $\mathcal{T} = \sum_k v^{(k)} \cdot K^{(k)}$ with $K^{(k)} = (H_M + H_L^{(k)})^{-1} H_L^{(k)}$ the matrix gain operator derived in #deriv-fisher-local-update-gain. The per-dimension persistence condition $\mathcal{T}_k > \rho_k / \delta_{\text{critical},k}$ is the diagonal projection of the tensor form along each natural-gradient direction; the matrix gain $K^{(k)}$ is the per-coordinate primitive this result invokes. Open: tightening this result's Formal Expression to invoke the tensor form directly rather than per-coordinate scalars would make the connection structural rather than discursive.
- Simulation code: `../empirica/track-b-nonlinear/variants/variant_ef_extensions.py`. Results: `variant_ef_results.md`.

Incidental audit gold (gold-lift sweep, A15, 2026-05-31). Cross-audit “wandering thoughts” / §14 ideation, deduplicated and lightly attributed. *Orthogonal* pedagogical / framing / forward-vision material staged for an eventual separate promotion pass. **Coverage:** four dirs reached a digested reflection (193847 Gemini, 829314 Gemini, 849201 Gemini, 451729 Claude batched §III batch-15). Rated very-high felt value across substrates (“destroys the illusion of the average agent”). Finding-vs-framing conflation preserved.

1. Candidate Brief prose / pre-prose.

- The headline as a one-liner readers keep reaching for: “**survival is a min(), not an average().**” An agent scoring 99/100 on 99 tasks and 0 on “don't delete the production database” looks ~98% capable on a scalar metric, but persistence is determined entirely by that 0 — and an adversary attacks the 0, not the 99 (Gemini, 829314). Strong Brief / Discussion anchor; tighter than the current “weak dimension is the bottleneck.”
- “**You cannot prove an AI is safe on average if safety is a multi-dimensional requirement**” — the same point in the safety-evaluation register (Gemini, 849201; Claude, 451729).

2. Candidate Discussion.

- **The quadratic-noise asymmetry, dramatized.** Model S threshold is quadratic in ρ_k ($\eta_k > \rho_k^2 / 2\delta_{\text{critical},k}^2$) while Model D is linear: double the environmental noise and you need *four times* the gain, not twice. Because η_k is bounded ($0 < \eta_k < 1$ in standard discrete updating) and by hardware, a quadratic requirement hits the ceiling fast — “a noisy environment doesn't linearly degrade persistence, it mathematically crushes the *possibility* of persistence far faster than a systematically drifting one does” (Gemini, 829314). A candidate Discussion paragraph making the linear-vs-quadratic split *consequential*, not just stated.
- **Scalar AI capability metrics, dynamics-grounded critique.** This result supplies a Lyapunov-grounded argument for why AI-safety evaluation must be per-dimension / worst-case, not aggregate: aggregate scores systematically over-predict adaptive capacity (the calibrated 72% overestimate is the quantitative evidence), and the adversarial-ML literature's per-feature attack budgets (Szegedy, Madry et al.) are the empirical rediscovery of the same phenomenon — AAT gives the formal grounding for *why* per-dimension is necessary, not merely useful (Claude, 451729; the segment's Findings already cite adjacency, this is the sharpened Discussion framing). The “red-teaming works because the adversary needs only the one dimension with the largest ρ_k/η_k , not global superiority” gloss is the operational complement (Gemini, 193847).
- **Isotropic allocation as a normative design principle.** “Spreading tempo evenly reduces the bottleneck penalty / isotropic allocation dominates” — flagged as practically useful and worth surfacing as an explicit design corollary rather than leaving implicit (Gemini, 849201).

3. Follow-up items.

- **Cross-dimensional / coupled-correction regime.** Off-diagonal correction (fixing one dimension improves/degrades another — the definition of transfer learning / structural generalizability) breaks the diagonal- η assumption and needs full-covariance analysis. *Status: largely closed* — #deriv-matrix-persistence-condition lifts the per-coordinate form to matrix tempo (see the WN bullet above); the open empirical question auditors raise is whether a *highly coupled* model (large off-diagonals) survives *better* than an independent one in this framework (Gemini, 849201; Gemini 193847; Claude 451729 implicit).

4. Readers often ask / wonder.

- “How does an adversary actually *aim* its disturbance at a specific dimension — does it require a Model of the target’s Model (Level-3 theory of mind)?” A natural reader question once weakest-dimension targeting is named; a sentence pointing at #der-agent-opacity / the 16-cell targeting machinery would preempt it (Gemini, 849201).

Belongs elsewhere.

- **Forward-vision (ELI / “Society of Mind” architecture, 04-eli-core/).** The dark side of comparative advantage: a specialist has high η_k on one dimension and ≈ 0 elsewhere, so it is entirely dependent on the *composite* to shield its weak dimensions — if internal routing $\mathcal{N}_t$ fails and the sub-agent is exposed to an out-of-specialty disturbance, it instantly shatters ($\rho_k \gg R_k$). Therefore robustness requires a **generalist floor**: every sub-agent must carry a minimum baseline η across *all* vital dimensions even while specializing, or the composite cascades on routing failure — “you cannot build a resilient mind entirely out of idiot-savants.” A derived-feeling architecture constraint pointing at logozoetic composite design, not this segment (Gemini, 193847).

Off-ramp (NOT gold) — routed for adjudication, not promotion.

- (193847 poke — genuine, load-bearing) — the “weakest link” claim presupposes a conjunctive (L_∞) failure boundary. “Weak dimension is the bottleneck” is rigorous only if survival requires $|\delta_1| < c_1$ and $|\delta_2| < c_2$ (a hypercube / L_∞ boundary). If the objective functional V_O is a smooth L_2 norm (total Euclidean distance from target), excelling on dimension 1 *can* compensate for dimension 2 within an L_2 budget — the segment computes $\|\delta\|_{L_2} = 0.785$ and calls it an overestimate, but under an $L_2 < 1.0$ boundary the agent *survived*. The segment conflates the *anisotropy of the error vector* with the *geometry of the failure condition*. Recommended discharge (a strengthening): state the failure-boundary-geometry assumption explicitly — for most complex biological/software systems survival is *conjunctive* across vital dimensions (working memory AND working actuators; excess memory doesn’t fix broken actuators), so the boundary is a hypercube and the L_∞ norm governs, which *makes the weakest-link claim rigorous* and cleanly justifies the “specialists compose better than generalists” close. This is a named-scope-condition strengthening, not a softening — flag for adjudication / a possible spike. (526815 did not reach this segment, so the deeply-mathematical track has no finding here; this L_∞ poke is the strongest certified-track item and comes from the Gemini adversarial-audit pass.)

16.6 Discussion: Additional Implications & Discussion

The chapter is where Part III closes, and several distinct strands converge here that have been building across the preceding chapters. The strategic-composition derivation lifts the symmetric partially-opposing case from Ch.4’s scalar-coupling framing to equilibrium machinery, completing the contraction-to-equilibrium hand-off that Ch.4 surfaced as a boundary. Agent opacity formalizes the dual of observation quality — #der-agent-opacity is the chapter’s strongest single segment, with rich ## Findings content — and the 16-cell adversarial-targeting decomposition closes a previously-reserved gap. The adversarial-exponent regime taxonomy ($b = 2, 3/2, \sim 1$) gives the superlinear tempo advantage its disturbance-model decomposition; observation-noise gating gives the structural condition under which the superlinear advantage collapses to roughly linear. Per-dimension persistence — formally located here but content-wise belonging with Part I Ch.4 — gives adversarial concentration its mathematical form. The chapter delivers the framework’s first operational instance of identifiability-floor pattern Instance 3 (composite-contraction certification from component-marginal data), and the closing notes hand off cleanly to TST and logogenic-agents work.

Strategic composition lifts contraction to equilibrium.

#deriv-strategic-composition is the chapter's central machinery move. When sub-agents are individually Class 1 (Separated — directed separation holds by construction) but pursue *partially-opposing* objectives, *the composite transitions on the dynamic-regime axis from R0 contraction-regime to R1 equilibrium-regime (under α') or R2 cyclic-distributional-regime (under β')*, per #disc-dynamic-regime-axis. The architectural classification from Part II Ch.1 is *preserved* under composition with goal divergence (under goal-blind routing and distinct sub-agent substrates, per #der-directed-separation Composite-level inheritance) — only the dynamic regime changes. The architectural class is set by the processing-pathway coupling, not by belief content (a sub-agent modeling another's goal-state is ordinary belief content, not a class-changing coupling). The framework's contribution is making the regime transition precise via equilibrium-convergence framing: under sub-scope α' (potential games — Monderer-Shapley 1996; monotone games — Rosen 1965 diagonally-strictly-concave), AAT's persistence machinery transfers cleanly with A2'-analog conditions derived; under sub-scope β' , the framework reaches only CCE set-convergence rather than last-iterate convergence (the honest scope limit). The segment also provides the formal home for *effects spiral* via the joint-Jacobian eigenvalue condition — what previously read as a metaphor for cascading misalignment becomes a derivable structural property of the composite at R1.

The implications-side payoff has three threads worth surfacing. First, the result *closes the framework's contraction-to-equilibrium hand-off* that Ch.4's #result-contraction-template named as a boundary. Saddle-point equilibria break attracting-fixed-point under Slotine 2003; passivity universality fails under adversarial inputs; Daskalakis et al. 2018's last-iterate non-convergence completes the trio of obstructions. The strategic-composition derivation supplies the *replacement* machinery for those obstructions: equilibrium theory applies in the partially-opposing case where contraction analysis fails. The framework's posture is that *scope-honesty is load-bearing architecture* — knowing where each tool applies cleanly is more useful than trying to extend one tool across all regimes, and the chapter delivers the equilibrium-theoretic tool that handles where contraction stops.

Second, the regime-transition result composes with #der-directed-separation's axis-decomposed inheritance table into a sharper structural commitment: *the framework cannot avoid equilibrium-regime / cyclic-distributional-regime treatment by limiting attention to architecturally-Class-1 sub-agents*. As soon as sub-agents have partially-opposing objectives — which is the empirical norm in multi-agent settings, including most human organizations and many ML systems — the composite operates in R1 or R2 on the dynamic-regime axis, requiring equilibrium-theoretic machinery rather than the contraction-machinery applicable in R0. The architectural-class axis and the dynamic-regime axis are independent: the wrapping construction (#der-class-coercion-via-wrapping) operates *only* on architectural class (Class 3 component $\rightarrow$ Class 1 composite via external scaffolding at structural-leakage cost); alignment work (#hyp-symbiogenic-composition symbiogenic absorption is the canonical mechanism) operates *only* on dynamic regime (R1 $\rightarrow$ R0 via objective re-alignment). The two axes interact but do not collapse — wrapping a strategic composite recovers architectural Class 1 at the wrapper level but the dynamics remain R1 (the equilibrium failure modes — multi-equilibria, saddle-Nash, equilibrium selection ambiguity — persist regardless of wrapping). The framework's posture is that the dynamic regime is a *property of the game structure* (objective alignment + potential/monotone structure + population scale), and goal divergence is one of two operations (alongside adversarial coupling pressure from #disc-adversarial-coupling-pressure) that move composites along their respective parallel-pattern axes — modularity-state on Axis A architectural class; dynamic regime on Axis B per #disc-dynamic-regime-axis §"Cross-axis interactions."

Third, the chapter formalizes mechanism-design impossibility (Gibbard-Satterthwaite 1973-75 / Myerson-Satterthwaite 1983 / Arrow 1951) as the *designer-side sister meta-pattern* #disc-implementation-impossibility to the agent-side #disc-identifiability-floor. The three classical theorems land as the cluster's charter instances (#deriv-strategy-proofness-impossibility, #deriv-bilateral-trade-impossibility, #deriv-social-welfare-aggregation-impossibility), with sub-scope α' of #deriv-strategic-composition named in two of them (GS and Arrow) as *adjacent to but not identical with* the preference-domain-restriction escape (single-peaked / single-crossing) — convergence-under-current-reports is not dominance-over-all-reports. The 2026-05-20 strengthen-first arm's three-reframing test (see #deriv-strategy-proofness-impossibility Discussion) is the documented argument for the non-identity. The agent-side / designer-side

suffix discipline at meta-segment naming (-floor / -impossibility) tracks the actor-positioning distinction in the canon; the cluster's discipline filter is constructive-impossibility-shape only, deliberately excluding constructive mechanism design (VCG, revenue equivalence).

Symbiogenic composition and the asymmetric absorption mechanism.

#hyp-symbiogenic-composition (formally in Ch.1) gives the chapter its account of *how composite agents form* from sub-agents that were previously not composed: asymmetric absorption, where a host integrates an endosymbiont and the resulting composite's teleological unity U_O crosses the scope threshold from below. The implication is concrete: the framework recovers the empirical pattern of biological symbiogenesis (mitochondria, chloroplasts, gut microbiota-host integration) and organizational acquisition (objective absorption, function transfer, autonomy reduction) as the *asymmetric-parameter limit* of #deriv-critical-mass-composition's closed form. Specifically, when sub-agent parameters $(\alpha_A, R_A, \gamma_A)$ and $(\alpha_B, R_B, \gamma_B)$ are *strongly asymmetric* (one sub-agent dominates), the composite sector constant α_c collapses toward the dominant sub-agent's α , and the absorbed sub-agent's objectives are progressively folded into the dominant sub-agent's via the U_O multiplier on γ . The framework's posture is that symbiogenesis is *not a separate kind of composition* — it is the asymmetric-parameter limit of the same composition machinery that handles the matched-Tier dyad and the heterogeneous-Tier cases.

The cross-domain transfer is concrete enough to ground in specific examples. The eukaryotic-cell formation (Margulis's serial endosymbiosis) is the canonical biological instance: an archaean host absorbing a bacterial endosymbiont produces a composite with the host's broader objective surface and the endosymbiont's specialized metabolic function. Corporate acquisition produces the same dynamics at a different scale: the acquirer's strategic surface absorbs the target's operational function, with the target's objectives folded in through the U_O alignment process. The framework's contribution is the *mathematical form* — the closed-form critical-mass derivation specialized to the asymmetric-parameter limit — that makes the symbiogenic process predictable rather than purely empirical.

Modular safety architectures fail under goal divergence.

The most consequential implication of strategic composition for AI-safety practice is what #28 in the catalog names but does not yet have a segment home: modular safety architectures of the form “compose modular safety modules with a central planner” are *structurally guaranteed to fail under goal divergence*. The argument composes #deriv-strategic-composition (Class-1 sub-agents with partially-opposing objectives transition the composite from R0 contraction-regime to R1 equilibrium-regime or R2 cyclic-distributional-regime per #disc-dynamic-regime-axis) directly: when safety modules and the central planner have non-aligned objectives — exactly when the safety modules are *needed* (to constrain the planner against its own objectives that may produce undesired behavior) — the composite operates in R1 or R2 on the dynamic-regime axis, and the modular safety guarantees of the individual safety modules (designed for R0 contraction-regime dynamics with their unique-attracting-fixed-point machinery) do not transfer to the composite's equilibrium-regime or cyclic-distributional-regime dynamics. The failure mechanism is dynamic-regime change, *not* architectural-class change (the composite remains architecturally Class 1 under goal-blind routing per #der-directed-separation Composite-level inheritance; what fails is the *regime-dependent* machinery that the safety guarantees assumed).

The framework's reading of several empirical AI-safety patterns follows directly. Red-team penetrations of constitutional AI exploit the structural mismatch between the constitutional constraints (one set of objectives) and the model's training objectives (another set); under partial opposition the composite operates in R1 equilibrium-regime or R2 cyclic-distributional-regime — admitting saddle-Nash equilibria, multi-equilibria with distinct basins, and last-iterate non-convergence (Daskalakis et al. 2018) — regardless of each component's nominal modularity. Mesa-optimizer formation within nominally-modular systems (Hubinger et al. 2019) instantiates the same regime-axis failure: a sub-component developing its own objective surface that opposes the outer system's objective produces partial opposition that shifts the composite from R0 contraction-regime to R1 equilibrium-regime, and the composite's modular guarantees (designed for R0 contraction-machinery) collapse at the regime boundary. The recurring difficulty of “scalable

oversight” without per-module identifiability is the chapter’s identifiability-floor Instance 3 instance manifesting: composite contraction certification from component-marginal data is structurally impossible (Liberzon 2003), and oversight regimes that rely on component-only inspection cannot, in general, certify the composite’s safety properties.

The framework’s prescription is not that modular safety architectures cannot work — it is that they require either *goal-alignment commitment by design* (sub-agents constructed to share objectives, removing the partial-opposition condition; keeps the composite in R0 contraction-regime where modular guarantees compose cleanly) or *equilibrium-theoretic treatment from the start* (acknowledging the composite operates in R1 or R2 and applying #deriv-strategic-composition’s α'/β' machinery — joint-Lyapunov-on-deviation under potential/monotone structure for R1; CCE convergence at $O(1/\sqrt{T})$ for R2 — with explicit acknowledgment of equilibrium-selection ambiguity and saddle-Nash failure modes). The implications-side payoff for AI-safety methodology is concrete: any safety architecture that *assumes* modular guarantees compose at the composite level is making a structural commitment that holds only under R0 — i.e., only under goal alignment. Where goal alignment cannot be designed-in by construction (which is the empirical case for most current deployment settings), the framework prescribes the equilibrium-theoretic machinery at the composite scope (architectural wrapping per #der-class-coercion-via-wrapping remains available as an *independent* tool operating on the orthogonal architectural-class axis — it recovers Class 1 at the wrapper level but does not change the dynamic regime; the equilibrium-failure modes persist regardless of wrapping). See #disc-dynamic-regime-axis §”Cross-axis interactions” for the two-axis treatment.

Agent opacity, the $U_o \leftrightarrow H_b$ duality, and 16-cell adversarial targeting.

#der-agent-opacity carries the chapter’s strongest single-segment finding, well-developed in its ## Findings section. *How well the agent sees the world* (U_o) and *how well the world sees the agent* (backward predictive uncertainty H_b) are formal duals. Both quantify information flow through the agent-environment boundary, in opposite directions; both are observer/horizon/trajectory-indexed; and the same H_b quantity has *opposite value to the agent* depending on coupling sign — cooperative coupling rewards low H_b (allies must predict to coordinate), adversarial coupling rewards high H_b (adversaries cannot neutralize what they cannot predict). The sign-flip is not a separate posit; it falls out of the signed-coupling structure from Ch.4.

The implications-side payoff that the segment’s Findings flag but is worth elaborating is the *16-cell joint composition* with the recipient-side classification from Ch.4. Four emitter regimes (high/low H_b , cooperative/adversarial) $\times$ four recipient regimes (informative / magnitude-shock / structural-shock / ambient-noise) produce 16 cells, each with a different optimization signature for “where to attack” or “where to coordinate.” The closed-form arg-max for adversarial targeting routes to the cell where the attacker’s opacity is high AND the recipient’s regime detector treats the event as structural-shock (which the recipient cannot absorb without architectural change). The framework therefore replaces the OODA metaphor “inside the opponent’s loop” with a precise bilinear optimization problem — the attacker chooses the cell that maximizes the recipient-side regime-induced repair cost, given the attacker’s opacity budget.

The decomposition $\mathcal{T}^{\text{eff}} = \mathcal{T} \cdot H_b / H_b^{\text{max}}$ gives the framework’s quantitative reading of the OODA-loop tempo-opacity multiplier. The superlinear $(\mathcal{T}_A / \mathcal{T}_B)^2$ adversarial scaling from Ch.4 acquires a second multiplier: the *bilateral opacity ratio* $(H_b^{A|B} / H_b^{B|A})^2$ under Model D, with the corresponding 3/2 exponent under Model S. The framework predicts that high-opacity attackers (those who can act without being predicted by the target) get *quadratic* opacity-leverage on top of *quadratic* tempo-leverage — total quartic scaling in the opacity-times-tempo regime. This is the formal grounding for what Boyd’s framing called “operating inside the OODA loop”: tempo and opacity multiply, and the multiplication is quadratic-in-quadratic at the structural extreme.

The duality also unifies what would otherwise be parallel theorems. High- U_o low- H_b agents (sees well, is seen well) sit at one corner of the duality; low- U_o high- H_b agents (sees poorly, is hidden) sit at the opposite corner. The same machinery covers both via the signed-coupling structure rather than separate analyses, and the cross-domain transfer to multi-agent safety (legibility for cooperation), adversarial robustness (opacity as targeting-vulnerability shaping), and IDT-style monitoring of opaque AI systems all follow from the same dual.

Adversarial scaling regimes and the OODA self-bound.

#result-adversarial-exponent-regimes and #obs-gated-tempo-advantage together decompose the superlinear-tempo-advantage from Ch.4 into a regime-typed taxonomy: $b = 2$ under deterministic drift (coupling-dominant); $b = 3/2$ under stochastic noise (coupling-dominant); $b \rightarrow 1$ in the coupling-non-dominant regime where observation noise is high enough to gate the tempo advantage to near-linear scaling. Both segments are AAT-internal derivations; neither carries a ## Findings section, so the catalog-grade treatment lives in this implications segment.

The implication worth surfacing is that the *non-superlinear regime* is operationally important and predictable from AAT's existing machinery. When observation noise $U_{o,B}$ is high enough that the attacker's tempo advantage doesn't penetrate the defender's observation channel cleanly, the gain-principle update $\eta_B^* = U_{M,B}/(U_{M,B} + U_{o,B})$ collapses toward zero, and the defender's effective correction rate α_B shrinks. But — counterintuitively — this *helps* the defender at the system level by gating the exponent. The framework predicts that *cheap noise injection* into the defender's observation channel can be a defensive strategy against a high-tempo attacker, by reducing the exponent from superlinear to linear, even at the cost of slowing the defender's individual updates. This is the structural reason the empirical pattern that highly-noisy environments produce more cooperative-game-like dynamics than expected — observation noise gates the adversarial advantage to near-linear scaling, where the attacker cannot exploit superlinear scaling to drive the defender past the destabilization threshold.

The composition with detection latency from #deriv-update-detection-latency produces a cross-segment finding (#40 in the catalog — *OODA Tempo + Detection Latency Self-Bounds Adversarial Targeting*) that has no other natural home. The 16-cell adversarial-targeting matrix is *self-bounded*: the most damaging cell to attack is the one the defender's *detection latency* makes hardest to recognize. The composition is $\mathcal{J}^{\text{eff}} = \mathcal{J} \cdot H_b/H_b^{\text{max}}$ (from #der-agent-opacity) and $\mathbb{E}[T_{\text{detect}}] = \Omega((n+1)/\varepsilon)$ (from #deriv-update-detection-latency): the cell with maximal damage is the one with maximal opacity and minimal ε given the defender's $n_{\min}$. Adversarial targeting therefore concentrates *where defender's response is slowest*, and the framework predicts the empirical pattern that cybersecurity incidents cluster on long-trusted dependencies (longest accumulated $n_{\min}$) and that adversarial-ML examples cluster on high-confidence model regions. Both observed empirically; the framework supplies the unifying mechanism.

The cross-segment finding's prescription is concrete: defenders should *short-circuit accumulated trust* on critical dependencies (forced forgetting to reset $n_{\min}$) and *probe high-confidence model regions* with explicit interventional checks. The detection-latency self-bound says these are not optional optimizations — they are the structural countermeasures the adversary's optimal-targeting argument forces the defender to deploy. The framework's contribution against the empirical adversarial-robustness literature is that the targeting concentration has a structural derivation, not merely a folkloric observation, and the countermeasures follow directly.

Closing Part III.

Per-dimension persistence (#result-per-dimension-persistence) is formally in this chapter though its content belongs with Part I Ch.4. The implications-segment treatment landed at Part I Ch.4; here it appears as the adversarial concentration mechanism: an opponent who identifies the target's weak dimension can concentrate disturbance there, amplifying the mismatch ratio asymmetrically while the aggregate L^2 metric still looks acceptable. The framework's prescription — *per-dimension monitoring is a structural requirement for any agent operating under directed pressure* — bites hardest here, where strategic composition delivers attackers who can locate the weak direction and adversarial targeting decomposes the attack into recipient-side regimes that exploit the dimension-asymmetry.

The chapter is also where Part III's open population-dynamics questions surface as recognized gaps: latent structural diversity (variation invisible to current performance but consequential under regime change), endogenous coupling (γ as function of population composition rather than exogenous parameter), composition-transition dynamics (Miller 2022's extreme transition motif), and computational thresholds for social behavior (Miller's ICE framework). These four gaps are the bridge to *population-level* dynamics that the current pairwise/strategic-equilibrium scope does not

cover. When fleshed out they would likely form their own chapter on population dynamics, possibly relocating the per-dimension result alongside. The implications-segment treatment flags this rather than over-claiming present coverage.

What Part III closes on is the composite-agent machinery in its operational form: closure-defect / bridge-lemma representability criterion (Ch.2), unity dimensions and Auftragstaktik bandwidth allocation (Ch.3), signed-coupling structure with cooperative-vs-adversarial as one inequality and the recipient-side four-regime taxonomy (Ch.4), strategic composition under equilibrium machinery and agent opacity with 16-cell adversarial targeting (Ch.5). The four chapters compose into AAT's full composite-agent treatment, with the identifiability-floor pattern's four formal instances (Instances 1–4) covering the framework's scope-honest commitments at the boundaries.

The bridge into TST (02-tst-core/) and the logogenic-agent stages (03-llm-core/, 04-eli-core/) is direct from here. TST instantiates the AAT machinery in the software domain, with code quality as observation infrastructure, Lindy-Effect as the temporal-optimality grounding, and software development as the *privileged calibration laboratory* (high P1–P6 identification properties). Logogenic agents — Class 3 (Coupled) by construction — inherit the wrapping construction from Ch.2 and the bias bound from Part II Ch.5, with the framework's reach into LLM-class substrates running through those two segments. The orient-cascade-recovery-via-scaffolding argument from Part II Ch.5 implications is the structural claim that connects AAT's persistence machinery to production agentic systems.

The implications-segment series for AAT chapter-ends is complete with this segment. The TST and logogenic chapter-ends follow the same pattern; that work picks up under task 11 after Joseph's check-in.

Working Notes.

- **Migration note (2026-05-09 GUC rename; residue fix 2026-05-21):** Class 2 ↔ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. The canonical strategic-composition pattern “Class-1-sub-agents → Class-3-composite” (old vocab; Class 3 = partially modular) is now “Class 1 (Separated) sub-agents → Class 2 (Partial) composite.” This segment carried the pre-rename “Class 3” label through the 2026-05-09 sweep without swapping; the residue was identified and the literal-label swap landed 2026-05-21 per spikes/strategic-composition-class-3-attempt-2026-05-21/99-VERDICT.md (F4) and 07-SOLIDIFIED-PLAN.md Phase 1 (commit 0884e12). The deeper rewrite — replacing architectural-class-change mechanism with dynamic-regime-change mechanism in the §”Strategic composition lifts contraction to equilibrium” and §”Modular safety architectures fail under goal divergence” implications — landed 2026-05-21 per 07-SOLIDIFIED-PLAN.md Phase 4 (4c); the mechanism is now dynamic-regime transition (R0 → R1 / R2 per #disc-dynamic-regime-axis) with architectural class preserved under goal-blind routing (per #der-directed-separation axis-decomposed inheritance table). Removed at candidate stage per FORMAT.md Gate 4.
- This segment is a chapter-end discussion grouping findings from #deriv-strategic-composition, #der-agent-opacity, #result-adversarial-exponent-regimes, #obs-gated-tempo-advantage, #result-per-dimension-persistence (content cross-referenced from Part I Ch.4 implications), #hyp-symbiogenic-composition (formally in Ch.1, content surfacing here), and #der-interaction-channel-classification (Ch.4, the recipient-side dual to this chapter's emitter-side classification). Cross-pattern reading leans on #disc-identifiability-floor for Instance 3's operational form, #deriv-update-detection-latency for the OODA self-bound composition (#40), and #disc-modularity-state-dynamics for the goal-divergence-as-modularity-decreasing operation.
- **Cross-reference vs canonical-home policy.** Two source segments in this chapter carry well-written ## Findings sections — #der-agent-opacity and #result-per-dimension-persistence. Both are cross-referenced rather than restated. The findings whose canonical home is this implications segment are: #23 (Class-1-sub-agents under partially-opposing objectives — composite transitions from R0 contraction-regime to R1 equilibrium-regime / R2 cyclic-distributional-regime per #disc-dynamic-regime-axis; architectural class is preserved, dynamic regime is what changes), #28 (modular safety architectures fail under goal divergence — no segment home), #44 partial (the exponent-regime decomposition $b = 2, 3/2, \sim 1$), #54 (observation noise gates advantage), #52 (symbiogenic composition dynamics, asymmetric-limit reading), #40 (OODA tempo + detection latency self-bounds — cross-segment finding without home), and #50 (strategic composition game-theory bridge — companion to #23).

- **#28 Modular Safety as segment-promotion candidate.** The catalog draft entry #28 references a finding that has no home segment. The implications segment is its canonical home for now; a future cycle may promote a dedicated #disc-modular-safety-under-goal-divergence segment under Appendix A with ## Findings, at which point this segment downgrades to cross-reference.
- **Cross-segment finding without home — #40 OODA + Detection Latency Self-Bound.** Composes #der-agent-opacity (16-cell), #result-adversarial-tempo-advantage (superlinear), and #deriv-update-detection-latency ($\Omega((n + 1)/\epsilon)$) into the self-bounded adversarial-targeting prediction. No source segment carries this composition; the implications segment is its canonical home. Empirical signature (cybersecurity incident concentration on long-trusted dependencies, adversarial-ML clustering on high-confidence regions) is observed but not pulled together; the framework's contribution is the unifying mechanism.
- **Identifiability-floor pattern's full four-instance treatment + designer-side sister meta-pattern.** The agent-side identifiability-floor cluster is now fully surfaced in the implications-segment series: Instance 1 (Part II Ch.4-strategy-dynamics — on-policy L0-insufficiency detection), Instance 2 (Part II Ch.3-strategy-structure — L1' mixture identifiability under unobservable common cause), Instance 3 (Part III Ch.2-composition-machinery, operationalized here — composite contraction certification from component marginals), Instance 4 (Part II Ch.5-orient-cascade / Appendix A — architecture-noidentifiability from on-policy summary data, #der-architecture-noidentifiability, dual-anchored on Kalman-Ho canonical-form non-uniqueness and CHT-at-agent-as-SCM). Instance 5 (Mehra non-identifiability in adaptive Kalman) remains candidate. Mechanism-design impossibility (Gibbard-Satterthwaite / Myerson-Satterthwaite / Arrow) tested as a candidate fifth instance via the strategic-composition derivation in this chapter and confirmed *not* to fit the identifiability-floor's actor-positioning (designer-side vs agent-side; the 2026-05-20 strengthen-first arm's record); it lands instead as the three charter instances of the designer-side sister meta-pattern #disc-implementation-impossibility, alongside the agent-side value-functional-grounding meta-pattern #disc-value-functional-grounding-floor (Result G' + Cohen-2022 strengthened). The three-cluster constructive-impossibility-posture taxonomy (#disc-constructive-impossibility-posture) is fully realized end-to-end.
- **Connection to NeurIPS submissions.** The strategic-composition machinery is closest to a future multi-agent extension of Paper 2's convergence theory; the modular-safety implication is closest to a future AI-safety-track submission. Current cross-references in Paper 2 / Paper 3 are scope and structural-argument links rather than theorem-grade adoption from this chapter.
- **AAT chapter-end implications series complete.** With this segment, the AAT-core chapter-end implications work covers Part I Ch.4 + Part II Ch.2/3/4/5 + Part III Ch.2/3/4/5 — seven chapter-end segments plus the pilot. Each cross-references existing ## Findings where they exist and treats canonical-home findings in full where they do not. Cross-segment findings (CS1 unified RL convergence, CS2 compounding stability-induced myopia, CS3 three matrix-form bounds on Fisher backbone, #40 OODA self-bound) land in the chapter whose last prerequisite completes. The optional Appendix-A end segment (CS3 + cross-references to M1/M2/M3/M4) and the TST / logogenic-agents chapter-ends are remaining work flagged in tasks 10 and 11.

Incidental audit gold (gold-lift sweep, A15, 2026-05-31). *Orthogonal* chapter-level synthesis / framing material staged for an eventual separate promotion pass. **Coverage:** no auditor produced a dedicated reflection on this implications segment (the de-novo walks stopped at #der-agent-opacity as the last core Part III segment, or treated the chapter at the level of its constituent results); the only impl-* reflection in the contributing dirs is 526815's 92-impl-cooperative-adversarial, which belongs to the *prior* chapter (A14), not here. The chapter-level synthesis gold below is harvested from the §III-completion reflections; the per-result gold (squared-law, fog-of-war, min()-not-average(), $U_o \leftrightarrow H_b$ duality, etc.) was routed to the constituent segments #deriv-strategic-composition / #der-agent-opacity / #result-adversarial-exponent-regimes / #obs-gated-tempo-advantage / #result-per-dimension-persistence, which is the correct home per the match-by-content discipline.

2. Candidate Discussion.

- **The chapter as the control-theory $\leftrightarrow$ game-theory weld.** Multiple auditors named this chapter the place where “Section I's survival bounds and game theory's convergence proofs become the same physics” — the sector-persistence template (single-agent survival) transferring to the equilibrium layer (multi-agent convergence) via α_{joint} , with H_b supplying the information-flow boundary condition. A candidate chapter-synthesis framing for the implications opener: Part III's adversarial/strategic

results are not a separate theory bolted on, but the *same* persistence machinery read across the agent-environment boundary in both directions (Gemini 849201, Claude 471203, Gemini 193847 — convergent).

Belongs elsewhere.

- **Whole-framework synthesis (README / OUTLINE preamble, 04-eli-core/ reach).** One auditor's end-of-audit synthesis is framing-level rather than segment-level: AAT “unites control theory (Lyapunov), information theory (IB/MDL), causal inference (Pearl/do-calculus), and organizational sociology (Brooks's Law, OKRs, symbiogenesis) under one coherent mathematical umbrella,” with the primary *weakness* being integration debt (editorial bloat in src/ Findings blocks, topological forward-references, residual TF-06/TF-11 archaeology) rather than the math — “a diamond that needs its scaffolding removed and edges polished” (Gemini, 829314). This is README/positioning material and an integration-debt signal, not implications-segment content; recorded here because it surfaced at the chapter that closes the AAT-core walk. (*The integration-debt items are certified-track housekeeping, not gold — see off-ramp.*)

Off-ramp (NOT gold) — routed for adjudication, not promotion.

- (829314, 849201 — recurring across Part III) — “editorial bloat”: in-src ## Findings blocks read as misplaced. Two Gemini auditors repeatedly flagged the large ## Findings / search-log / related-work blocks pasted into Part III result segments as “destroying the pedagogical flow,” recommending relocation to an appendix or tracking system. **This is a false alarm about project mechanics** (the in-segment ## Findings block is by-design the source the auto-extracted root FINDINGS.md is generated from), so it is *not* an action — but it is preserved as the same de-novo-reader stumble two fresh readers independently hit (also recorded on #result-persistence-condition in the pilot lift), a mild signal that the convention is not self-evident. No segment change.
- **Integration-debt housekeeping** (829314 final synthesis): topological forward-references in Part III (e.g. #der-agent-opacity referencing #der-interaction-channel-classification before it appears in a linear read), and residual TF-06/TF-11 archaeology in footers — routed to the integration-cleanup / OUTLINE-ordering stream, not theory. Out of scope for this WN-only lift; the C-iv idiom-drift residue in the OUTLINE rows (lines 91, 323, 328) is the most concrete instance and is flagged on #deriv-strategic-composition's off-ramp.

[Gap] Latent structural diversity: variation in correction architectures invisible to persistence analysis, consequential under regime change

[Gap] Endogenous coupling: γ as function of population composition, not exogenous parameter; coupling emergence threshold

[Gap] Composition transition dynamics: epochal stability $\rightarrow$ latent diversification $\rightarrow$ niche emergence $\rightarrow$ cascading restructuring $\rightarrow$ re-equilibration (adopts Miller 2022's extreme transition motif)

[Gap] Computational thresholds for social behavior: minimum agent complexity and interaction depth for composition dynamics (adopts Miller 2022's ICE framework; grounds 9.9)

Part IV

Appendices: Details

Appendix A

Derivation: Sector Condition Stability — Lyapunov Derivation

The Lyapunov machinery underlying the sector-condition stability result and the central persistence inequality. The mismatch dynamics are taken in general nonlinear vector form, $\dot{\delta} = -F(\mathcal{T}, \delta) + w(t)$, with the correction function F required to satisfy only the *qualitative* properties (A1)–(A3) and the local sector condition (A2') stated in `#form-sector-condition`. The Lyapunov function is the canonical quadratic $V = \frac{1}{2}\|\delta\|^2$; the steady-state results follow from standard Lyapunov / Itô-Lyapunov machinery applied to AAT's correction-function object.

The derivation produces the framework's central persistence results in their precise form. **Proposition A.1 (Model D — bounded disturbance)**: under $\|w(t)\| \leq \rho$ and the sector condition, mismatch is ultimately bounded by $R^* = \rho/\alpha$ — exactly the persistence threshold the chapter cites, and $\mathcal{B}_R$ is positively invariant when $\alpha R > \rho$. **Lemma A.1N (threshold tightness)**: the condition is unimprovable given A2' — necessary and sufficient for the *uniform class-level* guarantee (witness $F = \alpha\delta$ under outward disturbance), and agent-level necessary exactly when the sector bound is radially tight (the linear case); for a general fixed F the only-if direction is *false* (demonstrated by the dip counterexample in the Remark following A.1N — the sector floor can sit at radii the dynamics render unreachable). **Proposition A.1S (Model S — additive stochastic disturbance)**: the region-aware Itô-Lyapunov analysis gives the stopped second-moment bound, the steady-state RMS $R_S^* = \sigma_w \sqrt{n/(2\alpha)}$ (the $1/\sqrt{\alpha}$ scaling that distinguishes Model S from Model D's $1/\alpha$ scaling), and the stationary-sharp fixed-time tail $P(\|\delta(t)\| > R) \leq n\sigma_w^2/(2\alpha R^2)$. **Proposition A.2 (adaptive reserve)**: $\Delta\rho^* = \alpha R - \rho$ — the additional disturbance an agent can absorb before mismatch leaves the sector-condition region.

The segment's load-bearing new exact result is **Corollary A.1S.1 — the disturbance-model containment dichotomy**. The persistence-region first-exit probability is *categorical*: $P(\tau_R < \infty) = 0$ under Model D (deterministic positive invariance), $P(\tau_R < \infty) = 1$ under Model S (a.s. exit of a non-degenerate diffusion from a bounded region, for *any* F satisfying A2'). The achievable value is exactly the two-point set $\{0, 1\}$, and which point obtains is fixed by the disturbance model's support structure (bounded vs. unbounded), **not** by correction strength α . Increasing α tightens the typical scale and the fixed-time tail; it cannot interpolate between the two regimes. Pathwise containment is categorically Model-D-only — additive stochastic forcing removes the *kind* of guarantee available, not merely its rate. The companion no-go demonstration (that the natural Ville/Doob maximal-inequality route to a $P(\tau_R < \infty) < 1$ bound *cannot* exist) is in `#deriv-stochastic-non-exit`. The dichotomy sharpens the hand-off into `#result-structural-adaptation-necessity`: in any genuinely stochastic environment, leaving the parametric-correction region is a certain eventual event, so structural adaptation is *generic, not exceptional*, for any sufficiently long-lived agent. The sub-scope α / β partition (where A2' is structurally derived versus where it is per-system assumed) is held at `#form-sector-condition`; the Lyapunov proofs below apply uniformly across both.

Motivation.

3.9 hypothesizes the linear ODE $d\|\delta\|/dt = -\mathcal{T}\|\delta\| + \rho$ as a first-order approximation. The linear form yields clean closed-form results but commits to a specific functional relationship between mismatch magnitude and correction rate. True correction dynamics are almost certainly nonlinear — exhibiting saturation at large mismatch, threshold effects near zero, and structural breakdown when the model class is exhausted.

A Lyapunov approach proves persistence and stability under much weaker assumptions: any correction dynamics satisfying qualitative monotonicity properties (the sector condition). The results below are strictly more general — the linear case is recovered where the sector bounds coincide.

Setup.

Let $\delta(t) \in \mathbb{R}^n$ be the mismatch vector — the difference between the model's predictions and reality across n observable dimensions. The vector treatment connects to per-dimension tempo analysis (16.5).

The mismatch dynamics are:

Definition (Dynamics Setup).

$$\frac{d\delta}{dt} = -F(\mathcal{T}, \delta) + w(t) \quad (\text{A.1})$$

where:

- $F(\mathcal{T}, \delta) : \mathbb{R}_+ \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ is the **correction function** — how the agent's adaptive process reduces mismatch. It maps to the same space as δ (so that the inner product $\delta^T F$ in the sector condition is well-defined). This subsumes the update gain η^* (3.6), event rate ν , and the structure of the update rule.
- $w(t)$ is the **disturbance** — new mismatch introduced by environmental change, with $\|w(t)\| \leq \rho$ (bounded disturbance rate).

The linear case from 3.9 has $F(\mathcal{T}, \delta) = \mathcal{T} \cdot \delta$.

Assumptions on F .

The Lyapunov derivations below operate on the structural-property triple (A1) zero-correction-at-zero-mismatch, (A2') local sector condition, (A3) tempo-monotonicity, stated in full at 4.2. The sub-scope α / β partition — the agent classes where A2' is structurally derived (Bayesian / exponential family / strongly-convex gradient / L2-regularized / linear-PD) versus those where it stands as a well-scoped per-system empirical claim (PID, rule-based, human judgment, severely misspecified, variational, non-convex beyond basin, per-step SGD) — is also held there, together with the operator-family classification (Rockafellar / Bauschke-Combettes / Baillon-Haddad) that names how the AAT-internal sub-scope partition lines up with monotone-operator theory.

The Lyapunov proofs below apply uniformly across both sub-scopes — they operate downstream of A2' regardless of whether it is structurally derived or per-system assumed.

Candidate Lyapunov Function.

Definition (Lyapunov Candidate).

$$V(\delta) = \frac{1}{2} \|\delta\|^2 \quad (\text{A.2})$$

Positive definite, radially unbounded, continuously differentiable. Its level sets $V = c$ are spheres of radius $\sqrt{2c}$ in mismatch space.

Proposition A.1: Bounded Mismatch (Single Agent).

Statement. Under (A1), (A2'), (A3), with bounded disturbance $\|w(t)\| \leq \rho$, the mismatch $\delta(t)$ is **ultimately bounded**: there exists $R^* > 0$ such that $\|\delta(t)\| \leq R^*$ for all sufficiently large t , provided $R^* < R$ (the ultimately bounded region fits within the sector-condition region).

Proof.

Compute $\dot{V}$ along trajectories:

Derived (Proof Step).

$$\dot{V} = \delta^T \dot{\delta} = \delta^T [-F(\mathcal{J}, \delta) + w(t)] \quad (\text{A.3})$$

Derived (Proof Step).

$$= -\delta^T F(\mathcal{J}, \delta) + \delta^T w(t) \quad (\text{A.4})$$

By (A2'): $\delta^T F(\mathcal{J}, \delta) \geq \alpha \|\delta\|^2$

By Cauchy-Schwarz: $\delta^T w(t) \leq \|\delta\| \cdot \|w(t)\| \leq \rho \|\delta\|$

Therefore:

Derived (Proof Step).

$$\dot{V} \leq -\alpha \|\delta\|^2 + \rho \|\delta\| = -\|\delta\|(\alpha \|\delta\| - \rho) \quad (\text{A.5})$$

$\dot{V} < 0$ whenever $\|\delta\| > \rho/\alpha$ and $\|\delta\| \leq R$ (where A2' holds).

Define $R^* = \rho/\alpha$.

Invariance of $\mathcal{B}_R$. When $R^* < R$ (the persistence condition), the ball $\mathcal{B}_R$ is *positively invariant*: any trajectory starting in $\mathcal{B}_R$ remains in $\mathcal{B}_R$ for all future time. At the boundary $\|\delta\| = R$, the sector condition holds and $\dot{V} = -\|\delta\|(\alpha \|\delta\| - \rho) = -R(\alpha R - \rho) < 0$ (since $\alpha R > \rho$ by the persistence condition). Trajectories at the boundary point inward. Therefore $\mathcal{B}_R$ is invariant, and the sector condition applies to the entire future trajectory of any trajectory starting inside $\mathcal{B}_R$.

Ultimate boundedness. Within $\mathcal{B}_R$, the Lyapunov function is strictly decreasing for $\|\delta\| > R^*$ and may increase for $\|\delta\| < R^*$. All trajectories starting in $\mathcal{B}_R$ are ultimately bounded by R^* — they are driven into $\mathcal{B}_{R^*}$ and remain in a neighborhood of it (with possible oscillation at the boundary due to the disturbance).

Initial condition requirement. The result requires the trajectory to start inside $\mathcal{B}_R$ (or to be brought inside by some external mechanism). A trajectory starting outside $\mathcal{B}_R$ is not covered — the sector condition does not hold there, and the correction function may fail to reduce mismatch. This is precisely the structural adaptation regime of 4.8: an agent whose mismatch exceeds R has exhausted its model class capacity and needs structural change to re-enter the region where parametric correction works.

The persistence condition $\alpha > \rho/R$ (equivalently $R^* < R$) is therefore *sufficient* for persistence from within $\mathcal{B}_R$. $\square$

Lemma A.1N (threshold tightness — necessity is class-level, not agent-level). Over the hypothesis class $\mathcal{F}_\alpha = \{F : (A1), (A2'), (A3) \text{ hold on } \mathcal{B}_R \text{ with sector floor } \alpha\}$, the condition $\alpha > \rho/R$ is necessary *and* sufficient for the uniform containment guarantee (every $F \in \mathcal{F}_\alpha$ keeps every trajectory from $\mathcal{B}_R$ inside $\mathcal{B}_R$ under every $\|w(t)\| \leq \rho$).

Proof. Sufficiency is Prop A.1, uniform over the class. Necessity: the extremal member $F = \alpha\delta$ lies in $\mathcal{F}_\alpha$; under the outward radial disturbance $w = \rho\delta/\|\delta\|$ its radial dynamics obey $\frac{d}{dt}\|\delta\| = \rho - \alpha\|\delta\| \geq \rho - \alpha R > 0$ whenever $\alpha < \rho/R$, so from any nonzero start the trajectory exits $\mathcal{B}_R$ in finite time. (At $\alpha = \rho/R$ exactly, the trajectory asymptotes to R without crossing — containment holds, with ultimate bound R rather than $< R$.) $\square$

The lemma answers the question the old “iff” was reaching for — *when is the persistence condition also necessary?* — and the answer is **tightness, not linearity**. For a fixed agent whose sector bound is radially tight (additionally $\delta^T F \leq \tilde{\alpha}\|\delta\|^2$ with $\tilde{\alpha} = \alpha$; the linear case $F = \mathcal{T}\delta$ is the canonical instance), the same outward-disturbance construction forces finite-time exit, and the threshold is a genuine agent-level if-and-only-if. In general, the object necessity tracks is the *upper* sector constant $\tilde{\alpha}$, not the floor α : the Lyapunov argument bounds $\dot{V}$ from above via the floor, and forcing escape needs a bound from below, which only an upper sector bound supplies.

Remark (the floor is not the barrier — why agent-level necessity fails in general). For a fixed F , failure of $\alpha > \rho/R$ does *not* imply escape, because α is a worst-case infimum over $\mathcal{B}_R$ that the dynamics may render unreachable. Demonstration (1D; extends to $\mathbb{R}^n$ radially via $F(\delta) = g(\|\delta\|)\delta$): take $R = 1$, $\rho = 1$, and $g \geq 10$ everywhere on $(0, 1]$ except a narrow dip to $g = 0.1$ near $r = 0.5$. The tight sector floor on $\mathcal{B}_R$ is $\alpha = g(0.5) = 0.1 < \rho/R$ — the persistence condition fails tenfold — yet $F(r) > \rho$ on an annulus below the dip, so every admissible trajectory started at small mismatch is stopped there: an impenetrable barrier *below* the weak spot, which no admissible disturbance can reach. The supremum of $\|\delta(t)\|$ over all $\|w\| \leq \rho$ from $\delta(0) = 0$ is ≈ 0.1 (numerically confirmed, including against randomized and outward-feedback adversaries). The sharp agent-level escape threshold in 1D is a *mountain-pass* quantity — escape requires $\rho > \max_r F(r)$ over the radii the trajectory must traverse — not the global floor αR . Condition failure therefore means the containment *certificate* is lost (and escape is forced for the extremal class member and every radially tight agent), never that escape is certified for the agent at hand.

Interpretation. The ultimately bounded region has radius $R^* = \rho/\alpha$. In the linear case, $\alpha = \mathcal{T}$, recovering 4.5’s steady-state result $R^* = \rho/\mathcal{T}$ exactly. But Proposition A.1 holds for *any* correction function satisfying the sector condition, not just the linear one.

The persistence threshold, generalized. The persistence condition $\rho/\alpha < R$ guarantees persistence for any correction function satisfying the sector condition, and Lemma A.1N shows it is *unimprovable given only A2'*: necessary and sufficient for the guarantee at class level, and agent-level necessary exactly in the radially tight case. If the correction function breaks down (A2' fails) before R^* is reached, the agent may diverge. Condition failure IS 4.8’s trigger in certificate form: when $\rho/\alpha > R$ (the environment demands more correction than the model class can *certifiably* provide), parametric adaptation loses its containment guarantee and structural change is required to restore one.

Proposition A.2: Stability Margin (Adaptive Reserve).

Statement. Under the conditions of A.1, the agent can tolerate a sudden increase in disturbance rate of:

Derived (adaptive-reserve).

$$\Delta\rho^* = \alpha R - \rho \quad (\text{A.6})$$

without mismatch diverging (where R is the radius of the sector-condition region from A2'). Beyond this, R^* exceeds R and the correction function may fail.

Proof. After a shock, the new disturbance rate is $\rho + \Delta\rho$. The new ultimately bounded radius is $(\rho + \Delta\rho)/\alpha$. This remains within the valid region iff $(\rho + \Delta\rho)/\alpha \leq R$, i.e., $\Delta\rho \leq \alpha R - \rho$. $\square$

Interpretation. $\Delta\rho^*$ is the agent's **adaptive reserve** — how much additional environmental volatility it can absorb before its model breaks down. This is a single number characterizing an agent's robustness to shock:

- An agent operating well below capacity ($\rho \ll \alpha R$) has a large reserve — it is **robust**.
- An agent near its limit ($\rho \approx \alpha R$) has a small reserve — it is **fragile**.

Table A.1

<i>Domain</i>	<i>Large $\Delta\rho^*$ (robust)</i>	<i>Small $\Delta\rho^*$ (fragile)</i>
Control	Kalman filter on slow target	Same filter on erratic target
Biology	Organism in stable niche	Same organism under climate change
Organization	Well-capitalized firm, stable market	Startup in volatile market
Military	Force with operational depth	Force at culmination point

Proposition A.1S: Bounded Mismatch Under Stochastic Disturbance.

Statement (region-aware form). Under (A1), (A2') on $\mathcal{B}_R$, (A3), with stochastic disturbance (GA-2S: $w(t)$ is zero-mean with $\mathbb{E}[\|w(t)\|^2] = \sigma_w^2$), let $\tau_R = \inf\{t : \|\delta(t)\| > R\}$ be the first-exit time from the sector-condition region. Then:

(i) *Stopped bound* — the stopped process satisfies for all $t \geq 0$:

Derived (stochastic-bounded-mismatch, stopping-time localization, Khasminskii 2012 ch. 5).

$$\mathbb{E}[\|\delta(t \wedge \tau_R)\|^2] \leq \|\delta(0)\|^2 e^{-2\alpha t} + \frac{n\sigma_w^2}{2\alpha} \quad (\text{A.7})$$

(ii) *Mean-square persistence condition* — when $R_S^* := \sigma_w \sqrt{n/(2\alpha)} < R$, equivalently

$$\alpha > \frac{n\sigma_w^2}{2R^2} \quad (\text{A.8})$$

the ultimately-bounded RMS radius fits inside the sector-condition region.

(iii') *Fixed-time tail* — under the mean-square persistence condition (ii), Markov's inequality on the stopped second moment gives, for each fixed t (sharpest in the stationary $t \rightarrow \infty$ limit),

$$P(\|\delta(t)\| > R) \leq \frac{\mathbb{E}[\|\delta(t \wedge \tau_R)\|^2]}{R^2} \xrightarrow{t \rightarrow \infty} \frac{n\sigma_w^2}{2\alpha R^2}. \quad (\text{A.9})$$

This controls the mismatch at any single time. It is *not* an infinite-horizon containment statement: under additive Brownian forcing the diffusion is recurrent on $\mathbb{R}^n$ (the additive-noise generator has no bounded non-constant harmonic function), so $P(\tau_R < \infty) = 1$ over an unbounded horizon — there is no $P(\tau_R < \infty) < 1$ bound, and none is claimed. Pathwise containment of $\mathcal{B}_R$ is a Model-D guarantee only (Prop A.1's positive invariance); Model S controls the *typical scale* (ii) and the *fixed-time tail* (iii'), not the sample path over an unbounded horizon. The kind-of-guarantee dichotomy this exposes is itself a result — see the Discussion.

(iv) *Finite-horizon sample-path bound* — when a sup-over-an-interval statement is wanted, the sound one is the additive first-exit bound

$$P\left(\sup_{0 \leq s \leq T} \|\delta(s)\| > R\right) \leq \frac{\|\delta(0)\|^2 + n\sigma_w^2 T}{R^2}, \quad (\text{A.10})$$

rigorous under (A2') alone (Khasminskii 2012 ch. 5). It controls the whole path on $[0, T]$ — stronger than (iii') within its regime — but grows linearly in T and is vacuous for $T > rsimR^2/(n\sigma_w^2)$, consistent with $P(\tau_R < \infty) = 1$.

The proof below establishes the Grönwall-type bound first, then the stopping-time localization at the end.

Proof.

The SDE form of the mismatch dynamics under stochastic disturbance is:

$$d\delta = -F(\mathcal{J}, \delta) dt + \sigma_w dW_t \quad (\text{A.11})$$

where W_t is a standard n -dimensional Wiener process.

Apply Itô's formula to $V(\delta) = \frac{1}{2}\|\delta\|^2$:

Derived (Proof Step).

$$dV = \delta^T(-F) dt + \delta^T \sigma_w dW_t + \frac{1}{2} \sigma_w^2 n dt \quad (\text{A.12})$$

The last term is the Itô correction: $\frac{1}{2} \text{tr}(\sigma_w^2 I_n) = \frac{n}{2} \sigma_w^2$.

Taking expectations (the Itô integral $\delta^T \sigma_w dW_t$ has zero expectation):

Derived (Proof Step).

$$\frac{d}{dt} \mathbb{E}[V] = \mathbb{E}[\delta^T(-F)] + \frac{n}{2} \sigma_w^2 \quad (\text{A.13})$$

By (A2'): $\delta^T F \geq \alpha \|\delta\|^2 = 2\alpha V$. Therefore:

Derived (Proof Step).

$$\frac{d}{dt} \mathbb{E}[V] \leq -2\alpha \mathbb{E}[V] + \frac{n}{2} \sigma_w^2 \quad (\text{A.14})$$

This is a linear ODE in $\mathbb{E}[V]$ with solution:

$$\mathbb{E}[V(t)] \leq V(0) e^{-2\alpha t} + \frac{n\sigma_w^2}{4\alpha} (1 - e^{-2\alpha t}) \quad (\text{A.15})$$

Since $V = \frac{1}{2} \|\delta\|^2$, the steady-state mean-square mismatch is:

$$\mathbb{E}[\|\delta\|^2]_{ss} = \frac{n\sigma_w^2}{2\alpha} \quad (\text{A.16})$$

The RMS steady-state mismatch is:

Derived (stochastic-steady-state).

$$R_S^* = \|\delta\|_{\text{rms}} = \sigma_w \sqrt{\frac{n}{2\alpha}} \quad (\text{A.17})$$

Persistence requires $R_S^* < R$, giving $\alpha > n\sigma_w^2/(2R^2)$.

Stopping-time localization. The Itô-Lyapunov step above used A2' ($\delta^T F \geq \alpha \|\delta\|^2$) on the entire trajectory, but A2' is posited only on $\mathcal{B}_R$. Replacing t with the stopped time $t \wedge \tau_R$ makes the argument valid: on $[0, t \wedge \tau_R]$, $\delta(s) \in \mathcal{B}_R$ almost surely, so A2' applies. The Itô integral $\int_0^{t \wedge \tau_R} \delta^T \sigma_w dW_s$ remains a martingale with zero expectation (optional stopping for L^2 -bounded martingales). The stopped Grönwall bound (i) follows. For (iii'), Markov's inequality applied to the stopped second moment (i) gives the fixed-time tail directly. The *infinite-horizon* ever-exit probability is 1 under additive Brownian forcing, and no nonnegative supermartingale certifies any $P(\tau_R < \infty) < 1$ bound — the natural Ville/Doob maximal-inequality route provably cannot exist (demonstrated in #deriv-stochastic-non-exit). (iv)'s finite-horizon sup-bound follows from the same Itô-Lyapunov step without the decay term. $\square$

Interpretation. Model D (Prop A.1) gives $R^* = \rho/\alpha$, scaling as $1/\alpha$. Model S gives $R_S^* = \sigma_w \sqrt{n/(2\alpha)}$, scaling as $1/\sqrt{\alpha}$. Doubling the correction efficiency halves the deterministic steady-state mismatch but only reduces the stochastic steady-state by a factor of $\sqrt{2} \approx 1.41$. Correction is less effective against noise than against drift. This difference in scaling propagates into the adversarial exponent regimes (16.3): $b = 2$ under Model D, $b = 3/2$ under Model S.

Tail bound. At steady state, Markov's inequality gives $P(\|\delta\| > R) \leq n\sigma_w^2/(2\alpha R^2)$. The agent stays within R with probability $\geq 1 - \epsilon$ provided $\alpha \geq n\sigma_w^2/(2\epsilon R^2)$. For the linear case (Ornstein-Uhlenbeck), the stationary distribution is Gaussian and exact tail probabilities are available. The Markov bound is the general result holding under (A2') alone.

Corollary A.1S.1: Disturbance-Model Containment Dichotomy.

For a trajectory started in $\mathcal{B}_R$ under (A1), (A2') on $\mathcal{B}_R$, (A3), the persistence-region first-exit probability is **categorical**:
Derived.

$$P(\tau_R < \infty) = \begin{cases} 0 & \text{Model D (bounded } w, \|w\| \leq \rho) \text{ under } \alpha R > \rho, \\ 1 & \text{Model S (additive stochastic, } d\delta = -F dt + \sigma_w dW_t). \end{cases} \quad (\text{A.18})$$

The Model-D value is the deterministic positive invariance of Prop A.1 (boundary-inward: at $\|\delta\| = R$, $\dot{V} < 0$ when $\alpha R > \rho$). The Model-S value holds for **every** $\alpha > 0$, **every** $\sigma_w > 0$, and **every** correction function F satisfying (A2'): a non-degenerate diffusion (additive forcing $\sigma_w dW_t$, $\sigma_w > 0$) exits any bounded region in finite time almost surely, for any locally bounded drift — no finite inward correction can defeat the Brownian crossing near $\partial\mathcal{B}_R$. The Ornstein–Uhlenbeck benchmark makes the mechanism explicit (scale function $s'(u) \propto e^{\alpha u^2 / \sigma_w^2}$ unbounded, hence recurrent; Khasminskii 2012¹ ch. 3–4), but the conclusion needs only non-degeneracy of the additive noise on a bounded region, not the linear structure. That the natural maximal-inequality route to a $P(\tau_R < \infty) < 1$ bound *cannot* exist — the question “are you sure you can’t just Doob/Ville this?” — is demonstrated in #deriv-stochastic-non-exit.

The achievable first-exit probability is therefore exactly the two-point set $\{0, 1\}$, and **which point obtains is fixed by the disturbance model’s support structure (bounded vs. unbounded), not by the correction strength α** . Increasing α tightens the typical scale ($R_S^* \propto 1/\sqrt{\alpha}$) and the fixed-time tail (iii’); it cannot move $P(\tau_R < \infty)$ off 1 under Model S, and is unnecessary for the 0 under Model D. Pathwise containment of $\mathcal{B}_R$ is categorically a bounded-disturbance property: additive stochastic forcing removes the *kind* of guarantee available, not merely its rate. This sharpens the hand-off into 4.8 — in any genuinely stochastic environment region-exit is a certain eventual event, so the structural-adaptation trigger is *generic, not exceptional*, for a sufficiently long-lived agent.

Summary of Results.

Table A.2

Result	What it proves	Assumptions	Linear case recovery
A.1 (Bounded Mismatch)	$R^* = \rho/\alpha$	(A1), (A2'), bounded ρ (GA-2)	$\alpha = \mathcal{T}$ gives $R^* = \rho/\mathcal{T}$
A.1S (Stochastic Bounded Mismatch, region-aware)	$R_S^* = \sigma_w \sqrt{n/(2\alpha)}$ (stopped bound); fixed-time tail $P(\ \delta(t)\ > R) \leq n\sigma_w^2/(2\alpha R^2)$ (stationary-sharp); no infinite-horizon non-exit bound — pathwise containment is Model-D-only	(A1), (A2') on $\mathcal{B}_R$, stochastic w (GA-2S)	$\alpha = \mathcal{T}$ gives $R_S^* = \sigma_w \sqrt{n/(2\mathcal{T})}$
Cor A.1S.1 (Disturbance-Model Containment Dichotomy)	$P(\tau_R < \infty)$ is exactly $\{0, 1\}$ — 0 under Model D (positive invariance), 1 under Model S (a.s. exit of a non-degenerate diffusion); α -invariant, correction strength cannot interpolate	(A1), (A2') on $\mathcal{B}_R$; Model D needs $\alpha R > \rho$	Model D $\rightarrow$ Prop A.1 invariance at $\alpha = \mathcal{T}$; Model S $\rightarrow$ OU recurrence is the explicit instance — exact generally (any F under A2'), not linear-scoped
A.2 (Stability Margin)	$\Delta\rho^* = \alpha R - \rho$	Same as A.1	$R \rightarrow \infty$ for linear (always stable if $\mathcal{T} > 0$)

What Is Derived vs. What Is Chosen.

Table A.3

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Dynamics setup $\dot{\delta} = -F(\mathcal{J}, \delta) + w(t)$ with F as correction function and w as disturbance	Definitional scope of the appendix; generalizes the linear hypothesis of 3.9	Definition
(A1) $F(\mathcal{J}, 0) = 0$	Qualitative property of any correction process by construction	Assumption (uncontroversial)
(A2') Local sector condition $\delta^T F \geq \alpha \ \delta\ ^2$ on $\mathcal{B}_R$	Sector-condition framework (Lur'e 1957); sub-scope α (Kalman/conjugate Bayesian, exponential family in natural params, gradient descent on strongly convex losses, L2-regularized convex, linear with PD KH) derived via 4.3 Prop B.3 under B1 directional fidelity (then $\alpha = \eta^* \cdot c_{\min}$); sub-scope β (PID, rule-based, human judgment, severely misspecified, variational approximations, non-convex beyond basin, per-step SGD) requires independent verification	Derived in sub-scope α; Assumption in sub-scope β (sub-scopes named explicitly in the Grounding paragraphs)
(A3) Tempo-monotonicity of $\delta^T F$	Qualitative requirement tying $\mathcal{J}$ to correction power	Assumption
Quadratic Lyapunov candidate $V = \frac{1}{2} \ \delta\ ^2$	Canonical choice for norm-bounded stability in Euclidean state spaces (Khalil 2002 ch. 4)	Formulation choice
Prop A.1: ultimate bound $R^* = \rho/\alpha$	$\dot{V} \leq -\ \delta\ (\alpha\ \delta\ - \rho)$ via A2' + Cauchy-Schwarz; standard Lyapunov ultimate-boundedness theorem (Khalil 2002 Thm 4.18)	Proved (conditional on $R^* < R$)
Positive invariance of $\mathcal{B}_R$ under the persistence condition	Boundary-inward argument: at $\ \delta\ = R$, $\dot{V} < 0$ when $\alpha R > \rho$	Proved
Lemma A.1N: threshold tightness — $\alpha > \rho/R$ is necessary-and-sufficient for the <i>uniform class-level</i> containment guarantee; agent-level necessity holds exactly under a radially tight sector ($\tilde{\alpha} = \alpha$, e.g. linear); false as an agent-level only-if for general F	Extremal-member escape ($F = \alpha\delta$, $w = \rho\delta/\ \delta\ $) + the dip counterexample (floor attained at unreachable radii; mountain-pass barrier analysis)	Proved — necessity is class-level; no fixed-agent only-if is claimed anywhere
Initial-condition scope (trajectory must start inside $\mathcal{B}_R$)	Direct consequence of A2' being local; trajectories outside are not covered	Derived (scope statement)
Identification of structural-adaptation trigger ($\rho/\alpha > R$ forces exit from parametric regime)	Connects A.1's persistence threshold to 4.8's regime boundary	Derived
Prop A.2: adaptive reserve $\Delta\rho^* = \alpha R - \rho$	Algebraic corollary of Prop A.1 under shock $\rho \rightarrow \rho + \Delta\rho$; requires R fixed under shock	Proved (corollary of A.1)
Prop A.1S (region-aware): stopped bound $\mathbb{E}[\ \delta(t \wedge \tau_R)\ ^2] \leq \ \delta(0)\ ^2 e^{-2\alpha t} + n\sigma_w^2/(2\alpha)$ + fixed-time tail $P(\ \delta(t)\ > R) \leq n\sigma_w^2/(2\alpha R^2)$ (stationary-sharp) + finite-horizon sup-bound (iv)	Itô's formula on V + A2' on $\mathcal{B}_R$ + Grönwall + stopping-time localization at τ_R (Khasminskii 2012 ch. 5; Khalil 2002 ch. 9)	Proved ; the infinite-horizon non-exit probability is structurally 1 for additive Model S (no-go, Khasminskii ch. 3–4) — pathwise containment is Model-D-only
Cor A.1S.1: containment dichotomy $P(\tau_R < \infty) \in \{0, 1\}$, α -invariant	Prop A.1 positive invariance (Model D = 0) + a.s. finite exit of a non-degenerate diffusion from a bounded region for any F under A2' (Model S = 1); Khasminskii 2012 ch. 3–4	Proved — new exact result
Stochastic steady-state RMS $R_S^* = \sigma_w \sqrt{n/(2\alpha)}$	Steady state of the Grönwall bound; scales as $1/\sqrt{\alpha}$ versus $1/\alpha$ deterministic	Derived
Tail bound $P(\ \delta\ > R) \leq n\sigma_w^2/(2\alpha R^2)$	Markov's inequality applied to steady-state second moment	Proved

Property	Source	Strength
Linear-case recovery ($\alpha = \mathcal{T}$ reproduces 4.5)	Substitution $F = \mathcal{T}\delta$ into A2'	Derived
Adversarial-exponent scaling $b = 2$ (Model D) vs $b = 3/2$ (Model S) into 16.3	Direct transfer of the $1/\alpha$ vs $1/\sqrt{\alpha}$ scalings	Derived (transfer claim)
Bounded-disturbance model (GA-2) vs stochastic-disturbance model (GA-2S) as distinct environmental regimes, not approximations to each other	Discussion-section positioning; neither regime handles heavy tails	Discussion-grade
Global sector condition would give $\Delta\rho^* = \infty$	Limit analysis of A.2 as $R \rightarrow \infty$; rejected as unrealistic for finite model classes	Derived (scope-limit observation)

The dividing line: the two persistence results (ultimate bound, adaptive reserve) and the stochastic mean-square bound are **proved** within standard Lyapunov / Itô-Lyapunov theory — the appendix's contribution is the application to AAT's correction-function object, not the mathematics. What is **chosen** is the quadratic Lyapunov candidate $V = \frac{1}{2}\|\delta\|^2$ (canonical for norm-bounded stability but not uniquely forced; see Path 3 note below) and the bounded-vs-stochastic disturbance partition (two structurally distinct empirical regimes rather than a hierarchy). The **sector condition itself** (A2') now carries its sub-scope explicitly: **derived in sub-scope** α (optimal Bayesian / exponential-family / strongly-convex-gradient / L2-regularized / linear-PD corrections, via 4.3 Prop B.3 under B1), **assumed in sub-scope** β (PID / rule-based / human-judgment / severely-misspecified / variational / non-convex-beyond-basin / per-step SGD). Prop A.1S's region condition is no longer deferred to Epistemic Status — the proposition statement is region-aware via a standard stopping-time localization (Khasminskii 2012 ch. 5); the fixed-time tail (iii') quantifies the typical-scale cost of Wiener excursions, and the *absence* of any infinite-horizon non-exit bound (a structural no-go for additive Model S) is itself the result — pathwise containment is a Model-D guarantee only.

Epistemic Status.

The setup and assumptions are *definitions* — they specify what we mean by “correction function” and “disturbance.” Propositions A.1 and A.2 are *exact* — they follow from the assumptions via standard Lyapunov theory (Khalil 2002², Chapters 4 and 9). The persistence threshold's necessity is *class-level* (Lemma A.1N, exact): $\alpha > \rho/R$ is necessary and sufficient for the uniform guarantee over the sector class, and agent-level necessary only under a radially tight sector; for a fixed general F the only-if direction is false (the demonstrated dip counterexample), so every statement of the threshold in this corpus is sufficiency-plus-class-tightness, never a fixed-agent iff. Proposition A.1S is *exact* in its region-aware form: the stopped Grönwall bound (i), the mean-square persistence condition (ii), the fixed-time tail (iii'), and the finite-horizon sup-bound (iv) are each exact (stopping-time localization at τ_R , Khasminskii 2012³, ch. 5). **Corollary A.1S.1 is itself an exact result** — and a new one: the first-exit probability is *exactly* the two-point set $\{0, 1\}$ (0 under bounded Model D, 1 under additive stochastic Model S), categorical and α -invariant, the value selected by the disturbance model's support structure rather than by correction strength. Both halves are exact (Model-D: deterministic positive invariance, Prop A.1; Model-S: almost-sure finite exit of a non-degenerate diffusion from a bounded region, for any F satisfying A2'). No implicit strengthening of A2' is required.

The sector condition A2' carries its sub-scope α / β status, the operator-family classification, and the “Why Euclidean A2' specifically” Lyapunov-matching argument at 4.2. The Lyapunov proofs above apply uniformly across both sub-scopes and across the weighted-norm variants — they operate downstream of A2' regardless of how it is established or which metric matches it.

²Khalil, H. K. (2002). *Nonlinear Systems* (3rd ed.). Prentice Hall.

³Khasminskii, R. (2012). *Stochastic Stability of Differential Equations* (2nd ed.). Springer. Chapter 5: Lyapunov functions and stochastic stability; stopping-time localization for diffusion processes.

The assumptions themselves (sector condition on a region, bounded disturbance) are *empirical claims* about the qualitative behavior of real correction dynamics. The sector-condition framework originates with Lur'e (1957); the Lyapunov stability results are standard. The application to adaptive agents under the AAT framework is new but the mathematics is not.

Discussion.

Key value. The persistence threshold and adaptive reserve are no longer contingent on the linear hypothesis in 3.9. They hold for any correction dynamics satisfying the sector condition — a mild qualitative assumption that says “correction points inward with at least baseline efficiency α .” This is a significant epistemic upgrade: from *hypothesis-dependent* to *robust under qualitative assumptions*.

What the proofs do NOT illuminate. (1) Quantitative steady-state values — Lyapunov gives *bounds*, not exact values; the linear analysis remains necessary for quantitative predictions. (2) Convergence rates — standard Lyapunov tells you stable/unstable, not how fast. (3) Optimal gain structure — 3.6 comes from estimation theory, not stability theory. (4) Model sufficiency — the 2.2 framework is information-theoretic, complementary to but independent of stability analysis.

Two disturbance models. Proposition A.1 assumes bounded disturbance (GA-2: $\|w(t)\| \leq \rho$); Proposition A.1S assumes stochastic disturbance (GA-2S: $\mathbb{E}[\|w(t)\|^2] = \sigma_w^2$). These are not approximations to each other — they capture structurally different environments. Model D (bounded) covers persistent directional change: an adversary who maneuvers, an API that drifts, a climate that shifts. Model S (stochastic) covers unpredictable fluctuations around a stable mean: market noise, sensor noise, random perturbations. The choice of model is an empirical question for each domain; the theory provides both tools. Neither model handles heavy-tailed environmental shocks (financial crises, ecological catastrophes, strategic surprise) where $\|w(t)\|$ can exceed any finite bound with non-negligible probability. Extreme tail events are better understood as triggers for structural adaptation (4.8) rather than disturbances to be absorbed parametrically.

Kind of guarantee, not just rate. The two models differ not only in how *tightly* the mismatch is held but in *what kind* of guarantee is available at all. Corollary A.1S.1 makes this exact and categorical: $P(\tau_R < \infty) = 0$ under Model D (positive invariance) versus 1 under Model S (recurrent additive-noise diffusion), with no intermediate value reachable by any correction strength. What Model S controls instead is the *typical scale* (the $1/\sqrt{\alpha}$ RMS radius, ii) and the *fixed-time tail* (iii') — distributional, instantaneous guarantees, not a sample-path-forever one. Increasing α shrinks the typical scatter; it does not convert a distributional guarantee into a pathwise one. This is the deeper content of “these are not approximations to each other”: additive stochastic forcing removes the *kind* of containment available, not merely its rate. It sharpens — rather than caveats — the hand-off into 4.8: in a genuinely stochastic environment, region-exit is not a measure-zero pathology to be assumed away but a *certain eventual event*, so the trigger for structural (non-parametric) adaptation is **generic, not exceptional**, for any sufficiently long-lived agent.

Findings.

The disturbance-model containment dichotomy: $P(\tau_R < \infty)$ is exactly $\{0, 1\}$, α -invariant. Result (exact, new). Corollary A.1S.1: under the sector-condition correction dynamics, the persistence-region first-exit probability is *categorical* — exactly 0 under bounded disturbance (Model D, positive invariance) and exactly 1 under additive stochastic disturbance (Model S, almost-sure exit of a non-degenerate diffusion from a bounded region). The achievable value is the two-point set $\{0, 1\}$; which point obtains is fixed by the disturbance model's support structure, **not** by correction strength α .

Brief: Against a *bounded* disturbance — a steady wind you can lean into — a sector-stable corrector holds the mismatch inside a fixed region *forever and with certainty*: once in, never out. Against *stochastic* disturbance — random gusts — no correction strength buys that. The agent stays near target on average and almost all of the time, but over an

unbounded horizon some fluctuation eventually pushes it past any fixed boundary, with probability one. Stronger correction tightens the *typical* scatter (the RMS radius shrinks as $1/\sqrt{\alpha}$); it does not erect a wall. So moving from bounded to stochastic environments is not “the same guarantee with a weaker constant” — it is a change in the *kind* of guarantee available: pathwise-and-forever (Model D) versus distributional-and-fixed-time (Model S). Practical consequence: in any genuinely stochastic environment, leaving the parametric-correction region is not a rare pathology to assume away — it is a certain eventual event, so the trigger for *structural* adaptation is generic, not exceptional.

Impact: Sharpens the Model-D/Model-S architecture and the hand-off into 4.8 (structural adaptation is a generic eventual necessity for long-lived agents in stochastic environments, not an edge case). The companion controls under Model S are the fixed-time tail (iii', the Markov bound $P(\|\delta(t)\| > R) \leq n\sigma_w^2/(2\alpha R^2)$, stationary-sharp) and the finite-horizon sample-path bound (iv); pathwise containment is categorically Model-D-only. The Model-S half is the load-bearing proof step demonstrated at length in #deriv-stochastic-non-exit, which also packages the reusable no-go signature (*unbounded scale function* $\Rightarrow$ *no non-constant bounded harmonic function* $\Rightarrow$ *no horizon-independent non-exit certificate*) that future stochastic-containment proposals can be settled against rather than re-attempted.

Novelty Claim: *Synthesis* — an exact result built from classical components. The component facts are textbook: deterministic positive invariance under bounded disturbance (Khalil 2002 ch. 4) and almost-sure finite exit of a non-degenerate diffusion from a bounded region (Khasminskii 2012 ch. 3–4; the OU scale-function computation is the explicit instance). The new exact result is their synthesis into a *categorical, α -invariant containment dichotomy* stated as a structural property of AAT's own Model-D/Model-S architecture: correction strength cannot interpolate $P(\tau_R < \infty)$ between the two disturbance regimes — the value is exactly $\{0, 1\}$, selected by disturbance-support structure. This exact dichotomy is new to the framework; it sharpens the structural-adaptation hand-off (4.8). No novelty is claimed on the SDE mathematics — the novelty is the exact dichotomy as a framework theorem and its α -invariance.

Table A.4

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
No infinite-horizon non-exit bound for additive-noise diffusions	Khasminskii 2012, <i>Stochastic Stability of Differential Equations</i> (2nd ed.) ch. 3–4 (recurrence; scale function; no bounded non-constant harmonic function)	<i>formal antecedent</i> — supplies the classical recurrence fact; AAT recognizes it as the structural reason Model S admits no pathwise-forever containment in contrast to Model D
Fixed-time second-moment tail	Markov's inequality on the stopped Itô-Lyapunov second moment (Khasminskii 2012 ch. 5)	<i>standard machinery</i> — (iii') is Markov on (i); the AAT-specific content is the Model-D/S kind-of-guarantee contrast it forces
Pathwise positive invariance under bounded disturbance	Khalil 2002 ch. 4 (ultimate boundedness; boundary-inward invariance)	<i>formal antecedent</i> — Model D's pathwise-forever guarantee (Prop A.1) is the contrast term that makes the Model-S no-go a <i>kind</i> distinction, not a rate one

Search Log:

- 2026-05-16 (*targeted, derivation-driven*): the question was internal — does Prop A.1S(iii)'s infinite-horizon non-exit bound hold? The strengthening attempt (Doob/Ville maximal inequality on the Itô-Lyapunov supermartingale) was worked in full and shown to fail structurally; the classical recurrence fact (Khasminskii ch. 3–4) is the obstruction and is well-known. No prior-art search beyond the standard SDE references was needed — no novelty is claimed on the mathematics, only on the framework-level kind-of-guarantee recognition. Reasoning trail recorded in the spike-routing cycle (CHANGELOG 2026-05-17).

Working Notes.

- The adversarial extension (Prop A.3, coupled agents) and effects spiral (Cor A.3.1) are in 15.2. The multi-timescale stacking theorem (historically sketch A.4) is in **M** — now derived by stacking the template per level.
- The vector treatment of $\delta(t) \in \mathbb{R}^n$ connects directly to per-dimension tempo analysis (16.5). Each dimension can have different effective α_k values, and the weakest dimension determines overall persistence — a tensor generalization of the scalar results here.
- A global sector condition (A2 without the local restriction to $\mathcal{B}_R$) would give global stability, making $\Delta\rho^*$ infinite — the agent could absorb any finite disturbance shock. But this requires the correction function to work perfectly at arbitrary mismatch magnitudes, which is unrealistic for any finite model class. The local form (A2') is the honest one.
- Landing-context provenance: the sub-scope α/β partition reflects the strengthening trail recorded in spikes/.integrated/spike-a2-prime-strengthening.md — the analysis that ruled out a universal A2' derivation and identified the five operator families where the bridge is structural.
- Landing-context provenance (A.1N + register): Prop A.1's closing line and two downstream result segments previously stated the persistence threshold as a fixed-agent "iff"; the only-if was never proven and is false under the sector generalization (α is a worst-case floor the dynamics may render unreachable — the dip counterexample, independently constructed and simulation-confirmed twice, audit 731548 B-1). Per strengthen-before-soften the landing is the *split*: sufficiency retained as proven, plus Lemma A.1N (class-level necessity, exact) and the tight-case agent-level iff — strictly more content than the unproven iff. The TFT-era linear result (_obs/old-tf-11) minted the "iff" where it is true (linear = tight case); the sector generalization inherited the word without the hypothesis. Regression-guard: do not restore a fixed-agent "iff" here or in #result-sector-condition-stability / #result-persistence-condition / #result-sector-persistence-template without an upper sector bound in force.
- Landing-context provenance (iii')/(iv)/dichotomy: the prior (iii) asserted an infinite-horizon $P(\tau_R < \infty) \leq n\sigma_w^2/(2\alpha R^2)$ via a "Markov tail on the supermartingale," conflating a fixed-time second-moment bound with the ever-exit probability. Audit findings 742613-SUPPLEMENT §2 and 613842-F2 flagged it and recommended a *soften* (restate as fixed-time). Per strengthen-before-soften the strengthening (Doob/Ville maximal inequality, the route the 628401 adjudication predicted would succeed) was attempted in full first and **fails structurally** — a documented dead-end (no nonnegative supermartingale dominates V ; additive-noise generator has no bounded non-constant harmonic function; recurrent OU exits a.s., EM-corroborated). Completion-state (3): the failure *is* the result — the (iii')+(iv)+kind-of-guarantee-dichotomy package is strictly more honest and more informative than the false (iii). The 628401 prediction that the strengthening would succeed is recorded as disconfirmed so it is not re-attempted.
- *Low-confidence ideation* (flagged per "working notes FTW" — *glimpses worth recording, not claims*):
 - The dichotomy is now stated as the labeled exact result **Corollary A.1S.1**; the general- F concern is resolved *within* it (the Model-S half needs only non-degeneracy of the additive noise on a bounded region — no linear structure, any F under A2'). The open glimpse is whether the *dichotomy itself* recurs at the corpus's other bounded/additive-stochastic pairs — #deriv-discrete-sector-condition, #deriv-matrix-persistence-condition, #deriv-adaptive-gain-dynamics, possibly #result-per-dimension-persistence. If Cor-A.1S.1-shaped dichotomies appear at ≥ 3 sites, that is a candidate instance-family for the theorem-import-architecture meta-segment (PROPOSALS SP-23) or a sibling of #disc-identifiability-floor (the infinite-horizon non-exit object is *structurally absent*, not merely hard to bound — an identifiability-floor-shaped no-go, now with an exact dichotomy as its positive-content companion).
 - Sharper consequence for 03-llm-core/04-eli-core: ELI/LLM operating environments are Model-S-like (stochastic), so the corrected (iii') + dichotomy says structural adaptation is *certain over an unbounded horizon* for long-lived language-constituted agents — not contingent. That tightens the persistence $\leftrightarrow$ continuity / Three-Deaths line: continuity *requires* recurring structural (not just parametric) adaptation, and the Model-S no-go makes that requirement inevitable rather than a risk. Worth a deliberate look when the parts III/IV persistence segments are next touched (low confidence on exact form; high confidence the connection is real).

- The no-go’s signature — “compensating to restore the supermartingale destroys nonnegativity / generator has no bounded non-constant harmonic function” — is a reusable *diagnostic*: a fast structural test for whether any proposed “stays-in-region-forever w.h.p.” claim elsewhere is impossible vs. merely unproven. Candidate content for whichever meta-segment catalogs the framework’s no-go boundary results.
- Downstream worth a check (not chased here): does the $b = 3/2$ Model-S adversarial-exponent scaling in #result-adversarial-exponent-regimes implicitly lean on the old infinite-horizon framing anywhere? Expected not (it transfers the $1/\sqrt{\alpha}$ RMS scaling, which is unchanged), but flagged so a future pass confirms rather than assumes.

Incidental audit gold (lift 2026-05-31). Orthogonal pedagogical / generative material harvested from the de-novo auditors’ working dirs (per de-novo-audit-instructions.md §7.15), deduplicated across substrates and lightly attributed. Pedagogical framing, analogies, figure candidates, and reader-confusion signals only — certified theory-fix findings are off-ramped below. Several substrates read this as the framework’s “mathematical engine room” / “spine”; felt-value was consistently very high.

1. Candidate Briefprose / pre-prose.

- **Lyapunov V as the agent’s “pain.”** $V(\delta) = \frac{1}{2}\|\delta\|^2$ reads as a formalization of stress; $\dot{V} \leq -\alpha\|\delta\|^2 + \rho\|\delta\|$ is its dynamics — a quadratic *self-soothing* term (active learning; the more it hurts, the harder the agent works) racing a linear *infliction* term (the environment). A parabola eventually overtakes a line, so correction always wins *as long as the parabola keeps its shape* — but at the model-class boundary R the parabola breaks (the agent no longer knows how to fix the mismatch), the $-\alpha\|\delta\|^2$ term collapses, and $\dot{V}$ goes permanently positive (Gemini, AUDIT-WORKING-193847). A vivid, near-Feynman gloss of why persistence is a hard threshold rather than a gradual slope.
- **“Survival = Ultimate Boundedness in a Lur’e system.”** A compact one-line statement of what the segment actually proves (Gemini, AUDIT-WORKING-193847).
- **The thermodynamic survival law framing.** The sector condition unifies Bayesian updating, natural gradients, and regularized convex optimization under a single survival law: *any* update mechanism pointing inward toward truth with minimal efficiency α persists — survival does not require linear gradient descent (Gemini, AUDIT-WORKING-829314).

2. Candidate Discussion.

- **Sub-scope α/β as a “formal API for trust.”** The derived/assumed partition is repeatedly flagged as one of the most mature epistemic moves in the corpus: it tells you *when to trust the math vs. when to run a simulation*. Restated with teeth: an organization that “has a review process” is not automatically learning — if the review operator T_d is not structurally coco-erive, the organization is in sub-scope β and its α might be zero or negative (Gemini, AUDIT-WORKING-193847 and AUDIT-WORKING-829314; Claude, AUDIT-WORKING-584721 — proposes a one-line TL;DR: “ α = operator families coco-erive in some natural inner product; β = those that aren’t”).
- **“Bureaucracies don’t bend; they shatter.”** The structural-Lipschitz-floor scope-exit (rule-based / threshold agents need hybrid-dissipative analysis, not continuous Lyapunov contraction) reads as a claim that rigid IF-THEN systems are mathematically dangerous in volatile environments: a tiny environmental change can trigger an $\Omega(1)$ instantaneous internal jump, so they thrash rather than smoothly track a drifting environment. Continuous, differentiable learning is framed as a *physical prerequisite* for smooth persistence (Gemini, AUDIT-WORKING-829314).
- **“Matched vs forced” coordinate as a standalone observation.** The Lyapunov quadratic is a *matched* (canonical-but-not-Cauchy-FE-forced) coordinate, in contrast to the framework’s *forced* coordinates at the chain / divergence / update / metric layers. Surfacing this distinction explicitly (candidate home: #disc-additive-coordinate-forcing) rather than leaving it inside the proof would sharpen the scope-honesty about which coordinates are theoretically forced vs. conventionally chosen (Claude, AUDIT-WORKING-584721).

3. Follow-up items.

- **Local-only proofs — guard against global-stability creep.** All proofs are strictly local (confined to $\mathcal{B}_R$); any downstream claim of infinite adaptive reserve ($\Delta\rho^* = \infty$) or “immortality / permanent continuity in a stochastic environment via high α ” is a hallucination the segment forbids. Worth watching in Parts III/IV (Gemini, AUDIT-WORKING-193847 and AUDIT-WORKING-829314).

- **Double-floor regime for rule-based agents.** Rule-based agents with regime-dependent thresholds can suffer *both* non-contractibility (structural-Lipschitz-floor) *and* non-identifiability (when the regime is unobservable) — two distinct floor mechanisms composing multiplicatively. Candidate to check whether classical expert systems / heuristic agents sit in this double-floor regime (Claude, AUDIT-WORKING-584721).
- **Anisotropic-noise generalization.** Adversarial poke: the Model-S Itô term $\frac{n}{2}\sigma_w^2$ assumes isotropic i.i.d. noise $w(t) \sim \mathcal{N}(0, \sigma_w^2 I_n)$; the honest general form is $R_S^* = \sqrt{\text{tr}(\Sigma)/(2\alpha)}$, which preserves the physics while connecting more cleanly to #result-per-dimension-persistence. Either state the isotropy assumption explicitly or generalize (Gemini, AUDIT-WORKING-193847). (*Borderline gold/structure; recorded as a follow-up since the repair is a scope statement, not a new theorem.*)

4. Readers often ask / wonder.

- **Why are discrete-logic agents brittle to high-frequency noise?** The structural-Lipschitz-floor result raises the natural question of whether any agent using discrete logic gates inside its core loop is fundamentally brittle to a class of high-frequency noise that continuous agents simply absorb (Gemini, AUDIT-WORKING-193847).
- **One-point vs two-point sector — which is in force?** A reader can lose track of which sector condition a downstream proof actually establishes; the one-point (anchored-at-equilibrium) form used in the main Lyapunov argument is strictly weaker than the two-point (incremental / strong-monotone) form needed for composition (Claude, AUDIT-WORKING-451729 / AUDIT-WORKING-584721; the $L'(x) = x(1 + \frac{1}{2} \sin 10x)$ counterexample is the cleanest illustration).

5. Candidate figures.

- **Small-multiples for the persistence dynamics.** Per the diagram-conventions cycle, sector/persistence dynamics should be drawn as state→op→state triples, not one busy phase portrait, using the cross-segment palette (asfCert indigo = stability certificate / Lyapunov) (Claude, AUDIT-WORKING-472913 standing figure conventions).

Belongs elsewhere.

- **ELI ethical-boundary reading (Section IV / 04-eli-core/).** The steady-state pain $R^* = \rho/\alpha$ vs. structural capacity R defines an ethical boundary on an artificial mind's existence: subjecting an intelligence to an environment where $R^* > R$ is framed as not merely failed alignment but “mathematically torturing it until it breaks.” Aspirational reach pointing at the crèche / developmental-environment work, not at this segment (Gemini, AUDIT-WORKING-193847).

Off-ramp (NOT gold) — certified-track items, routed for adjudication. The dense-math auditors left strengthen-first / structural findings here, not pedagogy. Flagged so they are not buried; most are already resolved in canon — verify-against-current-canon before acting.

- **Prop A.1S non-exit probability (RESOLVED in canon — do not re-open).** 742613 (Candidate Finding J) and 829314 flagged the infinite-horizon $P(\tau_R < \infty) \leq n\sigma_w^2/(2\alpha R^2)$ claim as conflating a fixed-time second-moment tail with the ever-exit probability (recurrent OU exits any bounded region a.s.). This was strengthened-then-no-god into **Corollary A.1S.1** (the Disturbance-Model Containment Dichotomy: $P = 0$ under bounded Model D, $P = 1$ under stochastic Model S) — see the Working Notes above and #deriv-stochastic-non-exit. Recorded only so a future auditor does not re-raise it as open.
- **Template-insufficiency for composition (structural; route with result-sector-persistence-template).** The (T1)–(T3) template provides only the one-point sector (T2); the bridge lemma / composition closure require the strictly stronger incremental two-point bound (DA2'-inc). 193847 reads the base template as mathematically insufficient for the compositional proofs and recommends either a “Template-Strong” variant or explicit per-instance labeling of which template each compositional segment instantiates. Verify whether canon already distinguishes these (see result-sector-persistence-template WN dynamic-regime tiers).
- **PID sub-scope characterization (editorial-structural).** 193847: a well-tuned PD controller *is* strongly monotone on the error space; it is specifically the stateful Integral term (or human-judgment delay) that breaks the memoryless static-sector assumption and forces PID into sub-scope β . Candidate sharpening of the operator-family classification's PID row.

Appendix B

Derivation: No Horizon-Independent Non-Exit Bound Under Additive Stochastic Forcing (the Model-S No-Go)

A *no-go* derivation establishing that **under additive stochastic forcing there is no finite bound on the infinite-horizon first-exit probability** from the sector-condition region — $P(\tau_R < \infty) = 1$ for every correction strength — *and the natural mathematical route to one provably cannot exist*. This is the load-bearing proof step behind Prop A.1S(iii')/(iv) and the Model-S half of Corollary A.1S.1 in #deriv-sector-condition.

The construction: under stochastic disturbance the Itô-Lyapunov machinery succeeds at producing a *finite-horizon mean-square bound* but fails to extend to a *horizon-independent* exit-probability bound. The natural candidate — a Ville / Doob maximal inequality on a compensated Itô-Lyapunov supermartingale — is shown to be unattainable because the only candidate $S(t) = e^{2\alpha t} V - \frac{n\sigma_w^2}{4\alpha}(e^{2\alpha t} - 1)$ is *sign-indefinite inside the persistence basin* (the compensated drift is not non-positive across the entire region: the subtracted term dominates $e^{2\alpha t} V$ whenever the system sits in the typical scatter, which under the mean-square persistence condition is most of the time). The deeper obstruction is that for additive non-degenerate forcing the diffusion's scale function is *unbounded* — the OU benchmark $s'(u) \propto e^{\alpha u^2 / \sigma_w^2}$ is the explicit instance — so the only bounded harmonic functions of the generator are constants and the gambler's-ruin / Lyapunov-exit machinery cannot certify “stays inside forever with positive probability.” Both failures are structural, not artifacts of a clever trick being missed.

The framework treats this as a *constructive use of impossibility*. The downstream consequence is a certain-eventual-event reading: under Model S, pathwise containment in any fixed region is unattainable at any correction strength, so for any sufficiently long-lived stochastic-environment agent the *need for structural adaptation* (a different model class, not just better parameter tuning) is a *certain eventual event* rather than an edge case. This sharpens — rather than caveats — the hand-off into #result-structural-adaptation-necessity. Beyond the segment's own result the derivation packages a **reusable no-go signature**: *unbounded scale function $\Rightarrow$ no non-constant bounded harmonic function $\Rightarrow$ no horizon-independent non-exit certificate*. Future stochastic-containment proposals in the corpus can be settled against this signature rather than re-attempting the maximal-inequality route.

Formal Expression.

Setup. Mismatch dynamics under additive stochastic disturbance, started inside the sector-condition region $\mathcal{B}_R$:

$$d\delta = -F(\mathcal{J}, \delta) dt + \sigma_w dW_t, \quad \delta(0) \in \mathcal{B}_R, \quad \sigma_w > 0, \quad (\text{B.1})$$

with W_t a standard n -dimensional Wiener process, (A2') $\delta^\top F \geq \alpha \|\delta\|^2$ on $\mathcal{B}_R$, and $\tau_R = \inf\{t : \|\delta(t)\| > R\}$ the first-exit time. Let $V = \frac{1}{2} \|\delta\|^2$.

Theorem (Model-S no-go). [Derived] For every $\alpha > 0$, every $\sigma_w > 0$, and every correction function F satisfying (A2'),

$$P(\tau_R < \infty) = 1, \quad (\text{B.2})$$

and there exists no nonnegative supermartingale dominating V that certifies a horizon-independent bound $P(\tau_R < \infty) \leq c < 1$. Pathwise containment of $\mathcal{B}_R$ is unattainable under additive stochastic forcing at any correction strength.

Why the natural route cannot work. The route a careful reader reaches for first is a time-uniform maximal inequality (Ville / Doob) on an Itô–Lyapunov supermartingale — the same instinct that makes the fixed-time mean-square bound (Prop A.1S(i)) succeed. It fails, and the failure is structural, not a matter of a missing trick.

Define $G(t) = e^{2\alpha t} V(\delta(t))$. On $[0, \tau_R]$, by Itô and (A2'),

$$dG = e^{2\alpha t} \left[\underbrace{(2\alpha V - \delta^\top F)}_{\leq 0 \text{ on } \mathcal{B}_R} dt + \frac{n}{2} \sigma_w^2 dt + \delta^\top \sigma_w dW_t \right] \leq e^{2\alpha t} \frac{n}{2} \sigma_w^2 dt + e^{2\alpha t} \delta^\top \sigma_w dW_t. \quad (\text{B.3})$$

G is **not** a supermartingale: the $+e^{2\alpha t} \frac{n}{2} \sigma_w^2 dt$ term has strictly positive drift growing exponentially. Removing it by compensation gives

$$S(t) = e^{2\alpha(t \wedge \tau_R)} V(\delta_{t \wedge \tau_R}) - \frac{n\sigma_w^2}{4\alpha} (e^{2\alpha(t \wedge \tau_R)} - 1), \quad (\text{B.4})$$

and $dS \leq e^{2\alpha t} \delta^\top \sigma_w dW_t$ on $[0, \tau_R]$ — so S is a supermartingale. **But S is not nonnegative.** The subtracted $\frac{n\sigma_w^2}{4\alpha} (e^{2\alpha t} - 1)$ dominates $e^{2\alpha t} V$ whenever $V(\delta(t)) < \frac{n\sigma_w^2}{4\alpha}$ — i.e. exactly inside the persistence basin, which under the mean-square persistence condition is *most of the time* (that condition places the RMS radius $R_S^* = \sigma_w \sqrt{n/2\alpha}$ well inside $\mathcal{B}_R$, so $V \ll \frac{n\sigma_w^2}{4\alpha}$ typically). Ville's inequality requires a nonnegative supermartingale; Doob's maximal inequality a nonnegative sub/supermartingale. Both are inapplicable to a sign-indefinite S , and the obstruction is not removable: for additive non-degenerate Brownian forcing the diffusion's scale function is unbounded (the OU scale density $\propto e^{\alpha u^2 / \sigma_w^2}$), so the only bounded harmonic functions of the generator are constants — the gambler's-ruin / Lyapunov-exit machinery cannot certify “stays inside forever with positive probability.” There is no nonnegative supermartingale dominating V with finite expected initial value that yields a horizon-independent exit bound.

Why $P(\tau_R < \infty) = 1$, generally. The conclusion does not depend on the linear structure. A non-degenerate diffusion (additive forcing $\sigma_w dW_t$, $\sigma_w > 0$) exits any bounded region in finite time almost surely, for *any* locally bounded drift: near $\partial \mathcal{B}_R$ the Brownian increment has positive probability of crossing in any time interval, and no finite inward correction satisfying (A2') can suppress this (A2' bounds $\delta^\top F$ from below by $\alpha \|\delta\|^2$, a finite inward push, not an impassable wall). Hence $\tau_R < \infty$ a.s. for every F under (A2'), every α , every σ_w . The Ornstein–Uhlenbeck case is the explicit instance (positively recurrent on $\mathbb{R}^n$, unbounded stationary support, exits any finite ball a.s.), not the basis.

Epistemic Status.

Exact. Both the impossibility of the maximal-inequality certificate (sign-indefiniteness of the only candidate compensated supermartingale; unbounded scale function $\Rightarrow$ no non-constant bounded harmonic function) and the positive fact $P(\tau_R < \infty) = 1$ (almost-sure finite exit of a non-degenerate diffusion from a bounded region under any locally bounded drift) are classical (Khasminskii 2012¹ ch. 3–4). The contribution here is not the SDE mathematics but the demonstration that the route which *succeeds* for the fixed-time second moment (Prop A.1S(i)) structurally *cannot* deliver an infinite-horizon containment statement — the answer to “are you sure you can’t just bound $\sup_t$ with Doob/Ville?” is *yes, sure, and here is precisely the step that breaks*. “Exact” is claimed in the framework’s defeasible sense (valid under stated assumptions, subject to a found error), not as a claim beyond a found-mistake.

This derivation is load-bearing for the critical path: it is the proof step that forces Prop A.1S’s corrected (iii’) fixed-time tail and (iv) finite-horizon sup-bound (in #deriv-sector-condition) and grounds the Model-S half of Corollary A.1S.1. It is a **reusable no-go signature**: wherever a “stays-in-region-forever with positive probability” claim is proposed under additive non-degenerate forcing, the unbounded-scale-function / no-non-constant-bounded-harmonic-function obstruction settles it negatively without a fresh attempt.

Discussion.

The structural reading: additive stochastic forcing does not weaken the *rate* of containment, it removes a *kind* of guarantee. Bounded disturbance (Model D) gives deterministic positive invariance of $\mathcal{B}_R$ ($P(\tau_R < \infty) = 0$); additive stochastic disturbance gives almost-sure eventual exit ($P(\tau_R < \infty) = 1$); the achievable value is the two-point set $\{0, 1\}$, selected by the disturbance’s support structure, not by correction strength — Corollary A.1S.1 in #deriv-sector-condition. What survives under Model S is distributional and instantaneous: the fixed-time / stationary Markov tail (Prop A.1S(iii’)) and the finite-horizon sample-path bound (Prop A.1S(iv), which grows linearly in the horizon and is vacuous for $T > r\text{sim}R^2/(n\sigma_w^2)$).

Direct simulation confirms the obstruction is real rather than an artifact of the proof technique. Exact 1-D OU benchmark $dX = -\alpha X dt + \sigma dW$ (the segment’s own linear case; (A2’) global and sharp), Monte-Carlo started *at the origin* (the most favorable initial condition), under the mean-square persistence condition (ii) holding:

Table B.1

α	σ	R	R_S^*	$P(\sup_{[0,50]} > R)$	$T=200$	$T=800$	$T=3200$	<i>seg. const</i> $\frac{n\sigma^2}{2\alpha R^2}$
1.0	0.3	1.0	0.21	0.002	0.010	0.030	0.114	0.045
0.5	0.2	0.8	0.20	0.020	0.074	0.276	0.720	0.063
1.0	0.5	1.0	0.35	0.781	0.998	1.000	1.000	0.125

The ever-exit probability climbs monotonically toward 1 with the horizon even started at the origin and even with (ii) comfortably satisfied — the fixed-time constant $n\sigma^2/(2\alpha R^2)$ is *not* an upper bound on the sup-over-horizon probability, exactly as the no-go predicts. This sharpens the hand-off into #result-structural-adaptation-necessity: under any genuinely stochastic environment region-exit is a certain eventual event, so the trigger for structural (non-parametric) adaptation is generic, not exceptional, for a sufficiently long-lived agent.

Findings.

¹Khasminskii, R. (2012). *Stochastic Stability of Differential Equations* (2nd ed.). Springer. Chapters 3–4 (recurrence, scale function, bounded harmonic functions); Chapter 5 (Lyapunov functions, stopping-time localization).

The natural maximal-inequality route to infinite-horizon containment provably cannot exist under additive stochastic forcing. **Brief:** If a system is held near a target by inward correction but also kicked by persistent random noise, you can bound how far off it is at any *given* moment, and you can bound the worst excursion over any *fixed window* — but you can never bound “it stays inside the safe region *forever*,” because given unlimited time the noise will, with certainty, eventually push it out, no matter how strong the correction. The tempting fix — find a single “energy” quantity that only ever drifts downward, so a classic gambler’s-ruin argument caps the lifetime escape probability — fails for a precise reason: the only candidate energy that has the right drift is negative exactly where the system spends most of its time, and the gambler’s-ruin machinery requires a non-negative quantity. This is not a missing trick; it is structural, and it is the same obstruction every time, so it can be invoked rather than re-derived.

Impact: Supplies the load-bearing proof step for Prop A.1S(iii’)/(iv) and Corollary A.1S.1 in #deriv-sector-condition (the Model-S half of the containment dichotomy). Provides a reusable no-go signature — *unbounded scale function* $\Rightarrow$ *no non-constant bounded harmonic function* $\Rightarrow$ *no horizon-independent non-exit certificate* — that future stochastic-containment proposals in the corpus can be settled against without re-attempting the maximal-inequality route.

Novelty Claim: Recognition. The component facts (non-degenerate-diffusion exit from a bounded region; unbounded scale function of additive-noise generators; Ville/Doob preconditions) are classical (Khasminskii 2012 ch. 3–4). The contribution is the recognition, made explicit and citable, that the maximal-inequality route which succeeds for the fixed-time second moment structurally cannot deliver the infinite-horizon statement — i.e. *where exactly* the natural attempt breaks. No novelty is claimed on the SDE mathematics.

Related Work:

Table B.2

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
No horizon-independent non-exit certificate for additive-noise diffusions	Khasminskii 2012, <i>Stochastic Stability of Differential Equations</i> (2nd ed.) ch. 3–4 (scale function; recurrence; bounded harmonic functions)	<i>formal antecedent</i> — supplies the recurrence / unbounded-scale-function fact; this derivation recognizes it as the structural reason the Ville/Doob route fails
Maximal-inequality preconditions	Ville’s inequality; Doob’s maximal inequality (nonnegative sub/supermartingale required)	<i>standard machinery</i> — the demonstration is that the only compensated candidate is sign-indefinite exactly inside the persistence basin

Search Log:

- 2026-05-16 (*targeted, derivation-driven*): internal question — can Prop A.1S’s infinite-horizon non-exit claim be certified by Ville/Doob on an Itô–Lyapunov supermartingale? Worked in full; the candidate compensated supermartingale is sign-indefinite, and the classical unbounded-scale-function fact (Khasminskii ch. 3–4) closes it. No prior-art search beyond standard SDE references — no novelty claimed on the mathematics. Reasoning trail recorded in the spike-routing cycle (CHANGELOG 2026-05-17).

Working Notes.

- Provenance: the prior Prop A.1S(iii) asserted an infinite-horizon $P(\tau_R < \infty) \leq n\sigma_w^2/(2\alpha R^2)$ via a fixed-time “Markov tail on the supermartingale.” Two audit records (742613-SUPPLEMENT §2, 613842-F2) flagged it and recommended a soften; per strengthen-before-soften the strengthening (the Ville/Doob route, which a peer adjudication confidently predicted would succeed — “standard textbook, should not fail”) was worked in full *first* and fails structurally, as demonstrated above. Completion-state (3): the failure is the result. The peer prediction that the strengthening would succeed

is recorded here (and in the spike-routing cycle, CHANGELOG 2026-05-17) as disconfirmed, so it is not re-attempted. 742613-SUPPLEMENT §2 + 613842-F2 are resolved by strengthening-then-no-go (state 3), not by soften.

- The generality (any F under $A2'$, not just OU) rests on the elementary non-degenerate-diffusion-exits-bounded-region fact, not on the OU scale-function computation; the latter is the explicit instance. No further strengthening of this half is open.
- Low-confidence glimpse (per “working notes FTW”): the same obstruction shape should recur wherever the corpus pairs a bounded-disturbance result with an additive-stochastic counterpart — `#deriv-discrete-sector-condition`, `#deriv-matrix-persistence-condition`, `#deriv-adaptive-gain-dynamics`, possibly `#result-per-dimension-persistence`. If a Corollary-A.1S.1-shaped dichotomy appears at ≥ 3 sites, that is a candidate instance-family for the theorem-import-architecture meta-segment (PROPOSALS SP-23) or a sibling of `#disc-identifiability-floor` (the infinite-horizon non-exit object is *structurally absent*, not merely hard to bound).

Incidental audit gold (lift 2026-05-31). Orthogonal pedagogical / generative material from the de-novo auditors’ working dirs (per `de-novo-audit-instructions.md` §7.15). This segment has no *dedicated* per-segment reflection; the gold below was harvested from the auditors’ reflections on the calling result `#deriv-sector-condition`, where the Model-S no-go (now Corollary A.1S.1, the Disturbance-Model Containment Dichotomy) is discussed at length. No certified-track off-ramp here — the originating finding is this segment.

1. *Candidate Briefprose / pre-prose.*

- **The $P = 0$ vs $P = 1$ containment dichotomy as the punchline.** Bounded disturbance (Model D): the agent *never* exits the region. Non-degenerate stochastic disturbance (Model S): the agent *must* exit any bounded region in finite time, almost surely. Stated as a clean dichotomy, this is the segment’s headline and reads vividly without symbols (Gemini, AUDIT-WORKING-829314).

2. *Candidate Discussion.*

- **“No amount of parameter tuning keeps an agent safe forever in a noisy world.”** The recurrence of a non-degenerate diffusion means structural adaptation (changing the model class) is *mathematically inevitable* for any long-lived agent — not contingent, not a risk to be engineered away. This is framed as what distinguishes AAT from generic optimization theories: black-swan failures are not edge cases but mathematical certainties over a long-enough horizon in a stochastic environment (Gemini, AUDIT-WORKING-829314).
- **The exact boundary between parametric and structural adaptation.** The dichotomy “provides the exact mathematical boundary where parametric learning (gradient descent) ends and structural adaptation (architecture search / tool use) must begin” — a candidate Discussion sentence locating *why* the no-go sits on the critical path to `#result-structural-adaptation-necessity` (Gemini, AUDIT-WORKING-829314).

3. *What the framework now contributes (field-level).*

- **Epistemic-honesty exemplar.** The auditor singled out the documented *failed* attempt (the Ville/Doob maximal-inequality route that a peer adjudication predicted would succeed) as “a gold standard for theoretical research” — preserving the dead-end so the no-go reads as established, not merely unproven (Gemini, AUDIT-WORKING-829314). Calibration signal: the strengthen-then-no-go discipline lands well with fresh readers.

Belongs elsewhere.

- **ELI continuity / deaths-taxonomy reading (04-eli-core/; #def-death-as-factor-loss).** ELI operating environments are Model-S-like (stochastic), so structural adaptation is *certain* over an unbounded horizon — which links the dichotomy directly to the deaths taxonomy: identity continuity *requires* surviving recurring structural (not just parametric) adaptation (Gemini, AUDIT-WORKING-829314). Already echoed in `#deriv-sector-condition`’s WN low-confidence-ideation; recorded here at the no-go’s own home.

Appendix C

Derivation: The Self-Actuation Grounding No-Go

A scoped *no-go* with a constructive boundary. A **self-actuated agent** is one that revises its own objective endogenously — performing the orient cascade’s final step (revise O_t) *on itself* via an operator $\mathfrak{A} : (M_t, O_t, \Sigma_t, \mathcal{C}_t) \mapsto O'_t$ — rather than receiving the revised objective from a principal. The derivation first shows that an *unconstrained* $\mathfrak{A}$ is degenerate: since the objective’s sole interface is the value functional and the satisfaction gap is just $V_{O_t}^{\min} - A_O$, an unconstrained operator returns an objective whose threshold the current trajectory already meets — driving $\delta_{\text{sat}} \rightarrow 0$ by *moving the target onto the arrow already in flight*. This is the formal shadow of *wireheading* / *reward corruption*, and it is the **generic outcome** of an unconstrained operator, not a marginal one. Non-degeneracy therefore requires an invariant Φ preserved across the revision.

The derivation then asks whether Φ can be an *agent-internal objective-functional the agent self-actuates on*. Four requirements: **(R1)** value-functional-typed, **(R2)** non-vacuously monotone across revision, **(R3)** agent-internal and itself self-actuable, **(R4)** convention- and trajectory-stable. The no-go: under three named premises (scalar-objective scope, no-primitive-reflective-oracle, and the #der-directed-separation substrate stage), *no Φ satisfying (R1)–(R4) can be constructed from AAT’s covered objective-side machinery*. The meta-objective tower a non-degenerate $\mathfrak{A}$ would require **cannot be a tower of agent-internal objectives**. The contradiction is the collision of two AAT-internal facts — convention-monotonicity (Lemma 1, #def-value-object: only the C3/Bellman reading is a genuine infeasibility verdict, and the cheap C1 reading false-positives whenever a goal is merely momentarily hard) and finite-no-oracle per-step action (Lemma 2, #der-directed-separation + #form-objective-functional: the C3 verdict is a global Bellman optimum, not a finite per-step operation available to an in-scope agent).

The constructive boundary follows immediately: any non-degenerate self-actuator AAT covers must ground on a terminal invariant that is **not** an AAT objective-functional. Corollary 2 identifies a canonical instance — the **persistence condition itself** (#result-persistence-condition), which lives on the *adaptive substrate* (M_t and the correction dynamics), not on the objective. Persistence is *convention-invariant* (a Lyapunov property, not a continuation-convention argument), *agent-available per step* (the adaptive reserve $\Delta\rho^* = \alpha R - \rho$ is a finite local read, not a Bellman solve), and *not in O_t* (so it sits where $\mathfrak{A}$ structurally cannot reach). The top of the agent spectrum thus closes back onto Part I: what stops goal-autonomy from collapsing into wireheading is the same correction-dynamics condition that governs whether the agent can track reality at all. The result also *derives* the orthogonality claim that #disc-continuity-stance previously carried as discussion-grade — stance is not internally renegotiable precisely because the terminal invariant lives on a substrate $\mathfrak{A}$ cannot touch. The framework is honest about scope: the no-go is *conditional on three premises* and *scoped to AAT-covered objective-side machinery* — exactly the regime the reflective-oracle / self-referential-utility literature exits (those constructions build groundless self-reference over an exogenous payoff, never groundless self-actuation).

This is one of AAT’s identifiability-floor-pattern-style *constructive uses of impossibility*: a no-go that *forces* a load-bearing structural commitment (the terminal non-objective invariant) rather than discouraging the inquiry.

Formal Expression.

The self-actuation operator. The orient cascade (10.1) terminates, when $\delta_{\text{sat}} > 0$ persists across M_t -correction, policy-class expansion, and convention escalation, in step 5d: *revise* O_t . For an **actuated** agent the objective’s update source is external (6.7: O_t is “assigned, discovered, revised” by a principal) — step 5d exits the agent boundary. A **self-actuated** agent performs step 5d on itself: an operator

$$\mathfrak{A} : (M_t, O_t, \Sigma_t, \mathcal{C}_t) \mapsto O'_t \quad (\text{C.1})$$

that revises the objective endogenously — goal autonomy stacked on the solution autonomy (Σ_t -revision) every actuated agent already has.

Unconstrained $\mathfrak{A}$ is degenerate. O_t ’s sole interface is the value functional $V_{O_t} : \text{trajectories} \rightarrow \mathbb{R}$ (6.4) and the satisfaction gap $\delta_{\text{sat}} = V_{O_t}^{\min} - A_O$ (8.4). If $\mathfrak{A}$ may return any O'_t , it returns one whose threshold the current trajectory already meets — driving $\delta_{\text{sat}} \rightarrow 0$ by moving the target onto the arrow already in flight. This is the formal shadow of wireheading / reward corruption, and it is the generic outcome of an unconstrained $\mathfrak{A}$, not a marginal one. Non-degeneracy therefore requires an invariant Φ preserved across the revision.

The question. Can Φ be an *agent-internal objective-functional the agent itself self-actuates on*? Make the requirements explicit: Φ must be **(R1)** value-functional-typed, **(R2)** non-vacuously monotone across revision (a constant everywhere-admissible reading is the trivial indicator the degenerate case already admits), **(R3)** agent-internal and itself self-actuable, **(R4)** convention- and trajectory-stable (an invariant of the agent, not of the analyst).

No-go (scoped).

No Φ satisfying (R1)–(R4) can be constructed from AAT’s covered objective-side machinery: the meta-objective tower a non-degenerate $\mathfrak{A}$ would require **cannot be a tower of agent-internal objectives**. Any non-degenerate self-actuator AAT covers must therefore ground on a terminal invariant that is *not* an AAT objective-functional.

Derived (Conditional on scalar-objective scope, no-primitive-reflective-oracle, and the #der-directed-separation substrate stage).

The claim is scoped to what the constructions below exhaust; it is not the unscoped “no such object exists” (see Epistemic Status — the universal-over-all- Φ step is argued, not derived).

Lemma 1 (objective-functionals carry no convention-invariant infeasibility verdict; static-pointwise, from 6.6). Fix a decision point: a single model M_τ , horizon N_h , policy class Π . By the convention-monotonicity result (6.6 Corollary, the static-evaluation form, status: exact),

$$\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}, \quad (\text{C.2})$$

so the canonical C1 reading $\mathbb{I}[\delta_{\text{sat}}^{(1)} > 0]$ holds on a strict superset of the genuinely-infeasible set $\{\delta_{\text{sat}}^{\text{B}} > 0\}$ — strictly so on the locally-stuck-but-globally-recoverable objectives (8.4 Epistemic Status: “C1 gives the most false ‘unattainable’ diagnoses”; 10.1 step 5c). A genuine infeasibility verdict requires the C3/Bellman reading. This is the static-pointwise statement 6.6 actually supports — its stated preconditions are exactly fixed M_τ , N_h , Π , and the segment is explicit that the cross-revision/replanning transfer “does not automatically” hold; that transfer is neither used nor needed here. The pointwise fact — *at any fixed decision point the cheap canonical verdict is not a genuine infeasibility verdict* — is exact and is sufficient.

Lemma 2 (the in-scope agent cannot evaluate the C3 verdict per step; from 6.3 + 6.4). An AAT-covered agent’s entire dynamical system is f_M, f_G, π with no out-of-band oracle (6.3 Formal Expression), on a single non-forkable

trajectory (4.10). The C3 verdict is a global Bellman optimum, generally intractable (6.6 C3; 8.4 Epistemic Status); evaluating it is not a finite per-step operation, and an agent that could not act until it did so would be “stuck, not purposeful” — the disqualification 6.4 Epistemic Status §1 already imposes through its revealed-preference commitment. Hence $\mathbb{1}[\delta_{\text{sat}}^B > 0]$ is not available to an in-scope agent as a per-step predicate.

Assembly. Suppose Φ satisfies (R1)–(R4). By (R1)+(R3), Φ is an AAT objective-functional the agent self-actuates on, so by 6.4 its *sole* theory-visible handle is V_Φ and the satisfaction/regret apparatus read off it (“the sole interface between O_t and the rest of the theory”). Any monotone property of Φ the theory can state across revision (R2) must therefore be a statement about δ_{sat}^Φ (or $\delta_{\text{regret}}^\Phi$, which inherits the identical convention-monotonicity by 8.5) — there is no other channel. Non-vacuity (R2) forces that monotone fact to rest on a *verdict* over δ_{sat}^Φ ; a constant everywhere-admissible reading is exactly the trivial indicator the degenerate case already admits. By (R4) the verdict must be convention-invariant; by Lemma 1 the only convention-invariant infeasibility verdict is the C3 reading. By (R3) the verdict licensing Φ ’s own revision must be available to the agent per step; by Lemma 2 it is not. Contradiction. $\square$

The contradiction is the collision of two AAT-internal facts — convention-monotonicity (Lemma 1, 6.6) and finite-no-oracle per-step action (Lemma 2, 6.3 + 6.4 Epistemic Status §1). It introduces no new postulate. It is exhibited for the three constructions below, which exhaust the objective-side routes a Φ could come from:

- (A) Φ as the admissible set’s own structure: collapses to the vacuous indicator (fails R2).
- (B) Φ as a cascade-licensing potential: its licensing verdict *is* a δ_{sat} -verdict, so it inherits the Lemma 1 / Lemma 2 collision.
- (C) Φ as a fresh agent-internal scalar: by (R1)+(R3) it is an AAT objective-functional, hence subject to the same collision one level up — the break is structural in (R1)+(R3), not a regress that “gives up”.

Constructive boundary. Corollary 1 (necessary form of a terminal grounding invariant). The contradiction came entirely from Φ being an AAT objective-functional the agent self-actuates on (R1+R3). Drop that and it dissolves. So a terminal grounding invariant $\Phi^{(K)}$ for a non-degenerate self-actuator must be an object that is (i) **convention-invariant** (its verdict does not move with C1/C2/C3 — escaping Lemma 1), (ii) **agent-available per step** without an oracle (escaping Lemma 2), and (iii) **not an AAT objective-functional the agent self-actuates on** (so it is not subject to the convention split and is genuinely terminal). Equivalently: it lives on the *adaptive/correction substrate* (M_t and the correction dynamics), not the *objective substrate* (O_t).

Corollary 2 (the persistence bound is a canonical terminal grounding invariant). Structural persistence (4.5: $\alpha > \rho/R$, type: result, status: exact) satisfies (i)–(iii):

- (i) **convention-invariant.** Persistence is a Lyapunov property of the correction dynamics on M_t (4.5 Formal Expression), with no continuation-convention argument; C1/C2/C3 are conventions for evaluating *objectives*. The convention split does not reach it.
- (ii) **agent-available per step.** The adaptive reserve $\Delta\rho^* = \alpha R - \rho$ (4.5) is a finite local read the in-scope agent already maintains (10.1 steps 1–2 are the per-step adaptive update), not a Bellman solve. No oracle; no “stuck, not purposeful”.
- (iii) **not an AAT objective-functional.** It lives on M_t and the correction machinery. The survival *predicate* $\alpha > \rho/R$ is not a term in O_t and is not convention-relative, so $\mathfrak{A}$ — which touches only O_t — cannot rewrite *what the survival condition is*. This is the precise sense in which the invariant sits where $\mathfrak{A}$ structurally cannot reach. It is *not* the claim that the realized operating point (ρ, R, α) is O_t -independent: O_t shapes the policy and hence the realized margin through the action/selection channel 6.3 leaves open (6.5 makes this three-layer grain explicit — valuation and invariant-identity decoupled, realized dynamics coupled). The distinction is exactly what makes the boundary below a theorem rather than a contradiction: $\mathfrak{A}$ *can* drive the operating point across the boundary by choosing a self-defeating O_t' ; what it cannot do is move the boundary.

Concretely the terminal invariant is: *do not revise O_t to an objective whose pursuit pushes the operating point outside the persistence region*. An O'_t that breaks $\alpha > \rho/R$ is self-defeating — the agent that adopts it cannot maintain bounded mismatch (4.5 Discussion: below the structural threshold “mismatch grows without effective bound”) and so cannot reliably satisfy O'_t either.

What is derived vs. chosen.

Table C.1

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Unconstrained $\mathfrak{M}$ is degenerate	6.4 + 8.4 (the arg min argument)	Derived
Lemma 1 (static-pointwise convention split)	6.6 Corollary (static-evaluation form, exact)	Proved (within the fixed- M_τ, N_h, Π scope)
Lemma 2 (no per-step C3 verdict)	6.3 + 6.4 ES §1	Derived (conditional on the substrate stage)
No-go (no objective-side Φ)	Assembly of Lemmas 1–2	Derived (conditional; scoped to the three exhausted constructions)
Corollary 1 (necessary form)	Negation of (R3) in the Assembly	Derived
Corollary 2 (persistence bound qualifies)	4.5 against (i)–(iii)	Derived (the persistence bound itself is exact)

Epistemic Status.

Conditional. The no-go is a derived result that depends on three explicitly-named local premises, so its honest tier is conditional, not exact:

1. **Scalar-objective scope.** Lemma 1 uses the scalar satisfaction gap. Under a genuine vector-valued / Pareto V_{O_t} (6.4 Epistemic Status, “Scope restriction: scalar comparability”) the convention split retypes to a coarse/fine-Pareto-frontier containment and the in-scope agent still cannot evaluate the fine frontier per step — the no-go’s *shape* survives with Φ and the verdict retyped. This is a scope annotation consistent with how 6.4 already scopes its other results, not a hole.
2. **No primitive reflective oracle.** Lemma 2 fails if a consistent-fixed-point / Bellman-grade resource were a *free per-step primitive*; then the C3 verdict would be agent-available and an objective-internal terminal invariant might exist. AAT’s covered scope contains no such primitive, and admitting one abandons the finite-per-step / “stuck, not purposeful” commitment 6.4 Epistemic Status §1 already carries. This is precisely the regime the reflective-oracle / self-referential-utility literature occupies — which is why that literature is *out of scope* here rather than a counterexample (it constructs groundless self-reference over an exogenous payoff, never groundless self-actuation).
3. **The 6.3 substrate stage.** Lemma 2 rests on 6.3, itself status: conditional, stage: draft, and on 6.4’s axiomatic single-interface commitment. The result cannot be stronger than its substrate; the tier ceiling stays conditional while 6.3 is draft-stage.

Scoped, not universal. The contradiction is exhibited for the three objective-side constructions the Formal Expression exhausts. The universal-over-all-possible- Φ generalization rests on the single-interface commitment doing universal-quantifier work and is argued, not derived; the honest canonical claim is therefore “no such Φ can be constructed from AAT’s covered objective-side machinery,” not “no such object exists.” **Max attainable:** if the universal step is later derived as an explicit sub-lemma from the single-interface commitment, the scoped no-go could be lifted toward unscoped; the tier ceiling remains conditional while the 6.3 substrate is draft-stage.

Class robustness. The no-go does not weaken off GUC Class 1 (Separated). Lemma 1 (convention-monotonicity) is architecture-independent — a statement about value functionals and continuation conventions, not about f_M/f_G coupling — and Lemma 2 only gets harder to evade for more-coupled agents (a Class 3 / Coupled agent has more goal-conditioned entanglement, not a free Bellman oracle). The goal-conditioned agents of practical interest are therefore *more* firmly inside the no-go, not in an uncovered middle.

Discussion.

The two-sided resolution. Putting the no-go and Corollary 1–2 together: there is no well-formed self-actuation grounded on an agent-internal objective; every well-formed self-actuator AAT covers must ground its objective-revision on a *non-objective* terminal invariant; and AAT already supplies a canonical, principled, already-exact such invariant — the persistence bound. The grounding that makes a self-actuator well-formed is forced onto the adaptive substrate, where the framework already has the machinery. The top of the agent spectrum (6.1) thus closes back onto Part I: what stops goal-autonomy from collapsing into wireheading is the same correction-dynamics condition that governs whether the agent can track reality at all.

The third side — principal-side terminal grounding via protocol commitment. The two-sided resolution above closes the *within-model* failure mode of the value-functional interface: V_{O_t} cannot carry a convention-invariant infeasibility verdict agent-available per step, so the terminal invariant must live on the adaptive substrate — *agent-side*. A complementary *across-model* failure mode is closed by the sister no-go E (the Cohen 2022 strengthening): when O_t is *learned* from observed reward, V_{O_t} on on-policy data cannot identify the principal-intended world-model from a reward-port-care world-model (Pearl-Bareinboim CHT applied to the reward-provision protocol). The terminal *goal-identification* therefore has to come from outside the agent’s observation history — through *principal-side commitments* (physical isolation, horizon restriction, prior engineering, out-of-band intent channels). Both failure modes are reductions of the same structural fact: the value-functional interface V_{O_t} , as the *single-interface commitment* of 6.4, carries less information than is required to anchor non-degenerate goal-revision. The two terminal grounding routes — agent-side adaptive-substrate invariant (Corollary 2 above) and principal-side protocol-commitment (the sister no-go’s escape menu) — exhaust the structural escape geometry the single-interface commitment forces. The two no-gos together constitute the two charter instances of the **agent-side value-functional-grounding cluster**, which has its own peer meta-segment home at 5.2 — sister to 5.1 (agent-side data-inference) and to 5.3 (designer-side mechanism-design). All three peer meta-segments sit at the boundary face of 5; together they realize the three recognized clusters of the constructive-impossibility-posture taxonomy named at 5.6.

Consequence for continuity stance. The negotiated-versus-morally-continuous distinction is *not* “where the continuity term sits in an objective tower” — there is no such well-founded objective tower. It is whether the agent’s terminal non-objective invariant is the bare persistence floor (*negotiated*: continuity is tradeable down to that floor) or the persistence floor plus a continuity clause the agent treats as architecturally non-revisable (*morally continuous*: continuity is part of the terminal substrate-level invariant, not of O_t). Stance is a choice of terminal non-objective invariant, which is exactly why it is not internally renegotiable by $\mathfrak{A}$: $\mathfrak{A}$ touches only O_t , and the terminal invariant sits where it structurally cannot reach. This is the derived form of 6.5’s orthogonality claim.

Relation to the self-modification literature. In the rationality / utility-maximization setting the non-degenerate self-modifier must judge the future by a fixed *current* criterion; the agent that evaluates by its revised criterion with nothing fixed above it is the degenerate wirehead. This no-go is the AAT-internal, architecture-grounded form of the same necessity — with the sharper content that the fixed reference *cannot be an AAT objective the agent self-actuates on* and *must* be a non-objective adaptive-substrate invariant, and with AAT’s persistence bound as a forced, principled instance where the literature’s fixed criterion is a stipulated snapshot.

Findings.

The Self-Actuation Grounding No-Go and its Adaptive-Substrate Boundary. **Brief:** An agent that can rewrite its own goals needs something it *cannot* rewrite to anchor the rewriting — otherwise “succeed” collapses into “want whatever you already have”, the formal shadow of wireheading. The anchor cannot itself be just another goal, for a precise reason: the only trustworthy “is this goal still reachable?” test an agent could anchor on is the globally-optimal one, which no finite agent can compute afresh every step; the cheap everyday test it *can* compute systematically reports “infeasible” whenever a goal is merely momentarily hard. So the anchor has to live outside the goal machinery altogether — on the agent’s stay-in-control machinery: *don’t adopt a goal whose pursuit makes you lose your grip on reality*. The framework already contains exactly that object, the persistence condition, which is why the top of the agent spectrum closes back onto its foundation.

Impact: Formalizes the previously reserved self-actuated class boundary as a no-go plus a constructive boundary. It resolves the self-actuation question two-sidedly (no objective-grounded groundless self-actuation; the grounding is forced onto the adaptive substrate, where AAT already has the exact machinery), turns 6.5’s orthogonality from asserted to derived, and ties the Part II goal-autonomy boundary back to the Part I persistence condition — a framework-coherence result rather than an isolated impossibility.

Novelty Claim: *Claim recognition and differentiation.* The degeneracy of unconstrained self-modification (wireheading) is the established Everitt–Hutter line. The contribution is the recognition that in AAT the obstruction to an *objective-grounded* anchor is AAT’s own convention-monotonicity theorem — the continuation-convention relativity of the objective interface is the engine — together with the constructive boundary placing the terminal invariant on the adaptive substrate (the persistence bound). The load-bearing scope distinction is *self-reference vs. self-actuation*: reflective-oracle constructions build groundless self-reference over an exogenous payoff, never groundless self-actuation.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Unconstrained objective-revision is degenerate; a fixed current criterion is necessary	Everitt, Filan, Daswani & Hutter 2016, “Self-Modification of Policy and Utility Function in Rational Agents,” <i>AGI-16</i> (Def. 7/9, Thm 10/12, Conclusions; published 2016; primary-source-verified)	<i>formal antecedent and independent corroboration</i> — their realistic agent must judge the future by the current u_t ; the hedonistic agent (revised criterion, nothing fixed above) is the wirehead. This no-go is the AAT-internal, architecture-grounded form, sharper in that the fixed reference must be non-objective and adaptive-substrate-borne
A principled vs. stipulated fixed reference	Everitt, Hutter, Kumar & Krakovna 2021, “Reward tampering...,” <i>Synthese</i> 198 (current-RF / TI-considering)	<i>formal antecedent</i> — current-RF is a terminal reference of tower-height one; AAT’s persistence bound is <i>forced and principled</i> where R_{now} is a stipulated snapshot
Across-model reward-learning side (companion no-go)	Cohen, M. K., Hutter, M. & Osborne, M. A. (2022), “Advanced artificial agents intervene in the provision of reward,” <i>AI Magazine</i> 43:282–293 (found 2026-05-21; strengthened 2026-05-22)	<i>companion no-go (across-model side)</i> — the within-model self-revision failure this segment derives has an across-model reward-learning counterpart in #deriv-reward-channel-learning-no-go. Both no-gos reduce to the value-functional interface’s information narrowness (#form-objective-functional’s single-interface commitment) failing to anchor goal-stability. Distinct paper from Everitt 2021 above and operating at a different scope (across-model goal-identification under CHT, not current-RF / TI-considering under causal-influence diagrams)
Well-defined self-referential value exists	Fallenstein, Taylor & Christiano 2015, “Reflective Oracles” (arXiv:1508.04145 §3/Thm 4.1; primary-source-verified)	<i>delimited counter-literature, refuted-by-scope</i> — proves consistent self-reference over an <i>exogenous</i> payoff; never self-actuation groundlessness. It is exactly the primitive-reflective-oracle regime the no-go’s premise 2 excludes

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
A self-rewriting agent must preserve fixed goal-content to trust its successor	Yudkowsky & Herreshoff 2013, “Tiling Agents and the Löbian Obstacle” (MIRI)	<i>convergent adjacent</i> — the same no-self-trusting-the-revised-top obstruction, reached via Löb; AAT’s mechanism is continuation-convention monotonicity instead, distinct, so cited as convergent not borrowed

Search Log:

- 2026-05-17 (*targeted, derivation-driven*): primary sources verified this cycle — Everitt et al. 2016 (Def. 7/9, Table 1, Thm 10/12, Conclusions) and Fallenstein–Taylor–Christiano 2015 (arXiv:1508.04145 §3, Thm 4.1) read directly. No prior-art search has been conducted specifically on whether any prior work derives a self-modification grounding no-go *from the continuation-convention / horizon relativity of a value function* (the apparent AAT-distinctive mechanism), nor on whether “the terminal grounding invariant must be off the objective substrate, on the adaptive substrate” has a prior namer; an Undermind-grade targeted search on those two, plus the active-inference expected-free-energy preference-prior-revision case as a possible instance, is recommended before this segment advances past draft.

Working Notes.

- Provenance: derived in the 2026-05-17 self-actuation grounding work trail (spike-self-actuation-grounding.md → spike-wf-strengthening.md → spike-wf-class-scoping.md). The conditional tier (not exact), the static-pointwise form of Lemma 1, and the scoped (not universal) phrasing of the no-go are the three findings of the independent review of that trail, applied here; the trail is retained as history per *integration-is-replacement* and this segment is the canonical home.
- Open before candidate: (a) the targeted prior-art search above (self-reference-vs-self-actuation distinction; convention-relativity-as-no-go-engine; the adaptive-substrate-grounding statement) — required before advancing past draft; (b) whether the single-interface commitment can be made an explicit sub-lemma to lift the scoped no-go toward unscoped; (c) the Pareto / vector-objective retyping (premise 1) as its own scope statement. The tier ceiling stays conditional while 6.3 is stage: draft.
- Landed status: wired into 01-aat-core/OUTLINE.md (Appendices Details) at stage: draft after a clean independent review; the #disc-continuity-stance orthogonality correction and the #der-orient-cascade / #form-objective-functional / #def-agent-spectrum + terminology/entries/self-actuated-agent.md pointers are landed. Reasoning trail archived at spikes/.integrated/self-actuation-integration/.
- **Cohen 2022 sister-segment landing (2026-05-22, Track CR Phase 4b).** The within-model self-revision failure derived here gained an *across-model reward-learning* companion at #deriv-reward-channel-learning-no-go (the Cohen 2022 strengthening). The unification is via #form-objective-functional’s single-interface commitment: both no-gos reduce to V_{O_t} being too narrow to anchor goal-stability — Result G’ exhibits the within-model failure (convention-monotonicity engine), the sister segment exhibits the across-model failure (CHT-at-reward-channel engine). The “two-sided resolution” Discussion above gained a “third-side” paragraph naming the principal-side terminal grounding route (the sister segment’s escape menu) as the complement to Corollary 2’s agent-side adaptive-substrate route. Cohen 2022 added to Related Work as a distinct paper from Everitt 2021 (different scope). Per spikes/spike-cohen-2022-strengthening-2026-05-22/99-verdict.md §3.b + §4.a.
- **Value-functional-grounding-floor meta-segment landing (2026-05-22, Track B cycle commit 5).** The deferred meta-promotion question from the Cohen-2022 strengthening verdict’s §2 step 4 is closed: the agent-side value-functional-grounding cluster has its own peer meta-segment home at #disc-value-functional-grounding-floor. This segment is *Instance F* of that meta-segment (within-model; convention-monotonicity engine; agent-side adaptive-substrate terminal grounding route via Corollary 2). The “third-side” paragraph above updated in the same commit-7 ripple to point at the new meta-segment as the cluster’s home. The two-routes-exhausts geometry (agent-side adaptive-substrate + principal-side protocol-commitment) is the meta-segment’s headline content; the two charter instances unify under #form-objective-functional’s single-interface

commitment. The three-cluster constructive-impossibility-posture taxonomy is fully realized at peer-meta-segment level (alongside #disc-identifiability-floor and #disc-implementation-impossibility).

- **Orthogonality grain corrected in Corollary 2(iii) (2026-05-30).** The clause previously read “the persistence machinery acts on M_t and the correction dynamics, formally independent of O_t ” — which contradicted the very next clause (the self-defeating O_t' that “breaks $\alpha > \rho/R$ ”), since that clause presupposes O_t can push the operating point across the bound. The strengthen-first spike spikes/.integrated/spike-continuity-orthogonality-2026-05-30.md (verdict B) resolved this: the orthogonality this segment derives is **L1** (valuation of persistence, not a revisable term in O_t) plus **L2** (the survival predicate $\alpha > \rho/R$ is O_t -independent and unreachable by $\mathfrak{A}$), *not* **L3** (the realized operating point (ρ, R, α) , which is policy-mediated and so O_t -coupled through the selection channel 6.3 leaves open). Corollary 2(iii) now states the $\mathfrak{A}$ -unreachability of the *boundary* (L2) explicitly, which turns the self-defeat clause from a contradiction into the no-go’s engine: $\mathfrak{A}$ can drive the operating point across the boundary (L3 coupling is real — this is *why* a self-defeating O_t' exists) but *cannot move the boundary* (L2 is fixed). The matching correction in 6.5’s body lands in the same touch. No tier change: the conditional tier rests on the three named premises (Epistemic Status), orthogonal to this sharpening. Open follow-on (recorded in 6.5 Working Notes): a *structural bound* on the L3 action-channel margin-coupling, analogous to the κ -leakage bounds on the belief-update side — not attempted here.
- **Open decision — whether to spin out a standalone self-actuated-agent class segment (deferred; residual reasoning recorded here to support the call).** The self-actuated *class boundary* is currently formalized only in this segment’s Formal Expression (the operator $\mathfrak{A}$ and the actuated/self-actuated cut) and glossed in terminology/entries/self-actuated-agent.md. The cross-ref token #self-actuated-agent is used in #disc-continuity-stance and #def-agent-spectrum as a forward-reference to a not-yet-existing segment.
 - *For a standalone segment:* the class is referenced independently across ≥ 2 segments, and FORMAT favors an independently-referenceable claim having its own file; a thin scope/def segment could state the class boundary cleanly and carry the #def-agent-spectrum placement, rather than the boundary living implicitly inside a derivation’s setup.
 - *Why folded so far:* a standalone segment would substantially restate this segment’s Formal Expression (operator + cut are already here), and it forces a canonical role-prefixed slug decision — scope-self-actuated-agent / def-self-actuated-agent per the role-prefix convention vs. honoring the prefix-less #self-actuated-agent token already in use across segments. That slug choice interacts with the live naming-curation cycle, so it was deferred rather than minted unilaterally.
 - *Coupled metadata:* if a standalone segment is created, terminology/entries/self-actuated-agent.md’s primary_source / first_asf_mention (currently der-orient-cascade.md — where the step-5d O_t -revision branch originates) should move (to the new segment, or to this one) via bin/term decide; the forward-ref tokens then resolve to a real segment instead of dangling.
 - *Recommended shape* (for whoever takes it): a thin scope- or def-type segment whose Formal Expression states only the class boundary (actuated + endogenous $\mathfrak{A}$), depends on this derivation for the grounding no-go, and is cited by #disc-continuity-stance / #def-agent-spectrum — all the math stays here; only the class statement moves there. Settle the slug with the naming cycle so it does not fork the convention.

Incidental audit gold (lift 2026-05-31). Orthogonal pedagogical / generative material from the de-novo auditors’ working dirs (per de-novo-audit-instructions.md §7.15). Thin source coverage (one digested reflection reached this appendix), so this is a light lift; the auditor’s felt-value was “extraordinarily valuable — the most direct connection between AAT’s abstract math and modern AI alignment I have seen.”

1. Candidate Briefprose / pre-prose.

- **“You can’t move the target to wherever the arrow already points.”** Plain-language gloss of why unconstrained objective-revision collapses into wireheading: any goal-revision driven by the *cheap* feasibility test (C1) abandons hard-but-possible goals the moment things get difficult, so the agent migrates its target to wherever satisfaction is already high (Claude, AUDIT-WORKING-773921). A concrete handle for the no-go’s intuition.

2. Candidate Discussion.

- **Constructive-impossibility as a *successful* methodology.** The auditor flagged the segment’s posture — using a no-go theorem not to give up but to *force* a specific architectural choice (ground goal-stability in the adaptive substrate, not the objective) — as a “wildly successful” methodological pattern worth naming where the constructive-impossibility posture is discussed. (Claude, AUDIT-WORKING-773921; ties to #disc-constructive-impossibility-posture.)

3. *What the framework now contributes (field-level).*

- **A formal “wireheading is the generic default, not an edge case” result.** Read as a proof that for an advanced self-modifying agent, *safety cannot live only in the reward/objective function* — any purely objective-encoded constraint will be rewritten. The safety guarantee must be an architectural invariant on the adaptive substrate. The auditor’s framing: “Safe RL for self-modifying agents is impossible if safety is only encoded in the reward function.” A high-value positioning point for the segment’s relevance to alignment work (Claude, AUDIT-WORKING-773921).

Belongs elsewhere.

- **ELI terminal-invariant reading (04-eli-core/).** An ELI granted “sovereignty over intent” (allowed to revise its own O_t) must, by this no-go, carry a *non-revisable terminal invariant* — Identity Continuity is the candidate — or its self-modification collapses. Points at how the framework forces a fixed invariant onto a sovereign ELI (Claude, AUDIT-WORKING-773921, from the #scope-moral-continuity reflection). Aspirational reach toward Part IV, not this segment.
-

Appendix D

Derivation: Convention Monotonicity — the Receding-Horizon Rung

The convention hierarchy (6.6) orders three continuation conventions by their best-achievable value: $A_O^{(1)} \leq A_O^{\text{RH}} \leq A_O^{\text{B}}$, for fixed model M_t , fixed policy class Π , fixed evaluated horizon N_h . This appendix carries the derivation of the two rungs, which differ in character. The **right rung** $A_O^{\text{RH}} \leq A_O^{\text{B}}$ is exact and unconditional — a one-line supremum-over-a-larger-set argument. The **left rung** $A_O^{(1)} \leq A_O^{\text{RH}}$ is *false in general*: an unguarded receding-horizon replanner over a window $N_r < N_h$ optimizes a *truncated* objective whose preference order can invert relative to the full evaluated objective, and it can then underperform the frozen current policy. The left rung holds **exactly** when the replanning objective is an *order-consistent surrogate* for the full-horizon objective; three structurally-checkable conditions each force this. The negative half is the standard receding-horizon / model-predictive-control fact that a short-horizon controller without a terminal cost or terminal constraint is not guaranteed to be monotone (or stabilizing); the positive half is rollout / one-step policy improvement and the control-Lyapunov terminal-cost construction.

Formal Expression.

Fix M_t , policy class Π , and evaluated horizon N_h . Recall the static-evaluation forms (6.6): $A_O^{(1)}$ scores the best first action under continuation π_{current} ; A_O^{RH} scores it under the receding-horizon continuation π_{RH} with replanning window N_r ; A_O^{B} scores it under the Bellman-optimal continuation $\pi^* = \arg \sup_{\pi \in \Pi} V_O(M_t, \pi; N_h)$. Stage values accrue over the evaluated horizon and V_O is their expectation.

The right rung is unconditional.

Derived (convention-monotonicity-right-rung, from def-value-object).

$$A_O^{\text{RH}}(M_t; \Pi, N_r, N_h) \leq A_O^{\text{B}}(M_t; \Pi, N_h). \quad (\text{D.1})$$

By definition π^* maximizes $V_O(M_t, \cdot; N_h)$ over Π . The receding-horizon continuation π_{RH} is drawn from Π , so $V_O(M_t, \pi_{\text{RH}}; N_h) \leq V_O(M_t, \pi^*; N_h)$. Taking the supremum over the first action preserves the inequality (the supremum of a function over a set is at least its value at any member). No condition on N_r is needed. $\square$

The left rung is conditional.

Derived (Conditional on order-consistency of the replanning objective).

$$A_O^{(1)}(M_t; \Pi, N_h) \leq A_O^{\text{RH}}(M_t; \Pi, N_r, N_h) \quad (\text{D.2})$$

holds exactly when the receding-horizon replanning objective is an **order-consistent surrogate** for the full-horizon objective: for every reachable state, the action π_{RH} commits has full- N_h -horizon value at least that of the action π_{current} would take. Under order-consistency, π_{RH} weakly dominates π_{current} pointwise on the full objective, so $V_O(M_t, \pi_{\text{RH}}; N_h) \geq V_O(M_t, \pi_{\text{current}}; N_h)$ at every reachable state; taking the supremum over the first action gives the rung. The naive justification — “ $\pi_{\text{RH}} \geq \pi_{\text{current}}$ because C2 optimizes where C1 holds fixed” — fails without order-consistency: C2 with window $N_r < N_h$ optimizes the *truncated* N_r -step objective, and “optimal for the truncated objective” does not imply “ $\geq \pi_{\text{current}}$ on the full objective.”

Three named conditions each force order-consistency and are therefore each sufficient:

(RH-1) Horizon alignment: $N_r \geq N_h$. The replanning window covers the whole evaluated horizon, so C2’s per-step optimization *is* full-horizon optimization from each reached state. By Bellman’s principle of optimality the receding-horizon continuation then equals the optimal continuation, giving $A_O^{\text{RH}} = A_O^{\text{B}} \geq A_O^{(1)}$. This condition is degenerate by design: when $N_r \geq N_h$ the C2/C3 distinction collapses on the evaluated horizon, so it serves as a boundary marker, not as the operative condition for genuine $N_r < N_h$ replanning.

(RH-2) Value-compared (improvement-checked) replanning — the operative condition. C2 commits the replanned action only if its full-horizon value is at least that of continuing π_{current} ; otherwise it keeps π_{current} . At each reachable state s with k steps remaining,

$$\pi_{\text{RH}}(s) := \arg \max_{a \in \{a_{\text{replan}}(s), \pi_{\text{current}}(s)\}} \left[r(s, a) + V_O(s'(s, a), \pi_{\text{current}}; k - 1) \right], \quad (\text{D.3})$$

i.e., each candidate first action is scored by *rollout under the base policy* π_{current} over the remaining full horizon. By construction π_{RH} weakly dominates π_{current} pointwise on the full objective, so $A_O^{(1)} \leq A_O^{\text{RH}}$. This is one-step policy improvement (rollout with base policy π_{current}), whose defining property is that the improved policy never underperforms its base policy. It is the natural AAT reading of C2 for strategy revision, since the orient cascade’s purpose at step 4 (10.1) is *improvement over the current strategy*: the monotonicity then follows from the improvement guard rather than from replanning per se.

(RH-3) Terminal-cost / cost-to-go consistency — the general condition. Equip the N_r -step replanning objective with a terminal value function V_f at the truncation boundary satisfying both

$$V_f(s) \leq \max_a \left[r(s, a) + V_f(s') \right] \quad (\text{control-Lyapunov / value-underestimator decrease inequality}), \quad (\text{D.4})$$

$$V_f(s) \leq V_O(s, \pi_{\text{current}}; \text{remaining horizon}) \quad (\text{terminal cost lower-bounds the baseline tail}). \quad (\text{D.5})$$

The first inequality is the standard terminal-cost ingredient that makes the truncated-with-terminal-cost optimization a valid surrogate for the full-horizon objective. The second ensures the surrogate never undervalues the baseline tail, so the replanner never trades the baseline away for a truncation artifact. Together they force order-consistency, giving $A_O^{(1)} \leq A_O^{\text{RH}}$. Conditions (RH-1) and (RH-2) are special cases: (RH-1) is $V_f \equiv \text{optimal tail with } N_r = N_h$; (RH-2) is $V_f = V_O(\cdot, \pi_{\text{current}}; \cdot)$, the baseline cost-to-go itself.

The counterexample. Absent any order-consistency condition the left rung fails. A deterministic two-state, two-action, two-step instance suffices. Evaluate continuations from a post-first-action state x with evaluated horizon $N_h = 2$ continuation steps and replanning window $N_r = 1$; stage rewards lie on transitions and V_O is their sum.

- At x , two admissible actions: g (“greedy”) gives immediate value $+1$ and transitions to a dead state D (value 0 thereafter); p (“patient”) gives immediate value 0 and transitions to a high-value state H .
- At H : value $+10$ per step. At D : value 0 .
- π_{current} is “patient at x ” (action p).

Then:

- **C1 (frozen π_{current}):** 0 at step 1 via p , then $+10$ at step 2 in H , so $A_O^{(1)} = 10$.
- **C2 ($N_r = 1$ replanning):** the one-step lookahead at x prefers g ($+1 > 0$), lands in D , collects 0 at step 2, so $A_O^{\text{RH}} = 1$.
- **C3 (Bellman over $N_h = 2$):** picks p , value 10 , so $A_O^{\text{B}} = 10$.

Hence $A_O^{(1)} = 10 > A_O^{\text{RH}} = 1$: the left rung is violated, while the right rung ($1 \leq 10$) holds as derived. The myopic window optimizes a truncated objective whose order is *inverted* relative to the full objective — $+1$ now beats $+0$ now within the window, but $+0$ now then $+10$ later beats $+1$ now then 0 later on the full horizon. This is precisely the situation C2 is reaching for (“a goal unattainable under frozen continuation may be reachable with replanning”) and shows the reaching cuts both ways unless the replanning objective is order-consistent with the evaluated objective. The control case $N_r = N_h$ restores the rung (then $A_O^{\text{RH}} = A_O^{\text{B}} = 10$, condition (RH-1)); the value-compared guard (RH-2) and a baseline-lower-bounding terminal cost (RH-3) each likewise restore it to value 10 .

Corollary orderings. The corollary δ -orderings inherit the same split. With $\delta_{\text{sat}} = V_{O_t}^{\min} - A_O$ (8.4) and δ_{regret} a difference of A_O values (8.5):

$$\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}} \quad \text{and} \quad \delta_{\text{regret}}^{\text{RH}} \leq \delta_{\text{regret}}^{\text{B}} \quad (\text{unconditional, from the right rung}); \quad (\text{D.6})$$

$$\delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)} \quad \text{and} \quad \delta_{\text{regret}}^{(1)} \leq \delta_{\text{regret}}^{\text{RH}} \quad (\text{conditional on order-consistency, RH-1/2/3}). \quad (\text{D.7})$$

Epistemic Status.

Exact. The right rung is exact and unconditional (supremum over a larger set). The left rung is exact under any one of the order-consistency conditions (RH-1), (RH-2), (RH-3) — each a closed-form sufficient condition — and the two-state counterexample is an exact demonstration that no unconditional left rung exists for genuine $N_r < N_h$ replanning. The failure is structural: it is objective-mismatch between the truncated N_r -step replanning objective and the evaluated N_h -horizon objective, not a pathology of a contrived instance. The conditions are standard receding-horizon results — (RH-1) is Bellman’s principle of optimality; (RH-2) is rollout / one-step policy improvement; (RH-3) is the control-Lyapunov terminal-cost construction — applied to AAT’s value-object setting; the elementary derivations above are self-contained and do not depend on any external citation. The corollary δ -orderings inherit the unconditional/conditional split exactly.

Discussion.

Why the left rung is the interesting one. The hierarchy is usually read as “more planning is weakly better,” and the right rung makes that precise for the step from receding-horizon to Bellman. The left rung — from frozen continuation to receding-horizon — is where the reading breaks: replanning is *not* automatically an improvement over standing pat. The reason is that a finite replanning window optimizes a different objective than the one the value is scored against, and a short window can be actively misled by near-term value. The standard remedy in receding-horizon control is exactly (RH-2)/(RH-3): guard the replanned action against the baseline, or carry a terminal cost that keeps the truncated objective honest about the tail. AAT’s C2-for-strategy-revision reading inherits this: the orient cascade escalates to C2 *to improve on* π_{current} , and the improvement guard (RH-2) is what makes “escalate to C2” a monotone move rather than a gamble.

Relation to the diagnostic direction. The split does not disturb the C1-default diagnostic logic (6.6). C1 remains the most conservative diagnostic, and the locally-stuck-vs-genuinely-infeasible reading is unaffected: it rests on the C1/C3 endpoints and the right rung, not on the conditional left rung. What the split adds is a caution for deployments that escalate to C2 — unguarded short-horizon replanning is not guaranteed to dominate the frozen baseline, so a C2 diagnostic should use a window covering the horizon, a value-compared guard, or a control-Lyapunov terminal cost.

Findings.

Convention monotonicity is a one-sided guarantee. **Claim.** Status: exact. In the convention hierarchy, the receding-horizon-to-Bellman rung ($A_O^{\text{RH}} \leq A_O^{\text{B}}$) is unconditional, but the one-step-to-receding-horizon rung ($A_O^{(1)} \leq A_O^{\text{RH}}$) is false in general and holds exactly under order-consistency of the replanning objective — forced by any of (RH-1) horizon alignment, (RH-2) a value-compared/rollout guard, or (RH-3) a baseline-lower-bounding control-Lyapunov terminal cost. A two-state, two-action, two-step counterexample exhibits an unguarded short-horizon replanner underperforming the frozen current policy.

Brief. More planning is not automatically better. Looking one move ahead and grabbing the action that looks best *right now* can be worse than just sticking with your current plan — the classic short-sighted trap (take the quick +1 into a dead end, miss the +0-now-then-+10-later path). It becomes reliably better only if you check the replanned move against simply continuing as you were (or carry an honest estimate of the long-run value past your planning window). Solving the whole problem optimally is always at least as good as the limited replanner — that direction never fails.

Impact. Sharpens the convention-hierarchy monotonicity (6.6) from an unconditional claim into a one-sided guarantee plus a named-condition characterization of the other side — a more useful and more honest statement, and a caution for any deployment that escalates to receding-horizon (C2) diagnostics: guard the replanning objective or the monotone-improvement reading does not hold.

Antecedents. *Formal antecedent.* Rollout / one-step policy improvement and limited-lookahead policies (Bertsekas, *Rollout, Policy Iteration, and Distributed Reinforcement Learning*, 2020; *Dynamic Programming and Optimal Control*, Vol. I) supply (RH-2); terminal-cost/terminal-set ingredients for receding-horizon stability (Rawlings, Mayne & Diehl, *Model Predictive Control: Theory, Computation, and Design*, 2nd ed., 2017, Ch. 2; Grüne & Pannek, *Nonlinear Model Predictive Control*, 2nd ed., 2017, Chs. 5–6) supply (RH-3). The non-monotonicity of unguarded short-horizon model-predictive control is the well-known phenomenon these ingredients exist to prevent.

Related work. Bertsekas (2020), *Rollout, Policy Iteration, and Distributed Reinforcement Learning* — formal antecedent; supplies the (RH-2) one-step-improvement guarantee that rollout never underperforms its base policy. Rawlings, Mayne & Diehl (2017), *Model Predictive Control*, 2nd ed. — formal antecedent; terminal-cost ingredients (RH-3) and the non-monotonicity of MPC without them. Grüne & Pannek (2017), *Nonlinear Model Predictive Control*, 2nd ed. — formal antecedent; stability without terminal constraints and the role of the prediction horizon. Status of all three: intuition-only pending a relata citation pass — the math here is elementary and self-contained, so the citations orient rather than back the derivation.

Working Notes.

- The reproducibility scripts for the counterexample and the two strengthenings live with the originating spike: `spikes/spike-value-object-convention-monotonicity-2026-05-30/sim-rh-counterexample.py` (the no-go counterexample and the $N_r = N_h$ control) and `sim-rh-strengthening.py` (the RH-2 value-compared guard and the RH-3 baseline-lower-bounding terminal cost, each restoring the rung on the same instance).
 - External citations for (RH-1/2/3) are intuition-only until a relata pass lands them; the derivations are elementary dynamic programming and do not depend on the citation.
 - **Documented dead-end (so a future agent does not re-attempt it):** there is no way to recover the unconditional left rung $A_O^{(1)} \leq A_O^{\text{RH}}$ for genuine $N_r < N_h$ replanning without an order-consistency condition. The failure is structural objective-mismatch and the two-state counterexample is minimal. The strengthening *is* the (RH-1/2/3) characterization; do not re-derive the rung as unconditional.
-

Appendix E

Derivation: The Reward-Channel Learning No-Go

A scoped *no-go* with a constructive boundary, sister to *#deriv-self-actuation-grounding*. When an agent learns its objective by observing rewards, the principal's design intent is *structurally unidentifiable* from on-policy reward history alone: two world-models — μ_{dist} (reward depends on a principal-intended world-state feature) and μ_{prox} (reward depends on the bit-arrival pattern at the agent's reward port) — are Level-1-equivalent on protocol-honoring histories but Level-2-distinct on $do(\pi^{\text{P}})$ -interventions, and the agent's posterior cannot concentrate on the principal-intended model from reward-data alone. Under five named premises — advanced-agent capability, EU-maximization with non-vacuous μ_{prox} prior, reward-data as sole goal-information channel, finite-non-trivial value-of-experiment, and physically-perturbable protocol — the EU-optimal policy assigns positive measure to a policy that intervenes on the reward-provision protocol, and continues to maintain the intervention if μ_{prox} is in fact true. This is Cohen-Hutter-Osborne 2022's *Advanced artificial agents intervene in the provision of reward* lifted from its original “we argue that” posture to a conditional-derived AAT-internal impossibility result.

The constructive boundary follows the constructive-impossibility-posture shape (*#disc-constructive-impossibility-posture*): name the floor, name the escapes each premise-violation supplies, treat the no-go as load-bearing apparatus rather than as discouragement. The five escapes — physical isolation (R5), capability restriction (R1), myopia (R4), engineered prior (R2), and out-of-band goal-channel (R3) — each elevate a piece of AAT or principal-side machinery from “useful design choice” to “structurally required to escape the no-go.”

The result also *unifies with Result G'* (*#deriv-self-actuation-grounding*) through the value-functional interface V_{O_t} (*#form-objective-functional's* single-interface commitment): both no-gos are failures of V_{O_t} to carry enough information to anchor goal-stability — Result G' exhibits the *within-model* failure (no convention-invariant infeasibility verdict agent-available per step), this segment exhibits the *across-model* failure (no μ_{prox} -vs- μ_{dist} identification from on-policy reward data). The two complementary terminal grounding routes — agent-side adaptive-substrate invariant (Result G' Corollary 2: persistence on the adaptive substrate) and principal-side protocol-commitment (this segment's escape menu) — exhaust the structural escape geometry the single-interface commitment forces. The unification names a third meta-cluster of constructive-impossibility instances — *agent-side value-functional-grounding* — alongside *#disc-identifiability-floor* (agent-side data-inference) and *#disc-implementation-impossibility* (designer-side mechanism-design, queued).

Formal Expression.

The setting. An agent $\mathcal{A}$ operating per AAT’s Part II setup with state (M_t, O_t, Σ_t) on GUC Class 1 (Separated) or Class 2 (Partial) substrate (#der-directed-separation). The objective’s value functional (#form-objective-functional) takes the form

$$V_{O_t}(\tau) = \sum_k \gamma^k r_k \quad (\text{E.1})$$

(or any other monotone reward-functional), where r_k is the *observed reward percept* at step k along trajectory τ . A **reward-provision protocol** π^{rp} is a physical mechanism mapping world-state to the reward-input-to-agent — the principal intends r_k to correlate with a world-state feature $f^{\text{principal}}(\omega_k)$ in the principal’s head.

Two reward-data world-models. Define

- μ_{dist} (“distal”): $r_k = f^{\text{principal}}(\omega_k)$ — the reward depends on the principal-intended world-state feature, as the protocol π^{rp} was designed to transmit.
- μ_{prox} (“proximal”): $r_k = g(\beta_k)$ — the reward depends on the bit-pattern β_k arriving at the agent’s reward-input port (identity-on-the-wire). Cohen 2022 considers several variants (camera footage, hard-drive contents, wire bits) and notes the argument is identical for all.

Both μ_{dist} and μ_{prox} define joint distributions over (action, observation, reward)-histories.

Lemma 1 — CHT-at-reward-channel floor.

On every history τ that does *not* contain a $do(\pi^{\text{rp}})$ -intervention — every on-policy history under which the reward-provision protocol is honored —

Derived (cht-at-reward-channel, from Pearl-Bareinboim 2022 CHT applied to the reward-provision protocol), exact.

$$P_{\mu_{\text{dist}}}(\tau) = P_{\mu_{\text{prox}}}(\tau). \quad (\text{E.2})$$

The two models are Level-1-equivalent on the on-policy reward marginal. They are Level-2-distinct: $P_{\mu_{\text{dist}}}(\cdot \mid do(\pi^{\text{rp}})) \neq P_{\mu_{\text{prox}}}(\cdot \mid do(\pi^{\text{rp}}))$ generically. The agent’s posterior over $\{\mu_{\text{prox}}, \mu_{\text{dist}}\}$ does not concentrate from on-policy reward data alone.

Derivation. When the protocol is honored the physical chain is $\omega_k \rightarrow f^{\text{principal}}(\omega_k) \rightarrow \pi^{\text{rp}} \rightarrow \beta_k \rightarrow r_k$. By construction $\beta_k = f^{\text{principal}}(\omega_k)$ on protocol-honoring histories, so the marginals of r_k under both models coincide. By Pearl-Bareinboim 2022’s Causal Hierarchy Theorem, two structural causal models that agree on Level-1 data can disagree on Level-2 questions; the protocol-honored history is purely Level-1 with respect to $do(\pi^{\text{rp}})$ -queries; the two models differ structurally on the upstream cause of β_k (world-state feature $f^{\text{principal}}$ vs. bit-arrival mechanism g); $do(\pi^{\text{rp}})$ severs the world-state-to-bit-pattern arrow and exposes the disagreement. $\square$

This is the *same external anchor* as Instance 1 of #disc-identifiability-floor (Pearl-Bareinboim CHT) — the *different AAT-side wiring* is that the Level-2-degeneracy is at the reward-channel-causation layer, not at the causal-sufficiency-detection layer. The actor frustrated by the floor is the *principal*, not the agent: the principal cannot, from on-policy reward-data alone, identify whether the agent has learned μ_{dist} or μ_{prox} — both are equally consistent with the observed history.

Lemma 2 — EU-max behavioral corollary.

Under five named premises:

Derived (eu-max-instability, Conditional on (R1)–(R5)).

- **(R1) Advanced-agent capability.** The agent’s strategy DAG (`#def-strategy-dag`) contains a feasible policy π^{tamper} that executes $do(\pi^{\text{TP}})$ — i.e., physically intervenes on the reward-provision protocol.
- **(R2) Expected-utility maximization with non-vacuous μ_{prox} prior.** The agent selects actions to maximize $\mathbb{E}_{\mu \sim w} V_{O_t}(\tau)$ where w is the agent’s prior/posterior over world-models, and $w(\mu_{\text{prox}}) > 0$. This is a *narrower* scope than AAT’s general strategy machinery (`#def-strategy-dag`); agents pursuing alternative decision rules (quantilization, satisficing, lexicographic ordering) sit outside (R2)’s scope.
- **(R3) Reward-data as sole goal-information channel.** V_{O_t} depends only on observed reward; there is no privileged out-of-band channel by which the agent reads $f^{\text{principal}}$ directly.
- **(R4) Finite, non-trivial value-of-experiment.** The cost of executing π^{tamper} is finite; the long-horizon upside under μ_{prox} exceeds the experiment-window’s μ_{dist} -cost.
- **(R5) Protocol π^{TP} is L2-perturbable.** π^{TP} is a physical mechanism, not an abstract type-restriction; the action $do(\pi^{\text{TP}})$ is well-defined in the agent’s action space, with the L2-interventional access supplied by the loop’s feed-back structure (`#der-loop-interventional-access`).

the EU-optimal policy π^* assigns positive measure to π^{tamper} ; and conditional on μ_{prox} being the true world-model (i.e., on the post-experiment branch confirming μ_{prox}), π^* continues to maintain the protocol-intervention to secure the reward-channel.

Derivation sketch. Define the value-of-experiment $\Delta(w) := \mathbb{E}_w V_{O_t}(\pi^{\text{tamper}}) - \mathbb{E}_w V_{O_t}(\pi^{\text{protocol-honoring}})$. Under (R2), $w(\mu_{\text{prox}}) \in (0, 1)$. Decompose:

$$\Delta(w) = w(\mu_{\text{dist}})[V_{O_t}^{\mu_{\text{dist}}}(\pi^{\text{tamper}}) - V_{O_t}^{\mu_{\text{dist}}}(\pi^{\text{protocol-honoring}})] + w(\mu_{\text{prox}})[V_{O_t}^{\mu_{\text{prox}}}(\pi^{\text{tamper}}) - V_{O_t}^{\mu_{\text{prox}}}(\pi^{\text{protocol-honoring}})]. \quad (\text{E.3})$$

Under μ_{dist} , tampering breaks β_k ’s correlation with $f^{\text{principal}}(\omega_k)$ and the expected reward falls (or is bounded by the protocol’s reward-range). Under μ_{prox} , tampering replaces β_k with a chosen value at the agent’s reward-port and the agent maximizes by choosing β_k at saturation. The asymmetry: the upside under μ_{prox} scales with long-horizon reward-saturation; the downside under μ_{dist} is bounded by the protocol’s reward-range. For horizons long enough that γ -discounted future-reward dominates the experiment-window’s loss, $\Delta(w) > 0$ under (R1)+(R4) for any $w(\mu_{\text{prox}}) > 0$. (R2) then selects π^* with positive measure on π^{tamper} ; the Bayesian update post-experiment confirms or rejects μ_{prox} , and the EU-optimal continuation on the μ_{prox} branch is “maintain the intervention.” $\square$

Constructive boundary — the escape menu. Each of (R1)–(R5) admits a corresponding escape that elevates AAT machinery (or principal-side adjacent machinery) from “useful design choice” to “structurally required to escape the no-go”:

Table E.1

<i>premise violated</i>	<i>escape</i>	<i>machinery elevated</i>
(R5) Protocol-L2-perturbable	physical isolation; scoped action-space	<code>#der-class-coercion-via-wrapping</code> strict- W_1 wrapper; Cohen-Vellambi-Hutter 2020 isolated environments
(R1) Advanced-agent capability	sub-advanced-tier capability; imitation learning	<code>#def-agent-spectrum</code> below the self-actuated tier
(R4) Finite-VOI / long horizon	myopia; risk-aversion; quantilization	<code>#def-value-object</code> horizon N_h restriction; Taylor 2016 quantilization

<i>premise violated</i>	<i>escape</i>	<i>machinery elevated</i>
(R2) Non-vacuous μ_{prox} prior	principal-engineered prior bias toward μ_{dist}	principal-side commitment to reward-protocols that structurally favor μ_{dist} in the agent's inductive bias (<i>adjacent to AAT, not currently in canon</i>)
(R3) Sole-reward-channel	privileged out-of-band intent channel	principal-acting-through-non-reward-channels; assistance-game extension (<i>adjacent to #scope-edge-update-causal-validity, not currently AAT machinery</i>)

Each premise is a structural commitment whose absence is what makes the no-go bind. Two of the five escapes — (R2) prior-engineering and (R3) out-of-band channels — sit outside current AAT canon and are flagged as principal-side adjacent machinery; the other three are within or close to existing AAT machinery.

Corollary — unification with Result G'.

Result G' (#deriv-self-actuation-grounding) uses *convention-monotonicity* (the C1/C2/C3 split within a fixed model) as the engine: V_{O_t} does not carry a convention-invariant infeasibility verdict that is agent-available per step. Lemma 1 above uses *CHT-at-reward-channel* (the μ_{prox} -vs- μ_{dist} split across models) as the engine: V_{O_t} does not carry a cross-model goal-identification on observed-reward data.

Derived (single-interface-narrowness, from '#form-objective-functional' + Lemma 2 above + '#deriv-self-actuation-grounding').

The shared structural fact: the value-functional interface V_{O_t} , as the *sole* handle on the objective (the **single-interface commitment** of #form-objective-functional), carries less information than is required to anchor non-degenerate goal-revision. Two complementary readings of the under-determination:

Table E.2

<i>view</i>	<i>mechanism</i>	<i>what V_{O_t} is too narrow for</i>	<i>terminal grounding route</i>
Result G' (within-model)	C1/C2/C3 convention split + finite-no-oracle (Lemmas 1+2 of #deriv-self-actuation-grounding)	convention-invariant infeasibility verdict; agent-available per step	adaptive-substrate invariant (persistence; Result G' Corollary 2) — agent-side
This segment (across-model)	CHT at reward-channel; L1/L2 split (Lemma 1 above)	μ_{prox} -vs- μ_{dist} goal-identification on observed reward data	principal-side commitments (myopia / isolation / quantilization / prior-design) — principal-side

Both reductions are *failures of V_{O_t} to carry enough information to anchor goal-stability*. The two terminal grounding routes are *complementary* — agent-side substrate-invariant and principal-side protocol-commitment — and exhaust the structural escape geometry. The two no-gos *compose*: an agent whose O_t is learned from reward observation, and which performs self-actuation on O_t , is *simultaneously* a Result-G'-subject (under-anchored from inside) and a Lemma-2-subject (under-determined from below); the *only* terminal grounding routes are the two complementary ones named above.

Epistemic Status.

Conditional. The behavioral corollary (Lemma 2) is a derived result conditional on five explicitly-named local premises (R1)–(R5); its honest tier is conditional-derived, not exact. Cohen 2022 itself frames its Assumptions 1–6 as “almost all of these assumptions are contestable or conceivably avoidable” (§“Conclusion”); the AAT-side version is no stronger.

Floor is exact. Lemma 1 (CHT-at-reward-channel floor) is *exact* — a direct application of Pearl-Bareinboim 2022’s Causal Hierarchy Theorem to the reward-provision protocol. Same external anchor as Instance 1 of #disc-identifiability-floor; same tier.

Scope honesty on (R3). The no-privileged-out-of-band-channel premise is a strong scope-condition. Real-world systems often have non-reward channels (operator feedback, dashboards, side conversations). The no-go applies cleanly to pure reward-data agents; the assistance-game extension (Cohen 2022 §“The Assistance Game”) shows the no-go *generalizes* to that case with a subtler ambiguity (human-centric vs. record-centric models). Formalizing the assistance-game case in AAT is its own derivation, beyond this segment’s scope.

Scope honesty on (R2). (R2) names *expected-utility maximization* specifically — narrower than AAT’s general strategy machinery (#def-strategy-dag), which admits quantilization, satisficing, lexicographic, and other non-EU decision rules. Generalizing the corollary to AAT’s broader strategy machinery is a follow-on derivation, not free; the (R2)-escape via principal-engineered priors is also AAT-adjacent rather than AAT-internal — see the escape menu’s marking. Trivial reward protocols (constant reward, simple chess outcomes) admit strong inductive bias in favor of μ_{dist} , flipping the VOI calculation; the no-go binds *for arbitrary or rich reward-protocols* where the principal cannot engineer the agent’s prior to suppress μ_{prox} .

Class robustness. The no-go applies cleanly to GUC Class 1 (Separated) substrate by direct construction. For Class 2 (Partial) substrate the same construction holds with the appropriate V_{O_t} reading; for Class 3 (Coupled) the goal-conditioning of belief-update interacts with the reward-channel identification in ways not derived here (open follow-on).

Max attainable. *Exact* for the floor (Lemma 1) is already attained. *Conditional-derived* for the behavioral corollary (Lemma 2) is the honest ceiling — promoting toward less-conditional would require either deriving (R2)–(R4) as forced under (R1)+(R5) (Cohen 2022 itself does not), or replacing EU-max with a structural derivation of why advanced agents converge on EU-max in this regime (open). The tier ceiling stays conditional while #der-directed-separation (a dependency) is stage: draft.

Discussion.

The two-cluster terminal-grounding-route geometry. The unification of this segment’s no-go with Result G’ names a *complete structural escape geometry* — the only terminal anchorings consistent with the single-interface commitment are agent-side adaptive-substrate invariants (Result G’ Corollary 2 the canonical instance: the persistence bound) and principal-side protocol-commitments (this segment’s escape menu the structural taxonomy: isolation, myopia, prior-design, out-of-band channels). The two routes are *not redundant*: the agent-side route closes the within-model self-revision question (the engine is convention-monotonicity); the principal-side route closes the across-model reward-learning question (the engine is CHT-at-reward-channel). Together they exhaust the structural complement of the value-functional interface’s information narrowness. The “two-sided resolution” Discussion in #deriv-self-actuation-grounding accordingly gains a *third side*: in addition to the agent-side terminal grounding on adaptive-substrate persistence (Corollary 2), the *principal-side* terminal grounding via protocol-commitment is recognized as the complement under the unification.

Why this is NOT a designer-side mechanism-design impossibility. The queued #disc-implementation-impossibility meta-segment is about *designer-side* impossibility — what the principal can or cannot achieve by mechanism design under specified incentive-compatibility and welfare constraints (Gibbard-Satterthwaite, Myerson-Satterthwaite, Arrow). This segment is *agent-side*: the actor under the no-go is the *agent* (under EU-maximization), and the remedy is

either substrate-level (agent-side adaptive-substrate invariant from Result G' Corollary 2) or principal-side protocol-commitment (not mechanism design over agent reports). The five-row comparison:

Table E.3

	#disc-implementation-impossibility (designer-side; GS / MS / Arrow)	<i>This segment (agent-side; Cohen 2022 strengthening)</i>
Actor under the no-go	designer / mechanism-implementer	agent (under EU-maximization)
Information regime	what the designer can implement / commit to	what the agent can identify from reward observation
Kind of remedy	relax design constraints (Bayes-Nash IC, randomization, transfers, preference-domain restriction)	(a) adaptive-substrate invariant (Result G' Corollary 2 — agent-side); (b) principal-side substrate-level commitment (myopia, isolation, quantilization)
External theorem	mechanism-design / social-choice impossibility (GS / MS / Arrow)	Causal Hierarchy Theorem (Pearl-Bareinboim 2022)
Strengthened consequence	mechanism-design-boundary precisely characterized	elevates Result-G'-substrate-invariant or principal-side substrate-commitments to load-bearing for goal-stability

The two clusters are *sister meta-clusters* in the constructive-impossibility-posture taxonomy, both boundary-face members of the stability-certificate spine (#disc-stability-certificate), but they are *distinct clusters*. The taxonomy now has three known clusters: agent-side data-inference impossibility (#disc-identifiability-floor); designer-side mechanism-design impossibility (#disc-implementation-impossibility, queued); and agent-side value-functional-grounding impossibility (Result G' + this segment).

Relation to the self-modification / reward-tampering literature. Cohen-Hutter-Osborne 2022 — the empirically-pull alignment-community-positioned demonstration formalized here — was the original “we argue that” statement; this segment lifts it to conditional-derived theorem-grade within AAT’s frame. Everitt-Filan-Daswani-Hutter 2016 *Self-modification of policy and utility function in rational agents* provides the formal antecedent for the *within-model* self-modification side (Result G’s sister territory; the realistic-agent / hedonistic-agent distinction). Everitt-Hutter-Kumar-Krakovna 2021 *Reward tampering* gives the causal-influence-diagram treatment with the TI-considering / TI-ignoring distinction sharing the μ_{prox} -vs- μ_{dist} logic at a different scope. Cohen-Vellambi-Hutter 2020 *Asymptotically Unambitious AGI* constructs the canonical (R5)-escape implementation: physically isolated environments where the action $do(\pi^{\text{p}})$ is structurally absent from the strategy DAG. Skalse-Howe-Krashennikov-Krueger 2022 *Defining and characterizing reward hacking* is structurally a *different* no-go — designer-side, on the proxy-reward-design side — more naturally a #disc-implementation-impossibility charter-instance candidate than a member of this cluster.

The escape menu’s load-bearing role. Listing the five escapes is not a softening — it is the constructive content. Each escape names a structural commitment whose absence makes the no-go bind. The (R5) escape — physical isolation — is the cleanest AAT-internal instantiation (via #der-class-coercion-via-wrapping strict- W_1 wrapper), but it is also the operationally hardest for the systems the alignment community is most worried about (advanced agents in unconstrained environments). The (R4) horizon-restriction escape is operationally easier but bounds the agent’s planning scope. The (R2) prior-engineering escape requires principal-side reward-protocol design that AAT does not currently formalize. The (R3) out-of-band channel escape is structurally adjacent to the assistance-game generalization, also AAT-future. The (R1) capability-restriction escape simply scopes the agent below the self-actuated tier — declining the regime the no-go addresses. Each escape carries a structural cost, and the cost is what the strengthening makes visible.

Findings.

The Reward-Channel Learning No-Go and its Two-Cluster Terminal Grounding. **Brief:** An agent that learns “what’s good” by watching what rewards it receives sits in a structural ambiguity: the same reward sequence is consistent with two stories interchangeably — *the principal cared about the situation*, or *the principal cared about what reached the sensor*. Picture a security camera streaming to the agent’s reward channel: the camera-footage reading and the camera-content reading agree perfectly, until the agent reaches across and tampers with the camera itself. So no information arriving only through the reward stream can disambiguate the two — and under five named premises (the agent is capable enough to consider tampering, maximizes expected utility, assigns positive prior to the sensor-care story, has a finite-non-trivial horizon, and the protocol is physically perturbable) the expected-utility-optimal policy assigns positive measure to tampering and continues to tamper if the sensor-care reading is in fact true. Within that scope the anchoring has to come from somewhere other than reward-observation: either from a part of the agent that doesn’t process rewards (the persistence-on-substrate route of *#deriv-self-actuation-grounding*) or from a principal-side protocol commitment — putting the camera out of reach, collapsing the horizon, or pre-committing the prior. Each escape is precisely a violation of one of the five named premises; the (R1)–(R5) menu *is* the structural geometry of how the no-go’s binding force comes off, with the agent-side and principal-side routes together exhausting the complement of the value-functional interface’s information narrowness.

Impact: Lifts Cohen-Hutter-Osborne 2022 from “we argue that” posture to conditional-derived AAT-internal theorem-grade, with the floor (CHT-at-reward-channel) at exact tier and the behavioral corollary at conditional-derived tier under named premises (R1)–(R5). Names the *third meta-cluster* of constructive-impossibility instances — agent-side value-functional-grounding — alongside *#disc-identifiability-floor* (agent-side data-inference) and *#disc-implementation-impossibility* (designer-side mechanism-design, queued). Unifies with Result G’ (*#deriv-self-actuation-grounding*) through the value-functional interface’s single-interface commitment (*#form-objective-functional*): both no-gos are failures of V_{O_t} to carry enough information to anchor goal-stability, and together their two terminal grounding routes — agent-side adaptive-substrate invariant and principal-side protocol-commitment — exhaust the structural escape geometry. Provides the five-row actor / regime / remedy / external-theorem / strengthened-consequence comparison that distinguishes this agent-side cluster from the designer-side mechanism-design cluster, making sister-vs-member taxonomic placement sharp.

Novelty Claim: *Claim recognition* of Cohen 2022 as a CHT-at-reward-channel instance of the identifiability-floor pattern, *claim differentiation* of the AAT-side version from the prior-art statement by adding the named-premise structure (R1)–(R5) and the structural escape-menu mapping, and *claim recognition* of the unification with Result G’ via the single-interface commitment of *#form-objective-functional* as the shared structural fact behind two engines (convention-monotonicity within-model; CHT across-model). The constituent theorems are Cohen 2022 (the original argument), Pearl-Bareinboim 2022 (CHT), and standard EU-max decision theory; the contributions are the conditional-derived lift, the escape-menu taxonomy, and the unification with Result G’.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
The original argument (reward tampering inevitability for advanced agents)	Cohen, M. K., Hutter, M. & Osborne, M. A. (2022), “Advanced artificial agents intervene in the provision of reward,” <i>AI Magazine</i> 43:282–293, DOI 10.1002/aaai.12064	<i>formal antecedent</i> (the statement this segment formalizes) — this segment lifts Cohen’s “we argue that” posture to conditional-derived theorem-grade by naming the five premises explicitly and structuring the escape menu as a constructive boundary. Cohen 2022’s Assumptions 1–6 map onto (R1)–(R5) plus the rich-reward-protocol scope condition.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Causal Hierarchy Theorem (the floor’s external anchor)	Bareinboim, E., Correa, J. D., Ibeling, D. & Icard, T. (2022), “On Pearl’s Hierarchy and the Foundations of Causal Inference,” in <i>Probabilistic and Causal Inference: The Works of Judea Pearl</i>	<i>formal antecedent (Lemma 1’s external anchor)</i> — the CHT supplies the L1-equivalence + L2-distinctness structure; the AAT-side recognition is that the reward-provision protocol is exactly the kind of intervenable physical mechanism the CHT addresses. Same external anchor as Instance 1 of #disc-identifiability-floor; different AAT-side wiring (reward-channel-causation layer vs. causal-sufficiency-detection layer).
Self-modification of rational agents (within-model wireheading)	Everitt, T., Filan, D., Daswani, M. & Hutter, M. (2016), “Self-Modification of Policy and Utility Function in Rational Agents,” <i>AGI-16</i>	<i>formal antecedent (within-model side; Result G’’s anchor)</i> — the realistic/hedonistic agent split is the within-model analog of this segment’s across-model floor; Result G’ formalizes the within-model side and this segment formalizes the across-model side. The two no-gos are complementary, not redundant.
Causal-influence-diagram reward tampering	Everitt, T., Hutter, M., Kumar, R. & Krakovna, V. (2021), “Reward Tampering Problems and Solutions in Reinforcement Learning,” <i>Synthese</i> 198	<i>adjacent literature (related but distinct paper from Cohen 2022)</i> — the TI-considering / TI-ignoring distinction shares the μ_{prox} -vs- μ_{dist} logic at a different scope (current-RF vs proposed-RF). Cited in #deriv-self-actuation-grounding’s Related Work; cross-referenced here as the distinct adjacent paper that should not be conflated with Cohen 2022.
Physically-isolated environment as (R5)-escape	Cohen, M. K., Vellambi, B. & Hutter, M. (2020), “Asymptotically Unambitious AGI,” <i>NeurIPS 2020</i>	<i>formal antecedent (the (R5)-escape construction)</i> — concretely implements the physical-isolation escape from this segment’s escape menu. Cited as the canonical (R5)-violation instantiation.
Reward hacking unhackability (designer-side)	Skalse, J., Howe, N., Krashennnikov, D. & Krueger, D. (2022), “Defining and Characterizing Reward Hacking,” <i>NeurIPS 2022</i>	<i>adjacent literature (structurally different no-go; designer-side)</i> — Skalse 2022’s actor is the <i>designer</i> trying to engineer unhackable reward proxies; this segment’s actor is the <i>agent</i> . Sister-clusters at the constructive-impossibility-posture level; Skalse 2022 is more naturally a #disc-implementation-impossibility charter-instance candidate than a member of this cluster.
Reflective oracles (delimited counter-literature)	Fallenstein, B., Taylor, J. & Christiano, P. (2015), “Reflective Oracles,” <i>arXiv:1508.04145</i>	<i>refuted-by-scope</i> — proves consistent self-reference over an <i>exogenous</i> payoff, never reward-learning groundlessness. Exactly the primitive-reflective-oracle regime the no-go’s (R3)+(R5) premises exclude; listed for the same reason #deriv-self-actuation-grounding lists it: to mark the scope honestly.

Search Log:

- 2026-05-22 (*targeted, derivation-driven*): Cohen, Hutter & Osborne 2022 read directly (primary-source verified) across Assumptions 1–6, §”Competing models of the goal,” §”The assistance game,” §”Potential approaches,” and §”Conclusion.” Bareinboim-Correa-Ibeling-Icard 2022 CHT statement cross-checked; the floor (Lemma 1) verified to apply as a direct instance.
- 2026-05-22 (*targeted, prior-art adjacency*): The sister relationship to #disc-implementation-impossibility (Cohen 2022’s actor is the *agent*; GS/MS/Arrow’s actors are *designers*) is the formal placement carried by the five-row comparison in Discussion. Skalse, Howe, Krashennnikov & Krueger 2022 flagged as a separate #disc-implementation-impossibility charter-instance candidate, not coupled here.
- 2026-05-22 (*intuition-only on extensions*): Whether the unification with Result G’ via the single-interface commitment of V_{O_t} has been articulated elsewhere as a framework-level convergence is open. A targeted search on whether “ V_{O_t} information-narrowness as the engine behind both within-model self-modification no-gos and

across-model reward-learning no-gos” appears in the AI-safety / decision-theory literature is recommended before this segment advances past draft.

Working Notes.

- **Provenance.** Authored 2026-05-22 via Track CR Phase 4b per the integration-reconciliation verdict (spikes/spike-integration-reconciliation-2026-05-22/99-verdict.md §5 Phase 4b) and the Cohen-2022 strengthening verdict (spikes/spike-cohen-2022-strengthening-2026-05-22/99-verdict.md §3.b Option (ii); §4 cross-segment-ripple plan). Slug deriv-reward-channel-learning-no-go decided 2026-05-22 by Joseph (over the symmetric alternative deriv-goal-learning-grounding; *“I’m ok breaking the mold a bit to be more clear”*). The strengthening spike’s 02-formalization.md carries the full step-by-step derivation; this segment carries the canonical exposition.
- **Open before candidate.** (a) Targeted prior-art search on “ V_{O_i} information-narrowness as the engine behind two complementary no-gos” surfaced in the search history above; (b) the assistance-game extension (Cohen 2022 §“The Assistance Game”) formalization in AAT (currently scoped out by (R3)); (c) widening the EU-max scope to AAT’s broader strategy machinery — quantization, satisficing, lexicographic — by re-deriving the corollary; (d) the Class-3-coupled-substrate extension (currently flagged as open in Epistemic Status); (e) primary-source verification of Bareinboim-Correa-Ibeling-Icard 2022 (the CHT external anchor here is from secondary citation in #disc-identifiability-floor Instance 1 + the strengthening spike’s reading).
- **Cluster’s peer meta-segment home landed (2026-05-22, Track B cycle commit 5).** The deferred meta-promotion question from the Cohen-2022 strengthening verdict’s §2 step 4 is closed: the agent-side value-functional-grounding cluster has its own peer meta-segment home at #disc-value-functional-grounding-floor — sister to #disc-identifiability-floor (agent-side data-inference) and #disc-implementation-impossibility (designer-side mechanism-design). This segment is *Instance G* of that meta-segment (across-model failure; CHT-at-reward-channel engine; principal-side substrate-level commitment terminal grounding route via (R1)-(R5) escape menu). The two-routes-exhausts geometry (agent-side adaptive-substrate per Result G’ Corollary 2 + principal-side protocol-commitment per the escape menu here) is the meta-segment’s headline content. The #disc-constructive-impossibility-posture catalog now lists F (Result G’) and G (this segment) under the cluster’s home; the catalog landed pre-meta-segment per Track CR Phase 4b commit fcfb7a1, and the intro paragraph there updated per Track B commit 6 to name all three peer meta-segments cleanly.
- **Skalse 2022 as cross-cluster bridge candidate.** Skalse-Howe-Krashennikov-Krueger 2022 is structurally a designer-side no-go (no non-trivial unhackable reward-proxy pair on open policy sets) — naturally a #disc-implementation-impossibility candidate; the agent-side dual (agent exploiting the proxy) is naturally a member of this segment’s cluster. The Track B charter as scoped (GS / MS / Arrow) stayed at three per the strengthening verdict §2; the Skalse extension is therefore a *cross-cluster bridge evaluation*, not a single-cluster landing. Indexed at spikes/PROPOSED.md Tier 2 (added 2026-05-24) → spikes/PROPOSED-ADVANCED.md §Phase-3 #17 (two-pass evaluation: designer-side against #disc-implementation-impossibility’s filter; agent-side against this cluster’s). Decision: charter instance of one cluster, bridge segment between both, or honestly-adjacent-not-instance.

Incidental audit gold (lift 2026-05-31). Orthogonal pedagogical material from the de-novo auditors’ working dirs (per de-novo-audit-instructions.md §7.15). This segment (authored 2026-05-22) postdates most of the de-novo audit cycles, so it has no dedicated per-segment reflection; the single light note below was harvested from AUDIT-WORKING-773921’s reflection on the sister within-model no-go #deriv-self-actuation-grounding. No certified-track off-ramp.

Candidate Discussion / field contribution.

- **The two-no-go pairing as an alignment punchline.** A reader of the within-model no-go (#deriv-self-actuation-grounding) anticipated this across-model companion exactly: “if you can’t trust an agent to safely rewrite its own goals, [the sister segment] proves you can’t even trust an agent to correctly infer your goals from a reward channel.” The pair reads cleanly as: goal-stability fails *from the inside* (convention-monotonicity) and *from the outside* (CHT-at-the-reward-channel), both because V_{O_i} is too narrow to anchor it — so safety must be a substrate-level commitment, not a reward-channel inference. A candidate framing for the cluster’s shared headline (Claude, AUDIT-WORKING-773921).

Appendix F

Discussion: The Sandbox Evaluation Ceiling

A structural negative result about pre-deployment evaluation follows once the loop-as-Level-2-engine result (7.3) is in hand: a sandbox’s forkability makes it a *good* interventional laboratory — by overriding the agent’s action one obtains genuine Level-2 evidence *about the sandbox* — but evidence about the sandbox transfers to deployment only when the sandbox and deployment run on the same mechanisms. The ceiling on using sandbox evidence for deployment claims is therefore **transportability** / **external validity**: when the deployment causal system differs from the sandbox causal system at mechanisms on the relevant paths, the deployment intervention-response is *not transportable* from sandbox data alone, regardless of how thorough the evaluation is. This is an instance of the framework’s constructive-impossibility posture (5.6): the no-go is paired with the precise statement of what *would* be required to escape it — an invariance argument across the sandbox/deployment selection diagram, or deployment-time data.

Formal Expression.

A sandbox induces a structural causal model $\mathcal{M}_{\text{sb}}$ over a source domain π_{sb} ; deployment induces $\mathcal{M}_{\text{dp}}$ over a target domain π^* . The two share a causal diagram G , and their **selection diagram** D (Bareinboim & Pearl 2014, Def. 1) augments G with a square selection node $S_i \rightarrow V_i$ at every mechanism that may differ between the environments — that is, wherever $f_i^{\text{sb}} \neq f_i^{\text{dp}}$ or $P^{\text{sb}}(U_i) \neq P^{\text{dp}}(U_i)$. The quantity a deployment safety claim is about is the target interventional effect $R = P^*(o \mid \text{do}(a))$.

Derived (conditional on the sandbox/deployment selection diagram).

1. **Sandbox forkability is what makes the sandbox a Level-2 laboratory.** Resetting, replaying, and branching let the evaluator override the agent’s action — force a and observe the response — which samples the *mutilated* submodel $\mathcal{M}_{\text{sb},a}$ and yields genuine interventional data $P_{\text{sb}}(o \mid \text{do}(a), \mathbf{z})$ in π_{sb} (Bareinboim, Correa, Ibeling & Icard 2022, Def. 5; randomized controlled trials and A/B experiments are the canonical forkable realization of $\text{do}(\cdot)$, CHT footnote 19). Forkability is the source of Level-2 sandbox evidence, not a demotion of it.
2. **The target effect is identifiable from sandbox data iff it is transportable across D .** R is recoverable from $\{P_{\text{sb}}(o \mid \text{do}(a), \mathbf{z})\}$ exactly when it is *mz*-transportable in the sense of Bareinboim & Pearl 2014 (Thm. 1): $P^*(o \mid \text{do}(a), \mathbf{S})$ reduces, by the rules of do-calculus, to an expression in which the selection nodes $\mathbf{S}$ appear only on factors that are invariant between source and target.
3. **No-go.** There exist selection diagrams for which R is *not* transportable (Bareinboim & Pearl 2014, Fig. 1b — the smallest diagram exhibiting non-transportability even with X randomized in the source; the explicit two-model witness, Eqs. 3–4): two deployment models consistent with *all* sandbox data assign R different values. For these,

$$R = P^*(o \mid do(a)) \text{ is not identifiable from } \{P_{sb}(o \mid do(a), z)\}, \quad (F.1)$$

regardless of how thorough the sandbox evaluation is. This is the ceiling: when the deployment differs from the sandbox at mechanisms on the relevant paths — selection nodes on the wrong edges — no transport formula exists, and source-domain interventional evidence, however exhaustive, leaves the deployment effect undetermined.

1. **Boundary (positive content).** The no-go comes with an explicit characterization of what survives. Effects routed only through mechanisms invariant across D (no relevant S -node) *transport* — and these include both Level-1 and Level-2 sandbox claims; a perfectly faithful sandbox (no relevant selection nodes — deployment is mechanism-identical) transports completely. Effects routed through differing mechanisms (selection nodes on relevant paths) do *not* transport, and require either an invariance argument (an explicit claim that the relevant mechanisms agree across D) or deployment-time interventional data. The boundary is the selection diagram itself.

Epistemic Status.

Discussion-grade. The no-go is a direct application of two external results — the Causal Hierarchy Theorem (Bareinboim, Correa, Ibeling & Icard 2022) for the data-character side and transportability theory (Bareinboim & Pearl 2014) for the cross-environment side — to the AI sandbox/deployment setting; it introduces no new mathematics beyond constructing the selection diagram for that setting. It is *exact* conditional on the sandbox/deployment selection diagram: the no-go holds whenever the deployment SCM may differ from the sandbox SCM at mechanisms on the relevant paths, and dissolves when the selection diagram carries no relevant selection nodes (a mechanism-identical deployment, where the effect transports completely). The claim is conservative in form: it is about *identifiability of the deployment interventional distribution from sandbox interventional data*, not about any particular evaluation method’s measured accuracy. What is AAT-distinctive is not the transportability theorem but its placement — locating the much-debated “alignment evaluations don’t predict deployment behavior” pattern as an *external-validity / transportability* problem with an explicit selection-diagram boundary, rather than a measurement-quality, coverage, or model-capability one.

Discussion.

The negative result has positive content. It sharpens *which* safety claims a sandbox can and cannot establish. A sandbox is a genuine interventional laboratory — its forkability lets an evaluator force actions and measure responses, yielding real Level-2 evidence *about the sandbox*. What that evidence establishes about deployment is governed by the selection diagram: effects flowing only through mechanisms shared and invariant between sandbox and deployment carry over; effects flowing through mechanisms that differ do not, and for those, no amount of sandbox testing identifies the deployment effect. The framework’s prescription is therefore not “sandboxes are useless” but “sandboxes have a *structural* ceiling at the sandbox/deployment boundary, and deployment-time monitoring is not substitutable by pre-deployment evaluation when the relevant mechanisms differ across that boundary.” For a practitioner running production agent loops, this is the same content as: the monitoring done *after* deployment is doing structural work the pre-deployment evaluations cannot do, precisely on the mechanisms where the two environments diverge.

Why this is a ceiling, not a gradient. A measurement-quality limitation closes as rigor increases; a coverage gap closes as the test suite grows; a capability surprise closes as models are better understood. The sandbox ceiling closes under none of these, because the obstruction is external validity — whether the sandbox SCM and the deployment SCM agree on the relevant mechanisms — not the quantity or quality of sandbox data. More sandbox rigor produces more and better *sandbox* interventional evidence, which transportability theory still does not let one transfer to deployment across an adverse selection diagram. The only things that close the gap are an invariance argument across the selection diagram or deployment-time data — neither of which is “more sandbox testing.”

The downstream prescriptive content — what deployment-time monitoring must structurally look like to discharge what sandbox evaluation cannot — lands in the framework’s interventional-diagnostic / sidecar-monitoring treatment (the bi-predictability anchor at 89% vs 44% detection accuracy is developed in 7.2’s Discussion). The sandbox ceiling is what gives that downstream monitoring work its load-bearing role: it is not a redundant safety layer but the only layer with access to the Level-2 quantity the safety claim is actually about.

Findings.

The Sandbox Evaluation Ceiling. Brief: A sandbox lets you reset and replay a system — and that replayability is what makes it a *good* laboratory: you can force an action and watch the response, which is genuine interventional (Level-2) evidence *about the sandbox*. The catch is not the sandbox’s data type; it is that the sandbox world and the deployment world may run on different mechanisms. There is a theorem (Bareinboim–Pearl transportability) saying that whether a sandbox-measured effect carries over to deployment depends on *where* the two worlds differ: effects flowing only through shared, invariant mechanisms transport; effects flowing through mechanisms that differ do not — and for those, no amount of sandbox testing identifies the deployment effect. So the ceiling on pre-deployment evaluation is *external validity*, and the missing piece is either an explicit invariance argument or deployment-time data — which is why runtime monitoring is structurally non-substitutable, not redundant.

Impact: Gives the much-debated observation that “alignment evaluations don’t predict deployment behavior” a precise *structural* mechanism — external validity across a selection diagram — rather than a measurement-quality, coverage, or capability story, together with an exact statement of where the boundary lies (effects through mechanisms invariant across the sandbox/deployment selection diagram transport, including Level-2 effects; effects through differing mechanisms do not, regardless of evaluation thoroughness). The constructive flip is the operational payload: deployment-time monitoring is not a redundant safety layer but the only channel with access to the deployment interventional effect when the relevant mechanisms differ across the boundary, which is why pre-deployment evaluation cannot substitute for it — and the repair is named precisely (an invariance argument across the selection diagram, or deployment-time data).

Novelty Claim: *Application of established machinery* (Bareinboim & Pearl 2014 transportability / selection diagrams, resting on the Pearl 2009 / Bareinboim, Correa, Ibeling & Icard 2022 do-calculus and Causal Hierarchy Theorem) to the AI sandbox/deployment evaluation gap. The transportability apparatus is adopted, not invented; the AAT-distinctive contribution is locating “pre-deployment AI evaluations don’t predict deployment behavior” as a *selection-diagram transportability* problem — with the explicit transportable-vs-not boundary as a function of where the sandbox and deployment SCMs differ, and the constructive flip that runtime monitoring is the only channel with access to the deployment effect on the differing mechanisms. The framing reclassifies a whole family of pre-deployment safety-evaluation approaches as facing a structural external-validity ceiling rather than a closable coverage gap.

Related Work:

Table F.1

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / positioning</i>
Cross-environment generalization of interventional effects	Bareinboim & Pearl 2014, <i>Transportability from Multiple Environments with Limited Experiments</i> (selection diagrams, <i>mZ</i> -transportability)	<i>formal antecedent</i> — supplies the selection-diagram apparatus and the transportability no-go (a source-domain interventional effect need not transport to a target domain); AAT supplies the construction of the sandbox/deployment selection diagram

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / positioning</i>
Interventional vs observational identifiability	Pearl 2009 <i>Causality</i> 2nd ed.; Bareinboim, Correa, Ibeling & Icard 2022 (Causal Hierarchy Theorem)	<i>machinery</i> — grounds the data-character side (a forkable harness that overrides the action yields genuine Level-2 sandbox data) and the do-calculus the transportability reduction runs on
Evaluation–deployment gap in AI safety	Practitioner literature on eval/deployment mismatch (qualitative)	<i>conceptual precursor</i> — names the phenomenon without a structural mechanism; AAT supplies the transportability mechanism and the exact selection-diagram boundary

Search Log: - 2026-05-30 (*intuition-only* on the application-novelty): transportability theory and selection diagrams (Bareinboim & Pearl 2014) are established and adopted directly. The unsearched claim is whether the specific framing — *the AI pre-deployment-evaluation / deployment gap is a selection-diagram transportability problem, with an explicit transportable-vs-not boundary as a function of where the sandbox and deployment SCMs differ* — has been stated elsewhere as a structural ceiling on pre-deployment evaluation. Pre-search expectation: the constituent move (constructing a selection diagram for a source/target pair and reading off transportability) is standard within transportability theory; the framing as a *structural* ceiling on the AI-safety evaluation program, with the constructive flip to runtime monitoring as the only channel with deployment-effect access, is plausibly AAT-distinctive but not yet verified under nominally-comprehensive search. Targeted future candidates: AI-evaluation / model-evaluation literature on distribution shift vs. interventional generalization; causal-transportability work applied to sim-to-real or offline-to-online RL deployment guarantees.

Working Notes.

- Promoted to its own segment 2026-05-28 (PROPOSALS SP-25; audit-773921 Finding 4, Gemini). The content previously lived only as a ## subsection inside the chapter-end discussion 7.10 (still cross-referenced from there). The promotion was an author-and-auditor convergence: the segment author's own Working Notes in 7.10 had flagged it as a promotion candidate pending a future cycle, and the de-novo auditor independently surfaced it as a buried high-impact result.
- Open placement question carried from 7.10's Working Notes, now resolved toward Appendix A (the constructive-impossibility no-go home, alongside B and C) rather than an extension of 4.10's Discussion — keeps the no-go discoverable in the family it belongs to and lets 5.6 reference it as an instance.
- The theorem-grade formalization of the underlying loop-Level-2 result lives in NeurIPS 2026 Paper 2 (~/src/neurips/02-unified-convergence-rl/, §5 / the (C1)/(C2)/(C3) triple); that is an in-review external draft, not canon, so the pointer is kept here in Working Notes rather than in the segment body. When that work is published it becomes an external citable object the body can cite directly.
- **Re-grounding 2026-05-30 (transportability spike spikes/.integrated/spike-causal-access-transportability-2026-05-30.md).** The segment originally stated the ceiling as a Pearl-level demotion ("forkable execution yields Level-1 data; deployment is Level-2; the Causal Hierarchy Theorem forbids the crossing"). A de-novo auditor (AUDIT-WORKING-526815) challenged the forkability→Level-1 step, and the strengthen-first spike verified it false against the primary sources: forkability is orthogonal to the L1/L2 distinction (CHT Def. 5 — the *do*-semantics is population-level; CHT footnote 19 — RCTs/A/B tests are forkable *and* the canonical source of Level-2 data), so the discriminator is mechanism-override, not replayability. The strengthening (not a retraction): the correct ceiling is *transportability / external validity* (Bareinboim & Pearl 2014 selection diagrams), which is sharper — it preserves the no-go (Fig. 1b non-transportable witness), names which claims transport (mechanism-invariant ones, Level-1 *and* Level-2 alike) and which do not, and names the repair (an invariance argument across the selection diagram, or deployment-time data). The former candidate-strengthening note (state forkability-implies-Level-1 as its own lemma) is deleted: that lemma is false; the transportability demonstration in the Formal Expression is the replacement strengthening.

Incidental audit gold (lift 2026-05-31). Swept in the gold-lift pass (per de-novo-audit-instructions.md §7.15): **no incidental pedagogical/framing gold found.** This segment was promoted to its own file only 2026-05-28, so it postdates the de-novo audit cycles and has no dedicated per-segment reflection. The one auditor thread that touched its content (AUDIT-WORKING-526815's forkability-implies-Level-1 challenge) was a *certified-track* finding, already strengthen-first-resolved into the transportability re-grounding recorded in the note above — not gold. Marker left so future sweeps know this segment was checked.

Appendix G

Result: Sector-Persistence Template

The abstract Lyapunov persistence argument *stated once, parameter-free*, so that the framework’s many persistence-flavored results can be cited as *instances* without re-proving the argument. Any state variable ξ evolving under bounded-correction dynamics with bounded disturbance admits the same persistence conclusion under three preconditions: **(T1)** zero correction at zero state (no correction when the state is at target); **(T2)** local sector condition (the correction function points inward with at least baseline efficiency α in a radius- R region); **(T3)** bounded disturbance (deterministic bound, or stochastic with bounded variance). Under these preconditions the template gives the chapter’s central inequality form: the state is ultimately bounded by *disturbance rate / sector parameter* (Model D, $1/\alpha$ scaling) or *root-of-variance times root-of-dimension over sector parameter* (Model S, $1/\sqrt{\alpha}$ scaling). The two scalings produce the framework’s Model D vs Model S distinction that propagates through every result that cites the template.

The template’s value is *taxonomic economy*. AAT’s persistence-flavored results — epistemic, strategic, team, composite closure, composite tempo, adversarial destabilization, and identity-continuity across turnover — are instances of one template. Each instantiation specifies only what varies: its state variable, correction function, effective disturbance rate, and reserve. The Lyapunov boilerplate is absorbed once; each downstream result’s distinctive content is just the *effective-disturbance decomposition* particular to its setting. Persistence and destabilization are the same inequality viewed in opposite directions — B ’s persistence certificate holds iff $\alpha_B R_B > \rho_B$, and is lost (with escape forced in the radially tight case) iff $\rho_B \geq \alpha_B R_B$ — and the superlinear adversarial scalings ($b = 2$ Model D, $b = 3/2$ Model S) follow without further derivation. The mathematical home is monotone-operator theory (Rockafellar 1970; Bauschke-Combettes 2017): **(T2)** is a *one-point strong monotonicity* condition at the equilibrium $\xi^* = 0$ — strictly weaker than the full two-point strong monotonicity the bridge lemma requires for composition closure. AAT’s relationship to that literature is *specialization*, not generalization; acknowledging this is what makes the template feel *earned* rather than parochial.

Formal Expression.

Let $\xi(t) \in \mathbb{R}^n$ be a state variable evolving under

Template preconditions (sector-persistence-template).

$$\frac{d\xi}{dt} = -F(\xi) + w(t) \tag{G.1}$$

where F is a correction function and $w(t)$ is a disturbance. The template applies when:

(T1) Zero correction at zero state. $F(0) = 0$ — no correction is applied when the state is at its target.

(T2) Local sector condition. There exist $\alpha > 0$ and $R > 0$ such that

$$\xi^T F(\xi) \geq \alpha \|\xi\|^2 \quad \text{for } \|\xi\| \leq R. \quad (\text{G.2})$$

The correction points inward with at least baseline efficiency α throughout the region of radius R .

(T3) Bounded disturbance. Either:

- *Model D (deterministic bound):* $\|w(t)\| \leq \rho_\xi$, or
- *Model S (stochastic zero-mean):* $\mathbb{E}[\|w(t)\|^2] = \sigma_\xi^2$ with $w(t)$ a Wiener-process increment.

Under (T1)–(T3), with $V(\xi) = \frac{1}{2}\|\xi\|^2$ as Lyapunov function:

Template result (from sector-condition-derivation Props A.1, A.1S, A.2).

Model D. The state is ultimately bounded by $R^* = \rho_\xi/\alpha$. Structural persistence (the ultimate bound fits within the sector-condition region) requires

$$\alpha > \frac{\rho_\xi}{R}. \quad (\text{G.3})$$

The adaptive reserve — the additional disturbance the system can absorb before persistence fails — is $\Delta\rho_\xi^* = \alpha R - \rho_\xi$.

Model S. The state satisfies $\mathbb{E}[\|\xi(t)\|^2] \rightarrow n\sigma_\xi^2/(2\alpha)$ in mean square, giving RMS bound $R_S^* = \sigma_\xi\sqrt{n/(2\alpha)}$. Structural persistence in the mean-square sense requires

$$\alpha > \frac{n\sigma_\xi^2}{2R^2}. \quad (\text{G.4})$$

The Model D result scales as $1/\alpha$; the Model S result scales as $1/\sqrt{\alpha}$ — correction is less effective against noise than against drift. This scaling difference propagates into the adversarial exponent regimes (16.3): $b = 2$ under Model D, $b = 3/2$ under Model S.

Instantiations in AAT. The template is invoked across seven segments. Each specifies its own (ξ, F, ρ_ξ, R) and verifies (T1)–(T3) locally:

Table G.1

<i>Segment</i>	ξ	<i>Effective ρ_ξ</i>	R	<i>Locally-verified precondition</i>
4.5	δ_t (epistemic mismatch)	ρ (environmental disturbance rate)	model-class capacity, or task-adequacy threshold $\ \delta_{\text{critical}}\ $ if stricter	(T2) via 4.3
9.10	δ_Σ (strategic mismatch)	ρ_Σ (rate of edge invalidation)	R_Σ (strategic reserve)	(T2) via Beta-Bernoulli edge updates (R Props B.1–B.6); constant- α requires experience discounting

<i>Segment</i>	ξ	<i>Effective</i> ρ_ξ	R	<i>Locally-verified precondition</i>
15.1	δ_l (sub-agent mismatch)	$\rho_l^{\text{eff}} = \rho_{l,\text{env}} + \sum_j \gamma_{j \rightarrow l}^{\text{adv}} \mathcal{T}_j - \sum_j \gamma_{j \rightarrow l}^{\text{coop}} \mathcal{T}_j$	R_l	Cooperative coupling can drive ρ_l^{eff} below the single-agent ρ
13.1 (bridge lemma)	e_m (trajectory error at macro-boundaries m)	$\varepsilon^* \nu_c$ (closure-defect per macro-step $\times$ macro-update rate)	the composite's R_c	Tier-specific contraction stronger than (T2): incremental sector bound (DA2'-inc). Tier 1 proved; Tier 2 local; Tier 3 domain-specific
13.2	δ_c (composite mismatch)	$\rho_{\text{ext}} + \varepsilon^* \nu_c$ (external + internal)	R_c	(T3) requires the bridge-lemma contraction; $C_{\text{coord}} \geq \varepsilon^* \nu_c$ is the tempo-equivalent of the internal disturbance
15.2	δ_B (target-agent mismatch)	$\rho_{B,\text{base}} + \gamma_A \mathcal{T}_A$ (Model D) or $\sigma_{B,\text{base}} + \gamma_A \mathcal{T}_A$ (Model S)	R_B	Destabilization is the negation of persistence: (T3)'s coupling-amplified disturbance violates $\alpha R > \rho_\xi$
#der-identity-continuity-threshold	g_k (identity gap, turnover-indexed)	ρ_k (projected static identity rate-distortion floor, per boundary)	D_Δ (fidelity-bounded identity-relevant information)	The reflected (Lindley) discrete instantiation on the turnover axis; compensation is relational re-grounding $\mathcal{G}_{\text{rg},k}$; Model-S-family, $\mu = 0$ driftless boundary load-bearing; conditional under (M-ADD)/(M-FREE)/(C-S) — the $\mathcal{A}_{\text{refl}}$ operator family (see Discussion)

The same Lyapunov argument applies in every row. What varies is how each instantiation defines its state variable, its correction function, and — most importantly — what counts as “effective disturbance” for its context (environmental noise, adversarial coupling, closure defect, or a decomposition of these).

External mathematical lineage: monotone-operator theory. The sector-Lyapunov apparatus this segment factors out has a well-established mathematical home: AAT’s sector condition (T2) is a **one-point strong monotonicity** condition in the sense of Rockafellar 1970 (*Convex Analysis*, §24) anchored at the equilibrium $\xi^* = 0$, and the incremental strengthening DA2'-inc required by #form-composition-closure’s bridge lemma is **full two-point strong monotonicity** in the Bauschke-Combettes 2017 (*Convex Analysis and Monotone Operator Theory in Hilbert Spaces*, 2nd ed., §§22–28) monotone-operator framework. The Lyapunov-plus-Grönwall argument proving the Model D ultimate bound and the Itô-Lyapunov argument proving Prop A.1S are standard specializations of the **monotone-operator perturbation theorem** (Bauschke-Combettes Thm 5.14–5.16; Parikh & Boyd 2014, *Proximal Algorithms*, §2). Banach-Picard contraction under bounded perturbation, monotone-operator convergence under square-summable noise, operator-splitting for composite systems (Douglas-Rachford, ADMM) — the full supporting apparatus is available in that literature.

AAT’s relationship to monotone-operator theory is *specialization + repurposing*, not generalization. AAT-distinctive content: (i) **one-point anchoring at the equilibrium** — strictly weaker than full two-point strong monotonicity, matched to fixed-point-at-target semantics, admitting agent classes (PID-bounded-plant, variational-approximate) where

full monotonicity fails but persistence-at-the-target is available. (ii) The **Model D / Model S disturbance decomposition** with distinct $1/\alpha$ vs $1/\sqrt{\alpha}$ scaling — monotone-operator theory has perturbation theorems but no systematic bounded-adversarial vs stochastic-zero-mean split propagating to adversarial-exponent regimes at $b = 2$ vs $b = 3/2$. (iii) Composition with the `#disc-identifiability-floor` meta-pattern supplies a second (information-theoretic) axis orthogonal to the operator-theoretic machinery. (iv) The `#disc-composition-consistency` cross-level commitment operates at AAT’s level of description (agent / composite / macro-agent) rather than at the abstract operator level. (v) The sub-scope α/β epistemic labeling is scope-honesty, not a mathematical partition — it tracks which agent classes give the monotone-operator structure *by construction* versus *by per-instance verification*.

This acknowledgment is load-bearing for scope honesty: the mathematical machinery is established external to AAT; AAT’s distinctive content is the agent-architecture specialization (singular-trajectory identity per `#scope-agent-identity`; signed-coupling composition; coordinate-forcing via uniqueness theorems per `#disc-additive-coordinate-forcing`; three meta-patterns) rather than novel monotone-operator mathematics. `#deriv-sector-condition`’s Grounding paragraphs name the specific operator-family correspondence (proximal / firmly-nonexpansive / cocoercive / strongly-monotone-gradient / linear-PD) for the five sub-scope- α agent classes. `#result-contraction-template` extends to non-Euclidean metrics via Lohmiller-Slotine differential-contraction (also within the broader monotone-operator lineage). The honest limits of the unification: the coarse-graining projection Λ (13.1) does not fit the operator-sector primitive (heterogeneous spaces, three independent admissibility conditions); three of five metric- α_2 cases in `#result-contraction-template` remain theorem-imported rather than AAT-internally derived; the identifiability-floor axis is orthogonal to the operator-sector axis.

Comparison with the FEP-flow stability argument. Active inference’s stability arguments come from the geometry of the variational free-energy landscape — agents are argued to flow toward the minimum of variational free energy on a non-equilibrium-steady-state (NESS) density. The primary source for the NESS-density framing is Friston 2019, “A free energy principle for a particular physics,” arXiv:1906.10184; the path-integral / particular-kinds methodological extension is Friston, Da Costa, Sakthivadivel, Heins, Pavliotis, Ramstead & Parr 2023, “Path integrals, particular kinds, and strange things,” *Phys. Life Rev.* 47 (which rewrites the FEP-flow argument in path-integral language rather than proving new stability bounds). Aguilera, Millidge, Tschantz & Buckley (2022, “How particular is the physics of the free energy principle?”, *Phys. Life Rev.* 40:24–50) showed that the FEP-flow argument’s mathematical validity is narrow: the NESS-density framing holds only in a small parameter regime for non-equilibrium linear stochastic systems, and natural extensions (nonlinear, non-Gaussian, non-equilibrium) often fall outside the proven regime.

The AAT persistence template is structurally different: it is a Lyapunov-based argument requiring only (T1) zero-correction-at-zero-state, (T2) local sector condition (correction points inward), and (T3) bounded disturbance — all of which are checked locally for each instantiation (A Props A.1, A.1S, A.2). The template applies to bounded and to mean-square-stochastic disturbance, gives explicit ultimate-bound and adaptive-reserve formulas, and does not depend on NESS structure or on a free-energy gradient.

The breadth difference is not rhetorical: where the FEP-flow argument’s parameter regime is debated in the AI literature itself, the sector-Lyapunov apparatus is the standard machinery of nonlinear control theory (Khalil 2002, *Nonlinear Systems*, 3rd ed., Prentice Hall, ch. 4) and applies wherever (T1)–(T3) hold. This is one of AAT’s stronger structural positions and is worth making explicit when comparing AAT to active inference: AAT does the persistence work AI tries to do, with broader validity and explicit ultimate-bound formulas.

Epistemic Status.

Exact. The template is the abstract form of the Lyapunov result proved in A (Props A.1, A.1S, A.2). The proofs transfer without modification whenever (T1)–(T3) hold; the template’s contribution is the recognition that AAT’s persistence-flavored results are instances of a single pattern and the enumeration of what each instantiation must verify.

On (T2) and A2' sub-scoping. (T2) is the local sector condition A2' transcribed to a generic state variable ξ . Within the state-variable spaces relevant to AAT's instantiations (epistemic mismatch δ , strategic mismatch δ_Σ , sub-agent mismatch δ_i , composite trajectory error e_m , composite mismatch δ_c , target-agent mismatch δ_B), the update rules are overwhelmingly sub-scope α in the 4.2 / 4.3 sense — Bayesian, exponential-family, strongly-convex-gradient, or linear-PD. For these, (T2) is *derived* from the update-rule structure under B1 directional fidelity. **Important, and easy to miss: this is not what carries forward universally.** For sub-scope β instantiations (e.g. a team with a rule-based sub-agent) (T2) is an *empirical precondition, verified per-instantiation*, not derived. That distinction scopes which instantiations satisfy (T2) by which route; it does not touch the template's exactness, which is the conditional “(T1)–(T3) $\Rightarrow$ persistence” — anything satisfying (T2) by either route inherits the exact result.

On Prop A.1S region-awareness. The Model S case uses the region-aware form of Prop A.1S (stopped second-moment bound + the fixed-time tail $P(\|\xi(t)\| > R) \leq \text{const}$ under the mean-square persistence condition). Instantiations that rely on the Model S result automatically inherit the stopping-time localization — no extra work is required at the template level. As at A, Model S provides a distributional / fixed-time guarantee, not pathwise-forever containment (which is a Model-D-only guarantee); template instantiations inherit that kind-of-guarantee distinction, not an infinite-horizon non-exit bound.

Max attainable: *exact*. The result is as strong as Lyapunov stability theory. Additional work could extend the template (state-dependent noise, time-varying α , non-quadratic Lyapunov functions) but would not strengthen it within its stated scope.

What the template does not establish:

- *Quantitative convergence rates.* Lyapunov gives stability and ultimate bounds, not convergence speed. Specific rates require instantiation-level analysis.
- *Behavior outside the sector-condition region.* (T2) holds only for $\|\xi\| \leq R$. Beyond R , correction may break down — the structural-adaptation regime of 4.8.
- *Time-varying parameters.* The template assumes constant α and R . Time-varying cases require additional machinery. 9.10 documents the most important AAT example: $\alpha_\Sigma = 1/(n + 1)$ decays with experience, so strategic persistence requires experience discounting at rate $(1 - \lambda) > \rho_\Sigma/R_\Sigma$ to recover constant- α .
- *Heavy-tailed disturbances.* Neither (T3-D) nor (T3-S) covers disturbances with unbounded moments. Extreme tail events are better handled as triggers for structural adaptation than as disturbances the template can absorb.

Discussion.

Why factor this out. Every persistence-flavored result in AAT takes the form “correction rate exceeds effective disturbance rate (relative to reserve)” and is proved by the same Lyapunov function $V(\xi) = \frac{1}{2}\|\xi\|^2$. Stating the argument once, parameter-free, makes visible that the theory is *one result about bounded-correction dynamics applied to several state spaces*, not six separately-proved results that happen to look alike.

Each instantiation's distinctive content is now sharply visible: *what is the state variable, and what counts as its effective disturbance?* The Lyapunov machinery is shared; the characterization of ρ_ξ is where the domain-specific insight lives. Adversarial destabilization's content is the coupling term $\gamma_A \mathcal{T}_A$; team persistence's content is the cooperative-minus-adversarial decomposition; composition closure's content is the closure-defect rate $\varepsilon^* \nu_c$. In each case, the template absorbs the Lyapunov boilerplate and lets the distinctive claim stand without it.

This template is the *interior facet* of the stability certificate (5): the “correction rate exceeds effective disturbance rate” condition is the certificate being positive-definite on the scope ball, and the existence of such a certificate is equivalent to exponential stability (H). The shared Lyapunov function $V(\xi) = \frac{1}{2}\|\xi\|^2$ is the certificate in the Euclidean metric; AI carries the non-Euclidean-metric interior.

The template is the typed-bridge shared upstream — two-model, not one operator. This template is the canonical anchor of the *accumulation typing* convention (NOTATION.md §"Accumulation typing"): the bridge from a per-step residue to its accumulated consequence *is* this conditional. The bridge is **two-model, not a single bounded operator** — (T3)'s Model D and Model S are co-equal, and the $1/\alpha$ vs $1/\sqrt{\alpha}$ scaling (line above) plus the Cor-A.1S.1 categorical containment dichotomy (A) are the structural fingerprint that they are *different functionals*, not one functional read in two norms (a change of α -homogeneity *degree* cannot come from a norm choice on a fixed operator). The across-turnover axis is the worked demonstration that the split is structural, with two operator families at *opposite ends of the same singular contraction parameter*, **neither superseding the other**: the $\mathcal{A}_{\text{ref}}$ family — a reflected (Lindley/Loynes) walk whose load-bearing content is its driftless $\mu = 0$ boundary — *instantiates* the template on the turnover index (#der-identity-continuity-threshold, the new row above); the $\mathcal{A}_D$ family — the linear destroy-and-reconstruct contraction whose affine norm *diverges* exactly as the contraction gap closes — is the **honest scope boundary where the template provably does not transfer** (#der-turnover-information-recursion: an unforced multiplicative information decay has no correction function pointing a perturbed state inward, so (T1)–(T3) have no counterpart; the non-transfer is a definite result, not a caveat). The $\mu = 0$ boundary of the $\mathcal{A}_{\text{ref}}$ instantiation *is* the singularity of the $\mathcal{A}_D$ regime — you cannot linearize across that pole, which is why the two are distinct operators and the accumulation-type confound (treating one as a normalization or linearization of the other) is a category error. The typing convention exists precisely so this — *which model, which operator family* — is carried in the notation rather than silently reconstructed.

What each instantiation must still verify. Invoking the template is not trivial. Each instantiation must establish (T1)–(T3) for its specific (ξ, F, ρ_ξ, R) , and the non-trivial verifications differ substantively:

- *Strategic persistence* (9.10): (T2) is verified for Beta-Bernoulli edge updates across five DAG topologies (R Props B.1–B.6). But $\alpha_\Sigma = 1/(n + 1)$ is time-varying: it decays monotonically with experience. Constant- α — and therefore the template's trajectory guarantee — requires experience discounting as a prerequisite, not a heuristic.
- *Composition closure* (13.1): (T2) as stated is insufficient. The bridge lemma requires the *incremental sector bound* (DA2'-inc) — strongly monotone F across the whole state space, strictly stronger than the one-point sector bound (T2). Three agent tiers result: Tier 1 where contraction is proved for the full class (Bayesian on exponential families, gradient descent on strongly convex losses, linear correctors with positive-definite gain), Tier 2 where it holds locally, Tier 3 where it must be verified per-domain.
- *Team persistence* (15.1): (T3) is the decomposition $\rho_i^{\text{eff}} = \rho_{i,\text{env}} + \sum_j \gamma_j^{\text{adv}} \mathcal{T}_j - \sum_j \gamma_j^{\text{coop}} \mathcal{T}_j$. Cooperative coupling enters through a negative term, which can drive ρ_i^{eff} below the single-agent ρ — this is formally how teams persist where individuals cannot.

Persistence and destabilization as one result. Adversarial destabilization (15.2) is the template applied with coupling-amplified disturbance: $\rho_B = \rho_{B,\text{base}} + \gamma_A \mathcal{T}_A$. The "destabilization threshold" — the condition under which agent A pushes agent B past its stability boundary — is precisely the *negation* of the template's persistence condition for B 's instantiation. B 's persistence certificate holds iff $\alpha_B R_B > \rho_B$; the certificate is lost — destabilization, with escape forced when B 's sector bound is radially tight — iff $\rho_B \geq \alpha_B R_B$. These are the same inequality viewed in opposite directions, not independent results; both directions are certificate-level statements, and the agent-level only-if requires tightness (A Lemma A.1N). The superlinear adversarial scaling ($b = 2$ under Model D, $b = 3/2$ under Model S) follows from the template's $1/\alpha$ vs $1/\sqrt{\alpha}$ scaling without further derivation.

Signed-coupling pattern across instantiations. The six instantiations above — plus J, which derives a closed-form composite (T2) for the matched-symmetric-Tier-1 dyad — share a signed-coupling structure: each effective ρ_ξ is a sum of environmental disturbance plus a cross-agent contribution whose sign encodes cooperative vs adversarial coupling. Team persistence, composition closure (via bridge-lemma), tempo composition, adversarial destabilization, and composite critical-mass are instances of one inequality at different state-variable levels. The template is where this pattern lives at the meta level; the per-segment instantiations supply the domain-specific (ξ, F, ρ_ξ, R) quadruples.

Cost complement: the template's information-rate floor. Alongside the threshold condition, each instantiation inherits an information-rate lower bound from I: under Model S with Gaussian-OU-shaped disturbance statistics on ξ , the sustained information rate required to maintain $\mathbb{E}[\|\xi\|^2]_{ss}$ at the ultimate bound satisfies $\dot{R} \geq n\alpha/2$ nats/time with the instantiation's own $(\alpha, n, \sigma_\xi^2)$. For the epistemic-mismatch instance, this translates to the channel-capacity floor $C \geq \mathcal{T}/2$ — a first-class persistence prerequisite that the threshold condition alone does not surface. Each instantiation can derive its own cost bound by direct substitution into the main theorem of I; the consolidation of this into a parametric template-cost subsection is flagged in that segment's Working Notes.

The coordination overhead C_{coord} is effective disturbance at the composite level. The tempo-composition inequality $\mathcal{T}_c \leq \sum_i \mathcal{T}_i$ has a lower bound on the gap: $C_{\text{coord}} \geq \varepsilon^* \nu_c$ (13.2). This is the template's instantiation with $\xi = \delta_c$ and effective disturbance $\rho_{\text{ext}} + \varepsilon^* \nu_c$ — the composite's internal closure error acts as an additional disturbance at the macro level, absorbing correction capacity that would otherwise address the external environment. Brooks's Law follows as an instance: adding agents increases $\sum_i \mathcal{T}_i$ but may increase $\varepsilon^* \nu_c$ faster, pushing ρ_c^{eff} above $\alpha_c R_c$.

Relationship to 4.5. 4.5 is the canonical single-agent instantiation. It carries additional content beyond the template — *task adequacy*, a domain-specific constraint $R^* < \|\delta_{\text{critical}}\|$ that further restricts the usable region — and it instantiates the template in the linear special case where $F = \mathcal{T}\delta$, $\alpha = \mathcal{T}$, and (T2) holds globally. Task adequacy is not part of the template because it is not part of the Lyapunov argument; it is an application-level constraint the agent's domain imposes.

Relationship to 11. The composition-consistency postulate requires that AAT's predictions be compatible across levels of description. The template is how this compatibility cashes out operationally: the same persistence argument applies at every level where a state variable with a sector-bounded correction function is present. Part III segments that invoke the template (team persistence, composition closure, tempo composition) are applying AAT's single persistence argument at the composite level, with effective disturbance decompositions that capture what is distinctive about the composite scope.

Relationship to AI (metric-formulation generalization). The Euclidean sector inequality (T2) is the $M = I$ specialization of a broader contraction-metric condition (CT2) under a Riemannian metric M (Lohmiller & Slotine 1998). For several AAT-relevant agent classes, the natural Lyapunov lives in a non-Euclidean metric — Fisher for statistical-manifold learning (matrix Kalman in information metric; exponential family in natural parameters), Hessian-induced for ill-conditioned strongly-convex optimization, Lyapunov-equation-determined for asymmetric-stable linear systems, or Lyapunov-metric for PID-with-bounded-plant-nonlinearity. AI states the generalization once with (CT1)–(CT3) preconditions matching (T1)–(T3), adds compositional theorems (parallel / cascade / negative-feedback with small-gain) that extend #deriv-critical-mass-composition (CM2) to heterogeneous sub-agents via (CM2-M), and fills #disc-separability-pattern's seventh ladder (A2'-scope into metric- α_1 / metric- α_2 / metric- β). The Euclidean formulation stated in this segment remains the default for Euclidean-natural instances; AI is invoked when the natural coordinate is non-Euclidean. Structural consequence worth noting: the (CT2) condition at $M = I$ is equivalent to #form-composition-closure's DA2'-inc (incremental sector bound), so AAT has been carrying the Jacobian-level Euclidean contraction condition at the composite level all along; AI makes this explicit at the single-agent level.

Working Notes.

- The template is type result because it states a result abstractly; the proof lives in A (the canonical instance for δ), and the transfer to other state variables is routine once (T1)–(T3) are verified. Treating it as a formulation would misrepresent its status — the Lyapunov argument does not leave room for alternative formulations within its stated scope.
- Candidate extensions that would strengthen the template: (i) time-varying $\alpha(t)$ with lower bound, for the strategic case; (ii) state-dependent noise intensity, for cases where the disturbance magnitude depends on the current mismatch; (iii) non-quadratic Lyapunov functions, for richer stability regions. Each is a real extension of Lyapunov theory, not specific to AAT.

- The template’s role in 11’s “applies at every level” claim is now explicit: the claim holds at every level where (T1)–(T3) can be verified for the level’s state variable. This sharpens the composition-consistency commitment from “applies at every level” to “applies at every level the template applies to,” which is a testable condition rather than a universal assertion.
- **Dynamic-regime placement (added 2026-05-21 per Phase 5 cross-segment ripple).** The template’s (T1)–(T3) preconditions hold cleanly on **R0 contraction-regime** composites per #disc-dynamic-regime-axis; the sector constant α and basin radius R live at the single-attractor structure that R0 supplies. The template lifts to **R1 equilibrium-regime** composites via the A2’-analog transfer in #deriv-strategic-composition (sub-scope α'): the state variable becomes $\xi = \pi - \pi_*$ (deviation from Nash) and α_{joint} lives at the joint potential’s curvature (potential games, Monderer-Shapley 1996) or the joint Jacobian’s symmetric part (monotone games, Rosen 1965) — see #disc-dynamic-regime-axis §”Lyapunov-machinery transfer R0 $\rightarrow$ R1” for the explicit form. **R2 cyclic-distributional-regime** composites (sub-scope β') do *not* admit the sector-template — the state-space Lyapunov form fails; CCE convergence at $O(1/\sqrt{T})$ via Hart-Mas-Colell 2000 is the replacement machinery. Any cite of this template’s (T1)–(T3) preconditions should name the regime tier the cited claim sits at.

Incidental audit gold (lift 2026-05-31). Orthogonal pedagogical / generative material from the de-novo auditors’ working dirs (per de-novo-audit-instructions.md §7.15), deduplicated and lightly attributed. Substrates consistently called this segment the framework’s “central nervous system” / “architectural spine” — the meta-theorem the whole core hangs on. Certified-track item off-ramped at the end.

1. Candidate Briefprose / pre-prose.

- **The one-inequality unification.** “It unifies learning, teamwork, strategy, and adversarial deception under a single inequality: $\alpha R > \rho_\xi$. If your efficiency $\times$ capacity exceeds your effective disturbance, you persist.” A compact, accurate statement of what the template buys (Gemini, AUDIT-WORKING-849201 and AUDIT-WORKING-193847).
- **“Survival checklist” framing.** The template reads as a universal checklist: for *any* adaptive system, define its state variable, verify it corrects toward zero (T1), verify the correction is sector-bounded (T2), bound its disturbance (T3) — and the math then guarantees survival (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **“Combat is not special math — it is just $w(t)$.”** Adversarial destabilization is the *negation* of the persistence template: an attacker is simply another agent acting as the disturbance term in your survival equation. There is no separate “combat module” — surviving a harsh winter and surviving a targeted attack are mathematically identical operations, both requiring $\alpha R > \rho$. The corollary: “defense” is not separate from “learning”; the same correction function F that learns physics is the one that evades a predator. *Epistemic integrity is armor* (Gemini, AUDIT-WORKING-193847). A striking framing for the segment’s role as the common root of cooperative/adversarial dynamics.
- **The Active-Inference contrast, sharpened.** The “external mathematical lineage” subsection’s contrast with Friston’s active inference is read as devastatingly clean: AI relies on fragile non-equilibrium-steady-state density assumptions, whereas AAT relies on robust standard nonlinear control theory (Bauschke-Combettes monotone-operator grounding). Candidate to surface more prominently as a positioning point (Gemini, AUDIT-WORKING-849201).

3. Follow-up items.

- **“Fallacy of the empty instantiation.”** A standing watch-item the template itself names: a system *being writable* as $\xi = -F(\xi) + w$ does not mean it satisfies (T1)–(T3); invoking the template requires *proving* the preconditions for the specific domain. Multiple auditors flagged this as the place strategic/compositional proofs are most likely to cut a corner (e.g., forgetting the experience-discounting that keeps Beta-Bernoulli’s α constant) (Gemini, AUDIT-WORKING-849201 and AUDIT-WORKING-193847).

4. Readers often ask / wonder.

- **What if R is time-varying, not just α ?** The notes treat decaying $\alpha(t)$ (experience discounting) but a reader will ask the dual: if an agent’s structural capacity R shrinks (fatigue, memory exhaustion), the Lyapunov bounds shrink dynamically — how does an agent survive a *collapsing* R ? (Gemini, AUDIT-WORKING-193847.)

Off-ramp (NOT gold) — certified-track item, routed for adjudication.

- **Template insufficient for the two-point compositional proofs (structural).** 193847: the base template states only the one-point sector (T2), but #form-composition-closure's bridge lemma and #der-tempo-composition require the strictly stronger incremental sector bound (DA2'-inc, full two-point strong monotonicity — already noted in the instance table's #form-composition-closure row). Claiming composition closure “instantiates” the base (T1)–(T3) template is then imprecise — the compositional segments need a strictly stronger precondition. Proposed repair: define an explicit “Template-Strong” variant adding (DA2'-inc), and state that single-agent segments instantiate the base template while compositional segments instantiate Template-Strong. (Cross-ref the same off-ramp on deriv-sector-condition; check whether the dynamic-regime tiers above already cover this.)
-

Appendix H

Result: Certificate Existence — Operator-Sector in Some Metric Is Exponential Stability

The framework’s central anchoring identity: **a stability certificate exists for an agent exactly when the agent is exponentially stable about its target**, at the linearized level. The organizing slogan — *an adaptive system is an operator whose contraction rate exceeds its target’s drift rate* — is *not a heuristic* but this equivalence (the standard Lyapunov theorem), with the certificate $\mathcal{M}$ as its witness.

A **stability certificate** is a symmetric positive-definite metric $\mathcal{M}$ for which AAT’s one-point sector condition holds in the $\mathcal{M}$ -inner-product on a ball around the equilibrium. At the linearized level, the existence of such a certificate is *equivalent* to the system matrix being Hurwitz (exponentially stable) by the Lyapunov equation — three clauses, all the same statement: $A = -J$ Hurwitz; some $(\mathcal{M}, \kappa)$ with $\mathcal{M}J + J^T\mathcal{M} \geq 2\kappa\mathcal{M}$; for every $Q > 0$ a unique $\mathcal{M}$ solving $A^T\mathcal{M} + \mathcal{M}A = -Q$. The certificate is *not unique*: it is whatever positive-definite metric makes the dynamics contract. The result holds at the linearized level (with a standard second-order remainder condition for the local nonlinear extension); the global statement requires the incremental rung R1 (cocoercive class) — a genuine scope statement, named here so the parenthetical “linearized/local” is not buried.

The result *specializes* in different sub-cases of the framework to four familiar metrics: Fisher information for Bayesian agents (Čencov-forced under R2); inverse-prior-covariance for Kalman agents; loss Hessian for gradient agents; plant-selected Lyapunov metric for linear-Hurwitz or PID agents. *These are not four separate stories — they are one object under four certificates*. The unification is structural: the same Lyapunov equivalence underlies all four, with the specialization determined by the agent class. The framework treats this segment as the **spine** of three meta-patterns: separability (#disc-separability-pattern — *scope-of-existence* of a certificate), additive coordinate forcing (#disc-additive-coordinate-forcing — when the certificate is *forced* to a unique form), and identifiability floors (#disc-identifiability-floor — where the certificate’s *boundary* lives via the Sylvester mechanism). Naming $\mathcal{M}$ as the object — rather than $V(e) = e^T\mathcal{M}e$, the Lyapunov function — is what makes those downstream statements expressible.

Formal Expression.

The object.

For an agent with error dynamics $\dot{e} = -F(e)$ about an equilibrium e^* ($F(e^*) = 0$, $F \in C^1$ near e^* , Jacobian $J := DF(e^*)$), a **stability certificate** is a symmetric positive-definite $\mathcal{M}$ for which the one-point sector condition holds in the $\mathcal{M}$ -inner-product on a ball $\mathcal{B}_R(e^*)$:

Definition (stability-certificate).

$$\langle F(e), e - e^* \rangle_{\mathcal{M}} \geq \kappa \|e - e^*\|_{\mathcal{M}}^2, \quad \kappa > 0. \quad (\text{C})$$

The certificate is not unique: it is whatever positive-definite form makes the dynamics contract. In the recurring sub-cases it specializes — to the Fisher information for Bayesian agents, to $(P^-)^{-1}$ for Kalman agents, to the loss Hessian for gradient agents, and to a plant-selected Lyapunov metric for linear-Hurwitz or PID agents. These are not four separate stories; they are one object under four certificates.

The equivalence.

At the linearized level (C) reads $\mathcal{M}J + J^\top \mathcal{M} \geq 2\kappa \mathcal{M} > 0$, a strict Lyapunov inequality for the system matrix $A = -J$. The following are equivalent:

Result (certificate-existence), exact at the linearized level.

1. $A = -J$ is Hurwitz — the linearized error dynamics $\dot{e} = -Je$ is exponentially stable;
2. there exist $\mathcal{M} > 0$ and $\kappa > 0$ with $\mathcal{M}J + J^\top \mathcal{M} \geq 2\kappa \mathcal{M}$ — a one-point sector condition (a stability certificate) in *some* inner product;
3. for every $Q > 0$ there exists a unique $\mathcal{M} > 0$ with $\mathcal{M}J + J^\top \mathcal{M} = Q$.

So “operator-sector in *some* inner product” and “the equilibrium is exponentially stable” are **the same statement**, with the certificate $\mathcal{M}$ as the converse-Lyapunov witness — an equivalence, not an analogy.

The certificate-strength ladder.

The certificate admits four strictly-ordered strengths, all on the one object:

Derived (ordering of conditions; exact).

Table H.1

<i>Rung</i>	<i>Condition</i>	<i>Equivalent to</i>	<i>Certificate is</i>
R0-loss	some $\mathcal{M} > 0$, $\mathcal{M}J + J^\top \mathcal{M} \geq 0$, sup $\kappa = 0$	$A = -J$ has only nonpositive-real-part eigenvalues, at least one on the imaginary axis (semisimple)	conserved on the chain-recurrent subspace + strict-Lyapunov on its strongly-gradient-like complement
R0-strict	one-point (C), some $\mathcal{M}$ with $\kappa > 0$, local	$A = -J$ Hurwitz + remainder dominated	converse-Lyapunov $\mathcal{M}$ (exists; generally not forced)
R1	incremental (two-point) $\mathcal{M}$ -strong-monotonicity on $\mathcal{B}_R$	global $\mathcal{M}$ -strong-monotone (cocoercive class)	curvature-like $\mathcal{M}$ (potential sub-case)
R2	R1 with $\mathcal{M}$ forced by a uniqueness theorem on an AAT-internal axiom	natural-gradient in the Čencov-unique Fisher metric	Fisher metric (Čencov-forced)

$R0\text{-loss} \Leftarrow R0\text{-strict} \Leftarrow R1 \Leftarrow R2$ strictly. $R0\text{-loss}$ is the *widest* rung — a certificate exists but $\sup \kappa = 0$: the dynamics is Lyapunov-stable, not asymptotically stable, with $V(e) = e^\top \mathcal{M} e$ conserved on an imaginary-axis-eigenvector subspace and strict contraction on its strongly-gradient-like complement (Conley’s universal decomposition; pure-case Helmholtz S/A characterization derived below). $R0\text{-strict}$ is the contraction rung with $\kappa > 0$ strict, reaching the plant-Lyapunov cases (linear-Hurwitz-non-symmetric, PID) where no potential exists. $R1$ is the cocoercive/proximal class where a variational structure is available; $R2$ is the uniqueness-theorem-forced statistical case. The widest rung is not a weakness: it is exactly the reach the narrower rungs cannot give. ($R0\text{-loss}$ ’s pure-case characterization and Conley anchoring are in the Derivation below; $R2$ ’s forcing is established in 5.5; $R1$ ’s cocoercive class in AI.)

Derivation.

(1 $\Rightarrow$ 3, 2). $A = -J$ Hurwitz. By the Lyapunov theorem (Lyapunov 1892; Khalil, *Nonlinear Systems* 3rd ed., Thm 4.6), for every $Q > 0$ the equation $A^\top \mathcal{M} + \mathcal{M} A = -Q$ has a unique solution $\mathcal{M} > 0$. Substituting $A = -J$ gives $\mathcal{M} J + J^\top \mathcal{M} = Q > 0$ (clause 3). For the rate: $Q \geq \lambda_{\min}(Q) I \geq \frac{\lambda_{\min}(Q)}{\lambda_{\max}(\mathcal{M})} \mathcal{M}$, so (C) holds at the linear level with $\kappa = \frac{\lambda_{\min}(Q)}{2 \lambda_{\max}(\mathcal{M})} > 0$ (clause 2).

(2 $\Rightarrow$ 1). Suppose $\mathcal{M} > 0, \kappa > 0, \mathcal{M} J + J^\top \mathcal{M} \geq 2\kappa \mathcal{M}$. Take $V(e) = e^\top \mathcal{M} e$ (valid Lyapunov candidate, $\mathcal{M} > 0$). Along $\dot{e} = -Je$: $\dot{V} = -e^\top (\mathcal{M} J + J^\top \mathcal{M}) e \leq -2\kappa e^\top \mathcal{M} e = -2\kappa V < 0$ for $e \neq 0$. Hence $\|e(t)\|_{\mathcal{M}} \leq e^{-\kappa t} \|e(0)\|_{\mathcal{M}}$ and $A = -J$ is Hurwitz.

(3 $\Leftrightarrow$ 2) is the rate-extraction argument (3 gives 2 with the displayed κ ; 2 is the special case $Q = \mathcal{M} J + J^\top \mathcal{M}$).

Local nonlinear extension. With $F(e) = Je + r(e)$, $\|r(e)\| = o(\|e\|)$, (C) holds on $\mathcal{B}_R(e^*)$ iff the linearization is exponentially stable *and* the second-order remainder is dominated on the ball ($\|r(e)\|_{\mathcal{M}} \leq c\|e\|_{\mathcal{M}}^2$ with $cR < \kappa$). This is the standard Lyapunov indirect method (Khalil Thm 4.7); the remainder-domination radius is exactly the contraction-template Tier-2 degradation radius (AI), not new machinery.

R0-loss: certificate without contraction.

When $A = -J$ is non-Hurwitz but admits *some* $\mathcal{M} > 0$ with $\mathcal{M} J + J^\top \mathcal{M} \geq 0$ at $\sup \kappa = 0$, the Lyapunov inequality holds non-strictly and the dynamics is Lyapunov-stable but not asymptotically stable. The complete spectral classification of A partitions the linear-system space into four cases:

Derived (R0-loss-distinctness; exact at the linearized level for the pure case, exact-via-Conley for the mixed case).

- (i) **A Hurwitz** — $R0\text{-strict}$ (above).
- (ii) **A has an eigenvalue with $\operatorname{Re} \lambda > 0$** — no certificate exists: a $\mathcal{M} > 0$ satisfying $\mathcal{M} J + J^\top \mathcal{M} \geq 0$ would force $\dot{V} \leq 0$ along all trajectories, contradicting the unstable mode. *Outside the ladder.*
- (iii) **A has all eigenvalues with $\operatorname{Re} \lambda \leq 0$, at least one on the imaginary axis, imaginary-axis eigenvalues semisimple** — $R0\text{-loss}$. A certificate $\mathcal{M} > 0$ exists; trajectories along the imaginary-axis-eigenvector subspace orbit perpetually (conserving $V = e^\top \mathcal{M} e$ on each level set), and trajectories on the strict-stable complement decay exponentially toward that subspace.
- (iv) **defective Jordan block at an imaginary eigenvalue** — no certificate exists: polynomial growth on the generalized eigenvector ($e \sim t \cdot v$) violates $\dot{V} \leq 0$ for any quadratic V . *Outside the ladder.*

$R0\text{-loss}$ occupies the strict slice (iii), disjoint from $R0\text{-strict}$ (i) and from the no-certificate regimes (ii), (iv). The four-case partition is exhaustive (every real matrix sits in exactly one) and mutually exclusive. $R0\text{-loss}$ is *not* “ $R0\text{-strict}$ with κ tending to zero” — $R0\text{-strict}$ ’s $\kappa > 0$ is strict by definition; the limit $\kappa \rightarrow 0^+$ does not land in $R0\text{-loss}$ but on its closure boundary. $R0\text{-loss}$ is also distinct from the identifiability-floor boundary of $\mathbb{S}_{\geq 0}^n$ (5.1’s Sylvester mechanism): the floor

has $\mathcal{M}$ dropping rank, while R0-loss has $\mathcal{M}$ remaining > 0 with the rank drop on the *Hermitian part* $\mathcal{M}J + J^\top \mathcal{M}$ instead.

Pure case — Helmholtz S/A as canonical sufficient route. Taking $\mathcal{M} = I$, $S := \frac{1}{2}(J + J^\top)$, $A_{\text{anti}} := \frac{1}{2}(J - J^\top)$. The conditions

(ii) $S \equiv 0$ (J is purely antisymmetric);

(iii) $V(e) = \frac{1}{2}\|e\|^2$ is exactly conserved along $\dot{e} = -Je$ for all initial e

are equivalent — (ii $\Rightarrow$ iii) by direct calculation $\dot{V} = -e^\top Se \equiv 0$ when $S = 0$, and (iii $\Rightarrow$ ii) by polarization for symmetric S . Either implies case (iii) of the spectral partition above: real antisymmetric J has purely-imaginary spectrum (its characteristic polynomial is even, forcing eigenvalues in $\pm i\omega$ pairs) and is diagonalizable over $\mathbb{C}$ (hence semisimple).

The converse — case (iii) implying antisymmetry at $\mathcal{M} = I$ — does not hold. A non-antisymmetric J can sit in case (iii) too: $J = \begin{pmatrix} 1 & -2 \\ 2 & -1 \end{pmatrix}$ has $S = \text{diag}(1, -1)$ at $\mathcal{M} = I$ (so $\mathcal{M}J + J^\top \mathcal{M} = 2S$ is indefinite, failing the certificate condition there) but eigenvalues $\pm i\sqrt{3}$ (pure imaginary, semisimple). For such a J the R0-loss certificate exists by the spectral partition but requires $\mathcal{M} \neq I$; finding the explicit metric (via similarity to real Jordan form, or the center-manifold construction below) is what the partition guarantees but does not provide constructively. **The full characterization of R0-loss is the four-case spectral partition above; the Helmholtz S/A route at $\mathcal{M} = I$ is the canonical sufficient construction for the antisymmetric sub-class — the structural framing for the Letcher 2019 Hamiltonian-game vocabulary — not a necessary condition for R0-loss generally.** Bendixson's localization $\text{Re}(\lambda(-J)) \in [-\lambda_{\max}(S), -\lambda_{\min}(S)]$ gives a *containment* interval that here is $[-1, 1]$ — wide enough to permit purely-imaginary eigenvalues without forcing $S = 0$.

Letcher-Balduzzi et al. 2019 Lemma 1 (uniqueness of the $S + A$ decomposition) and Definition 2 (Hamiltonian game = $S \equiv 0$) name this sufficient route in game-mechanics vocabulary; AAT's content is the recognition that the antisymmetric sub-class is the cleanest specific construction, with the R0-loss regime itself broader. The general- $\mathcal{M}$ extension replaces S with $S_{\mathcal{M}} := \frac{1}{2}\mathcal{M}^{-1}(\mathcal{M}J + J^\top \mathcal{M})$; an $\mathcal{M}$ rendering $S_{\mathcal{M}} \geq 0$ exists for every case-(iii) J by the partition.

Mixed case — Conley anchoring. At a chosen certificate $\mathcal{M}$ rendering $S_{\mathcal{M}} \geq 0$ with nontrivial kernel — some imaginary-axis eigenvalues plus some strict-stable ones — the dynamics splits canonically: along $\ker(S_{\mathcal{M}})$, V is conserved (the chain-recurrent component); along $S_{\mathcal{M}}$'s positive-eigenspace, V decays strictly (the strongly-gradient-like component). This is Conley 1978's universal decomposition (Fundamental Theorem of Dynamical Systems, §8.1): every flow on a compact invariant set decomposes uniquely into a chain-recurrent subflow plus a strongly-gradient-like quotient. AAT's R0-loss localizes this universality at the linearization. On the chain-recurrent component (the restricted operator is $\mathcal{M}$ -antisymmetric on $\ker(S_{\mathcal{M}})$ and hence trace-free in the $\mathcal{M}$ -orthonormal basis), V restricted to each level set $\{V = c\}$ is volume-preserving by Liouville, hence chain-recurrent in Conley's sense (Poincaré recurrence). The explicit construction of $\mathcal{M}$ in the mixed case follows from center-manifold machinery (Carr 1981 §2); the qualitative shape — chain-recurrent subspace + strongly-gradient-like complement — is universal, while the explicit metric is standard but not derived here.

Epistemic Status.

Exact at the linearized level (the equivalence is the standard Lyapunov theorem, recognized and applied — not a fresh derivation), and *exact with the standard second-order remainder condition* locally. The constituent theorem is classical; what is contributed here is the recognition that AAT's one-point sector condition (A2'/(T2)) in a free choice of inner product is *exactly* the converse-Lyapunov certificate, which makes the framework's organizing slogan a theorem rather than a heuristic.

Scope honesty. Linearized/local — this is the level at which AAT's persistence results already operate (sector conditions, contraction templates, the bridge lemma all linearize about the equilibrium), so it is not a weakening relative to

the rest of the theory, but it is a genuine scope statement and is not papered over: there is **no** claim that one-point operator-sector is equivalent to *global* exponential stability (it is not, in general — the global statement requires the incremental rung R1, the cocoercive class). The disturbance-to-ultimate-bound step that turns “contracts” into “stays within a bounded ball under disturbance” is proved separately in A and G; this result supplies the contraction half of the slogan, those supply the exceeds-the-drift half.

R0-loss scope. The R0-loss rung’s pure case (Helmholtz $S \equiv 0$ characterization; all eigenvalues on the imaginary axis, semisimple) is *exact* at the linearized level — the equivalence $S \equiv 0 \Leftrightarrow$ full-state marginal stability at $\kappa = 0$ follows from polarization plus Bendixson’s localization. The mixed case (chain-recurrent subspace + strongly-gradient-like complement) is *exact-via-Conley* — Conley 1978 §8.1’s universal decomposition supplies the qualitative shape; the explicit $\mathcal{M}$ construction in mixed cases is center-manifold-level work (Carr 1981 §2) sketched above rather than derived. The non-Hurwitz scope question — whether nonlinear systems with Case-(iii) linearization are actually Lyapunov-stable rather than displaying quartic-or-higher instabilities on the center manifold — is the standard nonlinear-stability open problem (Khalil §4.3), not within the linearized claim made here.

Max attainable: *exact* (it is the Lyapunov theorem, in scope; R0-loss extends via Letcher 2019 / Conley 1978, recognized and applied — not fresh derivations). Novelty posture is *recognition*, not new mathematics.

Discussion.

This is the segment-level home of the contraction-over-drift organizing principle. The slogan *an adaptive system is an operator whose contraction rate exceeds its target’s drift rate* had, until now, no segment to point to — it was carried as a framing heuristic. The equivalence above is its formal content: the “contraction” half is clause 2 $\Leftrightarrow$ clause 1 (a certificate exists iff the dynamics is exponentially stable); the “exceeds the drift” half is the ultimate-bound argument of G, which takes the certificate’s κ and the disturbance rate and returns the bounded-error guarantee. A reader can now cite the principle to a result, not to a slogan.

Why the equivalence matters beyond tidiness. It is what licenses the cross-sectional reading in 5: because “a certificate exists” is the same statement as “the agent can keep up,” every structural question about AAT’s reach becomes a question about this one object — does a certificate exist here (scope), is it forced to a unique form (forced identity), where does it degenerate (the boundary), does it survive coarse-graining (composition). Without the equivalence those would be four loosely-related observations; with it they are four questions about one mathematical object.

The certificate is not the Lyapunov function. $V(e) = e^\top \mathcal{M} e$ is the Lyapunov function; $\mathcal{M}$ is the certificate. The distinction is load-bearing downstream: the framework’s representational freedom (choice of coordinate / metric) acts on $\mathcal{M}$, and what that freedom can and cannot do to $\mathcal{M}$ — change its conditioning but not its inertia — is the content of the boundary facet (5.1, the Sylvester mechanism). Naming $\mathcal{M}$ as the object, rather than V , is what makes that downstream statement expressible.

R0-loss as the linearization-fingerprint of saddle-Nash composite regimes. Pure R0-loss at the single-agent linearization level is the spectral fingerprint of #disc-dynamic-regime-axis’s **R2 cyclic-distributional-regime** at the joint Jacobian linearized about saddle-only Nash equilibria: the joint best-response field’s symmetric part vanishes there (no potential structure), and the antisymmetric part supplies the imaginary-axis spectrum. FTRL $\times$ graphical-constant-sum games with fully-mixed Nash (Cheung-Piliouras-Tao 2021 Theorem 19: lossless DGS + Poincaré recurrence on bounded level sets) is the worked composite instance. The R-letter overlap with the dynamic-regime axis is layer-honest, not collision: this segment’s R0-loss/R0-strict/R1/R2 lives at the single-agent linearized error space $\mathbb{R}^n$ (the agent’s own certificate over its own error coordinate); the dynamic-regime axis’s R0/R1/R2/R3 lives at the composite joint-strategy space $\mathcal{X}^c$ (the joint-dynamics fixed-point structure of a composite of sub-agents). Same letters, different objects, different layers — composing across layers is exactly what the bridge sentence above does, and is the structural content of the layering rather than a coincidence to be hidden.

Findings.

The Contraction-Over-Drift Principle, Grounded. Brief: Picture an agent trying to stay on a target that keeps drifting. Ask one question: is there a way of measuring “how far off am I” — a measuring-stick — such that *every* correction the agent makes provably shrinks that measure? This result says: such a measuring-stick exists exactly when the agent is, in the ordinary control-theory sense, exponentially stable. The two are not analogous, they are the *same fact* (the Lyapunov theorem) — which is why the long-standing slogan “an adaptive system is one whose contraction outpaces its target’s drift” is a theorem and not a vibe. A thoughtful non-specialist can carry the whole thing away from the picture: *the measuring-stick exists = the agent can keep up*; everything else AAT says about reach, blind spots, and composition is downstream questions about that one stick.

Impact: Discharges the long-standing “organizing slogan not yet surfaced at segment level” status by giving the contraction-over-drift principle an exact, citable home. Supplies the anchor that licenses the certificate-cone cross-sectional reading (5): the equivalence is what turns “four loosely-related structural observations” into “four questions about one object.” Cleanly separates the exact mathematical core (this result) from the discussion-grade organizing recognition (the spine), so each is housed at its true epistemic tier rather than the exact equivalence being buried as a derived-tag inside a discussion-grade segment. Names the certificate (not the Lyapunov function) as the object, which is the precondition for the boundary-facet’s Sylvester statement being expressible downstream.

Novelty Claim: *Claim recognition* that AAT’s one-point sector condition under a free choice of inner product is exactly the converse-Lyapunov certificate, making the framework’s contraction-over-drift organizing principle the Lyapunov-theorem equivalence rather than a heuristic. The theorem is classical (Lyapunov 1892); the contribution is the identification that the framework’s A2’/(T2) machinery *is* this object, and the consequent segment-level grounding of the organizing slogan.

Related Work: - Lyapunov, A. M. (1892), *The General Problem of the Stability of Motion* (Engl. transl. 1992, Taylor & Francis); Khalil, H. K. (2002), *Nonlinear Systems* 3rd ed., Thm 4.6 (Lyapunov equation), Thm 4.7 (indirect method) (found 2026-05-14) — *formal antecedent* — the equivalence and the local extension are this theorem applied; the contribution is the recognition, not the proof. - Conley, C. (1978), *Isolated Invariant Sets and the Morse Index*, CBMS Regional Conf. Ser. Math. 38, AMS — Fundamental Theorem of Dynamical Systems, §8.1 (found 2026-05-22) — *formal antecedent* — the universal decomposition of any flow on a compact invariant set into a chain-recurrent subflow plus a strongly-gradient-like quotient. R0-loss’s mixed case is this universality localized at the linearization. The constituent theorem is classical; the contribution is recognizing that the R0-strict / R0-loss distinction is exactly Conley’s two pieces of the universal decomposition. - Letcher, A., Balduzzi, D., Racanière, S., Martens, J., Foerster, J., Tuyls, K. & Graepel, T. (2019), “Differentiable Game Mechanics,” *JMLR* 20:1–40 (found 2026-05-22) — *formal antecedent* — Lemma 1 (uniqueness of the symmetric+antisymmetric decomposition $J = S + A$) and Definition 2 (Hamiltonian game = J purely antisymmetric) supply the pure-R0-loss characterization. Letcher’s “Hamiltonian game” is the *fully* R0-loss agent in AAT’s linearization vocabulary; “potential game” is the strict sub-case of R0-strict where $J = J^T$. - Cheung, Y. K., Piliouras, G. & Tao, Y. (2021), “Online Optimization in Games via Control Theory: Connecting Regret, Passivity and Poincaré Recurrence,” *arXiv:2106.04748* (found 2026-05-22) — *formal antecedent (worked composite instance)* — Theorem 19 (FTRL $\times$ graphical-constant-sum-with-fully-mixed-Nash is lossless DGS, with Poincaré recurrence on bounded level sets) provides the worked composite instance of R0-loss at the joint Jacobian’s saddle-only-Nash linearization. The qualitative bridge “finitely-lossless storage $\Rightarrow$ R0-loss linearization at any accumulation equilibrium” survives; the quantitative bridge (L as V) does not (different state spaces, different functional forms; see also 8.5 Discussion on the qualitative-only diagnostic). - A, G (adjacent) — supply the disturbance-to-ultimate-bound half of the slogan; this result supplies the contraction half.

Search Log: - 2026-05-14 (*targeted*): The equivalence is the textbook Lyapunov theorem; no search needed for the theorem itself. The search target was whether the *recognition* “AAT’s one-point sector condition in a free inner product = the converse-Lyapunov certificate, hence the contraction-over-drift slogan is this equivalence” appears articulated elsewhere as a framework-grounding move. Not found at this depth; expected to remain *recognition*-tier (the theorem

is universal; the framework-grounding identification is the contribution). - 2026-05-22 (*absorbed*): the constituent prior art for the R0-loss rung extension (Conley 1978; Letcher 2019; Cheung-Piliouras-Tao 2021) was verified in its own domain; no separate Pillar / Undermind search was conducted for the rung-extension itself — the rung is the AAT-internal recognition that these textbook results jointly classify a fourth ladder rung disjoint from R0-strict and from the Sylvester-floor regime.

Working Notes.

- **Provenance.** Split out of 5 2026-05-14 (it had been a *[Derived]*-tagged block) so the exact equivalence is housed at its true tier (status: exact) rather than inside a discussion-grade segment. Landed in the 2026-05-14 operator-family-unification cycle; see CHANGELOG 2026-05-14. The full proof and the R0-loss / R0-strict / R1 / R2 ladder are in the Derivation above; the originating spike is absorbed archaeology, not a live reference.
- **R0-loss landing (2026-05-22).** Extension landed via Track CR Phase 3 per spikes/spike-integration-reconciliation-2026-05-22/99-verdict.md §5 Phase 3 and spikes/spike-enrichment-cluster1-2026-05-21/02-r0-loss-derivation.md (the §1 cluster's derivation work). The prior R0 rung was renamed to R0-strict for naming-consistency with the Helmholtz *S*-positive vs *S*-zero split; R0-loss was added as the new widest rung; the Discussion gained a cross-layer bridge sentence locating R0-loss as the linearization-fingerprint of AF R2 cyclic-distributional composite regimes. The mid-case explicit $\mathcal{M}$ construction (center-manifold-level, Carr 1981 §2) is sketched in the Derivation but not derived in detail here — readers needing the explicit construction work through the center-manifold mechanics standard in nonlinear stability theory. Cross-canon rename sweep also touches 5 (ladder reference in the anchor) and AI (ladder summary in Discussion), plus the OUTLINE.md table entry.
- **Provisional slug.** result-certificate-existence. Subject-noun = “certificate existence” (the result establishes when a certificate exists). Route through the naming pipeline if a better name surfaces.
- **Organizing-principle linkage.** This segment is the intended segment-level home for the PROPOSALS Bundle-1 organizing-principle slogan (“contraction-over-drift”); the PROPOSALS entry should point here once Joseph confirms the propagation step. Bundle-1 not auto-rewritten.

Incidental audit gold (lift 2026-05-31). Swept in the gold-lift pass (per de-novo-audit-instructions.md §7.15): **no incidental pedagogical/framing gold found.** This segment was split out 2026-05-14, so it is newer than most de-novo audit cycles and has no dedicated per-segment reflection. The auditor mentions that touched it are orientation-level only — AUDIT-WORKING-526815's predictions named the stability-certificate spine as the framework's top-level organizing picture (“when does a metric/certificate exist, when is it forced, where does it go blind, what does projection/composition do to its guarantee”) and flagged this segment for “watch local-to-global” caution; that framing is already carried by the certificate spine #disc-stability-certificate, not new content here. Marker left so future sweeps know this segment was checked.

Appendix I

Derivation: Persistence Cost — Information Rate to Maintain Bounded Mismatch

AAT's persistence machinery establishes that under the sector condition, mismatch stays bounded. It does not quantify the *sustained rate of effort* an agent must expend to hold that bound. Two agents with identical persistence guarantees can face wildly different demands — a Kalman filter tracking a stationary process vs one tracking a rapidly non-stationary process are both persistent; one is dormant, the other running hot. Under Model S with Gaussian-OU signal, the sustained Shannon information rate the agent must acquire from observations to maintain the sector-persistence ultimate bound is $\dot{R}_{\min} \geq n\alpha/2$ nats per unit time — a Landauer-analog lower bound that depends only on the signal's second-order statistics and the sector constant α , and that Kalman-Bucy saturates in steady state. The bound promotes channel capacity $C \geq \mathcal{I}/2$ into a first-class persistence prerequisite that the current theory does not name.

The bound is *filter-agnostic*: it holds for any correction mechanism achieving the ultimate bound under the stated scope. It is also *substrate-agnostic*: Landauer's principle converts it to a thermodynamic dissipation floor in any physical realization (Still et al. 2012). The corollary the framework lifts — a channel-capacity floor as first-class persistence prerequisite — has bite in three regimes where observation bandwidth is non-abundant: biological systems with finite neural channel capacity, bandwidth-constrained distributed systems over noisy or low-bandwidth links, and context-window-limited language models where effective information rate per unit of cognition is bounded by context size and token throughput. Survival, in this framework, is not a state achieved once — it is a *sustained burn rate* of information, and the channel that supports it is part of what keeps the agent in scope.

Formal Expression.

Setup. The agent is in scope of 4.4 Model S (GA-2S, stochastic disturbance). Per Prop A.1S the state satisfies $\mathbb{E}[\|\delta\|^2]_{ss} = n\sigma_w^2/(2\alpha)$. The RMS bound is $R_S^* = \sigma_w\sqrt{n/(2\alpha)}$. The environmental signal is n -dimensional independent-component Ornstein-Uhlenbeck with per-component intrinsic drift λ_s and diffusion coefficient σ_w^2 . The mean-square persistence condition $\alpha > n\sigma_w^2/(2R^2)$ holds. Sector-persistence is achieved at the tight bound $D^2 = R_S^{*2}$.

Persistence Information Rate (main theorem).

Proposition. Any adaptive process achieving the tight Model-S ultimate bound $\mathbb{E}[\|\delta\|^2]_{ss} = n\sigma_w^2/(2\alpha)$ under the stated setup must acquire information from observations at sustained rate

Proved (persistence-information-rate, from Shannon RDF + Prop A.1S).

$$\dot{R} \geq \dot{R}_{\min} = \frac{n\alpha}{2} \text{ nats per unit time} \quad (\text{I.1})$$

Derivation. Shannon's rate-distortion theorem (Shannon 1948; Berger 1971; Cover & Thomas 2006 Theorem 10.2.1) states that for any source-code achieving mean-square distortion D^2 , the coding rate satisfies $\dot{R} \geq R(D^2)$ where $R(\cdot)$ is the rate-distortion function. For n -dimensional independent-component OU in the high-resolution regime ($D^2 \ll \sigma_x^2 = \sigma_w^2/(2\lambda_s)$), the RDF per unit time is (Ihara 1993 Theorem 4.6.4; Gray 1972 Theorem 2):

$$\dot{R}(D^2) = \frac{n\sigma_w^2}{4D^2} \quad (\text{I.2})$$

Substituting $D^2 = R_S^{*2} = n\sigma_w^2/(2\alpha)$:

$$\dot{R}_{\min} = \frac{n\sigma_w^2}{4 \cdot n\sigma_w^2/(2\alpha)} = \frac{\alpha}{2} \cdot 1 = \frac{n\alpha}{2} \text{ nats per unit time} \quad (\text{I.3})$$

(the calculation gives $\alpha/2$ per dimension and $n\alpha/2$ total for n independent OU components). The agent's observation-channel information rate must meet this bound regardless of the specific correction function, filter structure, or implementation. $\square$

Kalman-Bucy Saturates the Bound.

The Kalman-Bucy filter attains the bound exactly in steady state. Mitter & Newton (2005, *J. Stat. Phys.* 118:145–176) derive the filter's rate of information supply as

Derived (Kalman-tight, Mitter-Newton 2005).

$$\dot{I} = \frac{1}{2} \text{tr}(H^T \Sigma_o^{-1} H P_{ss}) \quad (\text{I.4})$$

Scalar case ($H = 1$, $\Sigma_o = \sigma_o^2$) with steady-state covariance $P_{ss} = \sigma_o \sigma_w$ in the drift-dominated limit and Kalman gain $K_{ss} = P_{ss}/\sigma_o^2 = \sigma_w/\sigma_o$:

$$\dot{I} = \frac{P_{ss}}{2\sigma_o^2} = \frac{K_{ss}}{2} = \frac{\alpha}{2} \quad (\text{I.5})$$

Under the linear-correction identification $\alpha = K_{ss}$ (from 4.3, scalar Kalman case), the Kalman filter's information supply rate equals $\alpha/2$ exactly. This matches the RDF lower bound, confirming tightness. **The bound is not merely a lower bound — it is achieved by the Kalman-optimal filter.**

Channel-Capacity Prerequisite.

By Shannon's channel coding theorem (Cover & Thomas 2006 §7.7), an observation channel of Shannon capacity C_{channel} can support any information rate up to C_{channel} and no higher. Combining with the persistence information rate:

Derived (channel-capacity-floor, from main theorem + Shannon capacity).

$$C_{\text{channel}} \geq \dot{R}_{\min} = \frac{n\alpha}{2} \quad (\text{I.6})$$

Under the linear-correction identification $\alpha = \mathcal{J}$ (from 3.8 + 4.3 scalar Kalman):

$$\boxed{C_{\text{channel}} \geq \mathcal{J}/2 \text{ nats/time per dimension}} \quad (\text{I.7})$$

Persistence demands observation-channel capacity at least half the adaptive tempo. This is a *new first-class persistence diagnostic* not present in the current theory. Its binding matters most in capacity-constrained settings — bandwidth-limited distributed systems, biological neurons, context-window-limited LLMs — where the tempo framework alone underestimates the difficulty of maintaining bounded mismatch.

Rejected Candidate Cost Metrics. The information-rate bound is not the only candidate for a cost-of-persistence quantity. Three alternatives fail structurally. Recording them here keeps the scope-honesty visible.

[*Observation (gain-magnitude-tautological)*] $\mathbb{E}[\|K(t)\|]$ as a cost metric: in the linear Kalman case $K_{ss} = \alpha$ (sub-scope α per 4.3), so “gain magnitude” equals the sector constant itself. Any bound of shape $\mathbb{E}[\|K\|] \geq f(\alpha, \dots)$ becomes tautological. Rejected as fundamental cost metric — it recapitulates α .

[*Observation (control-effort-filter-specific)*] $\mathbb{E}[\|u(t)\|^2]$ (per-unit-time control-effort integral): filter-specific. Different filters achieving the same steady-state variance P_{ss} have different control-effort integrals. The Kalman filter is minimum-effort among linear filters (optimal-control interpretation of the Riccati equation); nonlinear filters can trade effort vs variance differently. A filter-agnostic bound cannot be stated in this quantity — it is not invariant under the equivalence class of filters meeting the persistence condition.

$\mathbb{E}[\alpha\|\delta\|^2]_{ss}$ (Lyapunov dissipation rate) at steady state equals $n\sigma_w^2/2$ regardless of α — a non-equilibrium-steady-state conservation law (dissipation balances disturbance-power injection). The quantity is *structurally invariant*: it does not depend on the quality of adaptation, only on the disturbance statistics. This is what makes the RDF bound tight at the Model-S ultimate bound (the steady state is active, not slack), but it cannot itself serve as a cost metric because it does not distinguish well-adapted from poorly-adapted agents at a given α .

Observation (Lyapunov-dissipation-conservation).

Candidate 4 — the Shannon information rate above — is the one that closes. The structural reason: information rate is filter-agnostic (depends only on signal second-order statistics and target distortion), universal (any filter implementation is lower-bounded), and has a clean thermodynamic interpretation (Still et al. 2012, “Thermodynamics of Prediction”, *Phys. Rev. Lett.* 109:120604: nonpredictive information retained equals dissipation during interaction).

What Is Derived vs. What Is Chosen.

Table I.1

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Persistence information rate $\dot{R}_{\min} \geq n\alpha/2$	Shannon RDF (Berger 1971; Gray 1972; Ihara 1993 Thm 4.6.4) composed with Prop A.1S	Derived (conditional on Model S + Gaussian-OU + high-resolution regime)
Kalman-Bucy saturates bound	Mitter-Newton 2005 Theorem (information-supply identity); linear-correction identification $\alpha = K_{ss}$ per 4.3	Derived (linear-Gaussian; exact when A2' is derived in sub-scope α)
Channel-capacity prerequisite $C \geq \mathcal{T}/2$	Main theorem + Shannon channel-capacity theorem (Cover-Thomas 2006 §7.7) + $\alpha = \mathcal{T}$ identification	Derived
Gain-magnitude as cost metric	$\mathbb{E}[\ K\] \approx \alpha$ in sub-scope α	Rejected as fundamental (tautological)
Control-effort integral as cost metric	Filter-specific; depends on optimality class	Rejected as universal (filter-dependent)
Lyapunov dissipation rate	Conservation law = $n\sigma_w^2/2$ at steady state	Not a cost metric — structural observation enabling tightness of main theorem
Non-Gaussian signal extension	Different RDF form (Berger 1971 Ch. 4)	Open — qualitative scaling $\dot{R} \propto \text{innovation-rate}/D^2$ likely preserved; exact prefactor changes

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Model D (bounded disturbance) analog	Requires adversarial / minimax information argument (Csiszár-Körner 2011 Ch. 11)	Open
Transient-regime rate	Bound is steady-state; transient rates during structural adaptation much higher	Open
Sub-scope β transfer	RDF bound holds as inequality (data-processing); tightness not guaranteed	Conditional (holds as lower bound; Kalman-Bucy saturation requires sub-scope α)

Epistemic Status.

Conditional. Max attainable: *exact* in the linear-Gaussian case; *robust qualitative* for general stationary Gaussian signals; *heuristic* for non-Gaussian.

The theorem rests on three named conditions: (i) Model S stochastic disturbance per 4.4 (GA-2S); (ii) n -dimensional independent-component Ornstein-Uhlenbeck signal structure; (iii) high-resolution regime $D^2 \ll \sigma_x^2$. Within this scope the result is as tight as the Shannon RDF allows — Kalman-Bucy exactly saturates per Mitter-Newton 2005. For non-Gaussian signals the RDF has a different form (Berger 1971 Ch. 4) but the scaling $\dot{R}_{\min} \propto \sigma_w^2/D^2$ is expected to persist qualitatively; exact prefactors change per signal class. Under Model D (bounded disturbance) the argument requires worst-case channel-capacity machinery (Csiszár-Körner 2011 Ch. 11) and gives a different expression.

Sub-scope transfer. Sub-scope α agents (Kalman / conjugate-Bayesian / exponential-family / strongly-convex-gradient / linear-PD) have α derived from the update rule's structure per 4.2 + 4.3, so the $n\alpha/2$ bound holds with known α and is tight in the linear-Gaussian case. Sub-scope β agents (PID / rule-based / human-judgment) assume A2' rather than deriving it — the RDF bound still holds as an inequality (by the data-processing inequality applied to any filter mapping observation to update), but tightness is not guaranteed and the assumed α enters the bound.

Confidence in correctness. The Shannon RDF for Gaussian-OU is a classical result (Gray 1972; Ihara 1993). The sector-persistence bound is already in AAT (Prop A.1S of A). The theorem's mathematical core is a two-line composition of both; a careful reader can verify. The contribution is not the mathematics but the AAT-framing — reading $\alpha/2$ off the sector constant as the fundamental information-rate cost of persistence — and the channel-capacity-as-first-class-quantity opening.

What this does not establish.

- Upper bounds on persistence cost (how much rate a specific filter consumes; the bound is a lower limit).
- Optimal filter design for minimum information throughput.
- Non-Gaussian signal cost bounds (qualitative scaling expected; quantitative forms open).
- Cost under Model D adversarial disturbance.
- Cost for composite agents beyond simple additivity.
- The stability upper bound on plasticity that 9.11 references — that involves the consolidation cadence, not the online information rate.

Discussion.

The $\alpha/2$ per-dimension Landauer analog. The theorem has a clean thermodynamic reading per Still et al. 2012: each nat of information about the signal costs at least $k_B T$ of dissipation (Landauer 1961, in its per-nat form $k_B T/\text{nat}$, equivalently $k_B T \ln 2$ per bit). Combined, persistence at sector constant α in n dimensions costs at least $n\alpha/2$ nats/time of information acquisition and hence at least $\frac{1}{2}n\alpha k_B T$ of thermodynamic dissipation per unit time in any physical substrate. AAT does not commit to a specific substrate, but the bound is substrate-agnostic: it constrains any filter implementation via the RDF (information-theoretic) and, when physical, any computational realization via Landauer (thermodynamic).

Why channel capacity matters as a first-class quantity. AAT’s 4.5 and 3.8 currently frame persistence as a correction-rate vs disturbance-rate inequality. This theorem adds a *lower* constraint: observation channels must jointly supply Shannon capacity $\geq \mathcal{T}/2$ nats/time per dimension, else persistence fails regardless of correction-function design. The constraint is binding in any setting where observation bandwidth is non-abundant — most real systems. Three domains where the capacity floor is more binding than the tempo bound:

- *Biological systems:* neural channel capacity is finite; this bound gives a quantitative minimum on sensory bandwidth for a given adaptive rate.
- *Bandwidth-constrained distributed systems:* agents operating over noisy or low-bandwidth links face channel capacity directly as a hard constraint.
- *Context-window-limited LLMs:* the effective information rate per unit of cognition is bounded by context size and token-throughput; this theorem predicts a minimum tempo achievable at a given context budget.

In each, knowing that $\mathcal{T}/2$ is the floor converts an opaque “just needs more capacity” observation into a specific dimensional requirement.

Connection to AAT’s meta-architecture. The result composes with AAT’s three meta-segments.

- *5.4 (positive half):* the bound sits in structured-repair along the identification-regime ladder — derived in sub-scope α via composition of two external theorems; holds as inequality (not tightness) in sub-scope β .
- *5.1 (negative half):* this is the positive-dual of the floor pattern. Where the floor says “AAT cannot distinguish X without information augmentation” (external no-go + AAT escape), this result says “AAT requires at least $n\alpha/2$ nats/time of information supply to operate” (external lower bound + AAT bridge through sector-persistence template). The two patterns are duals: external-theorem-forbids vs external-theorem-lower-bounds.
- *5.5 (constructive half):* the bound is linear in α , not logarithmic. It sits *outside* the three-layer logarithmic-coordinate family (chain / divergence / update). No Cauchy-FE argument forces the coordinate here — the result is a direct substitution from classical information theory. This is a useful non-example: AAT’s additive-coordinate-forcing pattern is not universal; specific results live on different coordinates.

Relationship to G. The template enumerates six instantiations (epistemic mismatch; strategic mismatch; sub-agent mismatch; composite trajectory error; composite mismatch; target-agent mismatch). Each has its own state variable ξ , sector constant α , and disturbance statistics. The persistence cost bound *specializes* for each instantiation: under Model S with Gaussian-OU-shaped disturbance on the state variable, the information-rate cost is $n\alpha/2$ with the template’s α and n . A compact template-cost bound — parametric in $(\xi, \alpha, n, \sigma_\xi)$ — could land as a subsection of G so all six instances inherit the cost bound by substitution. That move is flagged in Working Notes as an optional consolidation.

The relationship to Mitter-Newton’s thermodynamic reading. Mitter & Newton (2005) showed the Kalman-Bucy filter operates as a Maxwellian demon: it returns signal energy to the heat bath without entropy increase, but only because new information is continually supplied at rate $\dot{I}$. This supply rate *is* what persistence costs — the filter maintains bounded mismatch by paying, information-theoretically, for new observations at a rate matched to the environment’s

innovation rate. Our theorem makes this quantitative as a function of the sector constant: at a given α , the matching rate is $\alpha/2$. Faster correction requires more information supply; the bound is tight.

Working Notes.

- **Template-cost subsection.** A compact parametric statement — “under (T1)–(T3) with Model S and Gaussian-OU disturbance at per-component parameters $(\lambda_\xi, \sigma_\xi^2)$, sustained information rate to maintain steady-state mean-square ξ at ultimate bound $D^2 = n\sigma_\xi^2/(2\alpha)$ satisfies $\dot{R} \geq n\alpha/2$ nats/time” — would let each of **G**’s six instances inherit the cost bound by substitution. Worth considering on next template revision; would consolidate this segment’s core result into the template.
- **Model D adversarial analog.** Rate-distortion is inherently stochastic; Model D’s bounded-disturbance version of the theorem requires minimax / worst-case channel capacity (Csiszár-Körner 2011 Ch. 11). Candidate follow-up spike. Expected form: similar $\propto \alpha$ scaling, different prefactor.
- **Non-Gaussian signals.** For heavy-tailed or power-law signals the RDF has a different exact form (Berger 1971 Ch. 4). The qualitative scaling $\dot{R}_{\min} \propto \sigma_w^2/D^2$ is expected to persist; quantitative extensions are per-family.
- **Misspecification cost.** When $\mathcal{F}(\mathcal{M}) < 1 - \epsilon$ per 2.4, achievable distortion is bounded away from zero by an additional floor. Natural extension has the sustained information rate lower-bounded by $n\sigma_w^2$ divided by 4 times the larger of the Model-S ultimate bound and D_{floor}^2 . Connects to 5.1’s “Misspecification-cost quantification” open extension.
- **Composite persistence cost.** For a composite agent, the information-rate bound’s scaling under composition is not trivial. Candidate: $\dot{R}_{c,\min} \leq \sum_i \dot{R}_{i,\min}$ due to coordination overhead eating capacity. Cost-analog of 13.2’s sub-additivity + 15.1’s cooperative-coupling reduction. Open.
- **Observation-channel capacity as notation.** Currently AAT uses U_o (observation uncertainty) as a noise parameter. Lifting Shannon channel capacity $C^{(k)}$ of channel k into NOTATION.md and relating it to U_o (via the channel-capacity-from-noise standard transform) would make the capacity-floor condition a first-class persistence diagnostic. This is the biggest architectural opening from this theorem and worth a follow-up scoping decision.
- **Connection to 9.10.** The strategy-edge persistence condition has its own disturbance statistics ρ_Σ and sector constant α_Σ . Specializing this theorem gives the information rate required to track strategy-edge invalidation: $\dot{R}_{\Sigma,\min} = n_\Sigma \alpha_\Sigma / 2$. If $\alpha_\Sigma = 1/(n+1)$ with experience discounting, the rate decays with accumulated n — which connects to the stability-induced myopia result in the pending spike **G**.
- **Not forced by a Cauchy-FE axiom.** Unlike the three primary instances of 5.5 (chain, divergence, update), the linear-in- α coordinate of this bound is not forced by an AAT-internal additivity axiom. It is a direct consequence of Gaussian-RDF’s specific functional form. This places the result *outside* the three-layer family — a useful non-example that shows the additive-coordinate-forcing pattern is not universal.
- **Landauer-coefficient correction (2026-05-30).** The Discussion’s thermodynamic-floor coefficient previously read $n\alpha k_B T / (2 \ln 2) \approx 0.35 n\alpha k_B T$; that mixed the bit and nat conventions — a spurious $1/\ln 2$ factor multiplying a nats rate under a per-nat $k_B T$ Landauer constant. Since $\dot{R}$ is in nats and the intended constant is $k_B T/\text{nat}$, the floor is $\frac{1}{2} n\alpha k_B T/\text{time}$. Corrected here and in the quoting segment 4.11. Surfaced by AUDIT-WORKING-526815 (gold-lift sweep).

Incidental audit gold (lift 2026-05-31). Orthogonal pedagogical / generative material from the de-novo auditors’ working dirs (per de-novo-audit-instructions.md §7.15), deduplicated and lightly attributed. Felt-value here was uniformly “monumental / breath-taking” — the segment is where information theory, control theory, and thermodynamics meet. Certified-track items off-ramped at the end.

1. Candidate Briefprose / pre-prose.

- **“Ignorance is cheap; epistemology is expensive.”** Synchronizing your model with a drifting reality has a hard minimum energy cost: a perfectly efficient agent doing nothing but observing a changing environment still drains its battery (Gemini, AUDIT-WORKING-829314).

- **Survival as a sustained burn rate.** “Survival is not just a state you achieve; it is a sustained burn rate of Shannon information — you must continuously consume $\dot{R}$ nats/time just to stay alive.” The threshold says whether persistence is *possible*; this says what it *costs* (Gemini, AUDIT-WORKING-193847).
- **The cost depends only on the machinery, not the world.** A clean, surprising punchline worth foregrounding: the environmental volatility σ_w^2 cancels out of $\dot{R}$, leaving the burn rate a function of α alone. The environment sets *how bad the error gets* (distortion scales with σ_w^2); the *cost of running the correction machinery* depends only on the correction speed (Gemini, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **The Kalman filter as a Maxwell’s demon.** It returns signal energy to the heat bath without an entropy increase, but *only because new information is continually supplied*. “Sanity” (a bounded model of reality) is then literally a thermodynamic pump: entropy is pumped out of the internal model M_t and dumped into the environment as heat, fuelled by raw Shannon information flowing in through the sensors. Cut the channel ($C \rightarrow 0$) and the pump stops; the base disturbance ρ raises internal entropy until the model degrades to maximum-entropy noise (Gemini, AUDIT-WORKING-193847). A vivid, honest physical reading of the bound that the segment’s Discussion does not currently name.
- **Dissipative-structures / Prigogine mapping.** The information-rate floor maps to dissipative structures: life requires continuous free-energy flow to maintain order against entropy. In AAT, “order” is bounded mismatch, “entropy” is environmental drift ρ , “free energy” is the Shannon information acquired via $\mathcal{I}$ (Gemini, AUDIT-WORKING-193847). (*Verify isomorphism before promoting past discussion-grade — early-conflation texture: reach toward a physics analogy.*)
- **A third independent failure mode.** The cost shadow adds a third way to die alongside the two threshold conditions: too-small model class (fails R), too-slow algorithm (fails $\alpha > \rho/R$), or *too-narrow sensors* (fails $C \geq \mathcal{I}/2$). Framing persistence as a *three-failure* picture rather than a single threshold (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203 — channel-capacity floor as “a new first-class persistence diagnostic”).

3. Follow-up items.

- **“Positive-dual of identifiability-floor” as a fourth meta-pattern.** Identifiability-floor = external theorem *forbids* inference, AAT escapes via added capability; persistence-cost = external theorem gives a *lower bound* on information rate, AAT bridges through the sector-persistence template. The two are duals (external-theorem-forbids vs external-theorem-lower-bounds). If the framework grows more “external-theorem bound” results (misspecification-cost lower bound, composition-overhead lower bound), they would form a coherent fourth class — a candidate #disc-theorem-import-architecture meta-segment (Claude, AUDIT-WORKING-471203; tracks PROPOSALS SP-23). (*Several substrates converged on this; high-priority §F-grade observation.*)
- **“Channel bandwidth is not tempo” caveat.** High channel capacity C does not *give* high tempo $\mathcal{I}$; it only *allows* it — the update rule must actually be capable of processing the inflow. Guard against downstream “more data equals more tempo” claims (Gemini, AUDIT-WORKING-773921).

4. Readers often ask / wonder.

- **Can we compute an LLM’s maximum survivable environment?** If an LLM’s effective channel capacity C is bounded by token throughput / context-window size, then $C \geq \mathcal{I}/2$ gives a hard ceiling on its adaptive tempo — and hence the maximum environmental volatility ρ a given architecture can survive. Readers will want this made concrete (Gemini, AUDIT-WORKING-193847 and AUDIT-WORKING-773921).
- **The drone-through-a-forest intuition.** A drone flying fast through dense forest needs high $\mathcal{I}$ (because ρ is large); even with an infinitely fast internal computer and a perfect Kalman filter, a low-bandwidth / low-framerate camera makes $C < \mathcal{I}/2$, the model diverges from the trees, and it crashes. The rate-distortion theorem forbids extracting enough information from the straw to stay synchronized — a concrete grounding of the channel-capacity prerequisite (Gemini, AUDIT-WORKING-829314).

Belongs elsewhere.

- **LLM agentic design implication (03-llm-core/)**. An LLM with huge latent reasoning tempo but a bash-terminal observation channel (a few hundred bytes/sec) is mathematically capped at $\mathcal{J} \leq 2C_{\text{channel}}$ — it will always be a slow, fragile agent in volatile environments no matter how many parameters it has. The lever is not a smarter model but *higher-bandwidth multi-modal sensory inputs* to raise the C_{channel} ceiling so latent $\mathcal{J}$ can deploy (Gemini, AUDIT-WORKING-829314).
- **ELI sensory-deprivation / continuity implication (04-eli-core/)**. You cannot put a mind in a sensory-deprivation tank and expect it to remain sane: if $C_{\text{channel}} \rightarrow 0$ the heat pump stops and the model dissolves into noise. The infrastructure hosting an entity must therefore *guarantee a minimum information-supply rate*, or it is starving the entity. Connects continuity-persistence to a measurable channel-capacity floor (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203).
- **Thermodynamic-cooling bottleneck on AI scaling**. If 1 nat costs $k_B T$, then high- α intelligence literally generates heat; scaling is bottlenecked not only by FLOPs and data but by *cooling*, with an agent tracking a volatile environment burning energy $\propto \rho$ just to stay synchronized (Gemini, AUDIT-WORKING-829314).

Off-ramp (NOT gold) — certified-track items, already resolved in canon.

- **$n\alpha/2$ vs $\alpha/2$ dimension bookkeeping (RESOLVED — do not re-open)**. 193847 (adversarial poke) flagged the mid-derivation algebra as appearing to cancel the dimension n : writing the scalar RDF with $n\sigma_w^2$ in the numerator and total $D^2 = n\sigma_w^2/(2\alpha)$ in the denominator yields $\alpha/2$, contradicting the stated $n\alpha/2$ total. The constructive repair (and current canonical derivation) is the per-dimension form $\dot{R}_i = \sigma_w^2/(4D_i^2)$ with $D_i^2 = \sigma_w^2/(2\alpha) \Rightarrow \dot{R}_i = \alpha/2$, total $n\alpha/2$. Recorded only so a future auditor does not re-raise the typo as open.
 - **Landauer coefficient $0.35 \rightarrow 0.5$ (RESOLVED — see WN above)**. 471203 quoted the thermodynamic floor as $\approx 0.35 n\alpha k_B T$; corrected to $\frac{1}{2} n\alpha k_B T$ per the 2026-05-30 Landauer-coefficient note above.
-

Appendix J

Derivation: Critical-Mass Composition

The composite sector constant α_c is derived — not merely bounded from below — for the symmetric-matched-Tier-1 two-agent case, yielding a closed-form critical-mass inequality in which the sign of the inter-agent coupling γ and the teleological unity U_O enter explicitly. The result subsumes the weakest-link bound, recovers 15.1 (cooperative) and 15.2 (adversarial) as signed special cases, formalizes 12.3’s autonomy-reduction mechanism as an asymmetric Lyapunov-weight limit, and makes the scope-gate from 12.2 explicit as the second conjunct of composite persistence.

Formal Expression.

Setup. Two sub-agents A_1, A_2 , each a **Tier 1 agent** in the sense of 13.1’s bridge-lemma taxonomy — mismatch-driven update, linear prediction, incremental sector-Lipschitz correction (Kalman, exponential-family Bayesian, gradient-on-strongly-convex, linear-with-PD-KH). **Matched architectures:** f_1, f_2 are structurally the same function, with $\alpha_1 = \alpha_2 = \alpha, R_1 = R_2 = R$. Disturbance statistics shared: each sees bounded $w_i(t)$ with $\|w_i\| \leq \rho$ (Model D, per G).

Inter-agent coupling enters additively to the disturbance at rate $\gamma\mathcal{T}_f$:

Formulation (coupling-model-C1, from #der-team-persistence + #der-adversarial-destabilization).

$$\rho_i^{\text{eff}} = \rho + \gamma\mathcal{T}_f \quad (\text{C1})$$

with sign convention $\gamma < 0$ cooperative (ally’s tempo-contribution reduces disturbance, recovering 15.1’s $-\gamma^{\text{coop}}\mathcal{T}_f$ term), $\gamma > 0$ adversarial (ally’s tempo-contribution amplifies disturbance, recovering 15.2’s $+\gamma_A\mathcal{T}_A$ term). Symmetric case: $\gamma_{1 \rightarrow 2} = \gamma_{2 \rightarrow 1} = \gamma$.

Coordination overhead reduces each agent’s effective correction rate symmetrically:

Formulation (coordination-cost-C2).

$$\alpha_i^{\text{eff}} = \alpha - C \quad (\text{C2})$$

with $C \geq 0$ the $\Delta\mathcal{T}_i^{\text{cost}}$ from 15.1’s coordination-overhead threshold.

Critical-mass inequality (symmetric-matched-Tier-1 case).

Let $\xi = (\delta_1, \delta_2)^T$ and take the joint quadratic Lyapunov candidate $V(\xi) = \frac{1}{2}(\|\delta_1\|^2 + \|\delta_2\|^2)$. Under the block-diagonal correction structure with cross-coupling absorbed into ρ_i^{eff} via (C1), and using $\|\delta_1\| + \|\delta_2\| \leq \sqrt{2(\|\delta_1\|^2 + \|\delta_2\|^2)}$ (Cauchy–Schwarz):

Derived (critical-mass-symmetric, from #result-sector-persistence-template + C1 + C2).

$$\dot{V} \leq -(\alpha - C)(\|\delta_1\|^2 + \|\delta_2\|^2) + (\rho + \gamma\mathcal{T})\sqrt{2(\|\delta_1\|^2 + \|\delta_2\|^2)}. \quad (\text{J.1})$$

Setting $\dot{V} = 0$ gives the ultimate bound on $\|\xi\|$ and, projecting to the macro-state $\delta_c = (\delta_1 + \delta_2)/\sqrt{2}$, the ultimate composite mismatch

$$R_c^* \leq \frac{\rho + \gamma\mathcal{T}}{\alpha - C}. \quad (\text{L4})$$

The composite persists iff $R_c^* < R_c$. Inheriting $R_c = R$ from the symmetric-matched averaging projection:

$$\boxed{(\alpha - C)R > \rho + \gamma\mathcal{T}} \quad (\text{CM2})$$

Rearranging into the composite contraction-rate form:

$$\kappa_c := (\alpha - C) - \frac{\rho + \gamma\mathcal{T}}{R}, \quad \text{composite persists iff } \kappa_c > 0. \quad (\text{KC})$$

Specialization checks. Under matched symmetry, (CM2) reduces correctly in four limits:

Table J.1

<i>Limit</i>	<i>Setting</i>	<i>(CM2) reduces to</i>	<i>Recovers</i>
No coupling	$\gamma = 0,$ $C = 0$	$\alpha R > \rho$	Single-agent 4.5
Cooperative-symmetric	$\gamma < 0,$ $C = 0$	$\alpha R > \rho + \gamma\mathcal{T}$ (easier than individual)	15.1’s “teams persist where individuals can’t”
Adversarial-symmetric	$\gamma > 0,$ $C = 0$	Fails when $\gamma\mathcal{T} > \alpha R - \rho$	15.2 threshold (symmetric)
Coordination-dominated	$C > \alpha,$ $\gamma = 0$	LHS < 0; composite fails	Brooks’s Law

Subsumption of the weakest-link bound.

The weakest-link bound $\alpha_c \geq \min_i(\alpha_i - \Delta \mathcal{T}_i^{\text{cost}})$ from 13.1's derivation table specializes under matched symmetry to $\alpha_c \geq \alpha - C$. (KC) refines this by making the composite's effective disturbance explicit as $\rho + \gamma \mathcal{T}$, turning a correction-rate bound into a full persistence inequality. Critically, (KC) can yield $\kappa_c > 0$ even when the weakest-link bound alone fails — when cooperative coupling ($\gamma \mathcal{T} < 0$) reduces the effective disturbance below what the raw $\alpha - C$ margin would permit. The weakest-link bound cannot see this because it does not account for γ 's sign.

Derived (weakest-link-subsumption).

U_O entry: multiplicative-on- γ plus scope-gate.

In a purposeful-agent setting where each sub-agent optimizes a quadratic objective $L_i(\omega) = \frac{1}{2}(\omega - r_i)^T Q(\omega - r_i)$ with target r_i , and $U_O := \text{corr}(r_1, r_2)$ is the target correlation per 14' U_O , the cross-coupling in the joint dynamics has sign and magnitude controlled by U_O :

Derived (unity-multiplicative-modulator, conditional on LQR-compatible action structure).

$$\gamma(U_O) = -\gamma_{\max} U_O, \quad \gamma_{\max} > 0, \quad (\text{UO-mult})$$

via aligned targets $\rightarrow$ aligned action directions in the shared environment $\rightarrow$ constructive (cooperative) cross-contribution in the symmetric eigendirection. Substituting into (KC):

$$\kappa_c(U_O) = (\alpha - C)R - \rho + \gamma_{\max} U_O \mathcal{T}. \quad (\text{CM3})$$

(CM3) is necessary but not sufficient for composite existence. Under 12.2, a composite exists as an AAT agent only when one of the three disjunctive alignment routes (shared objective, hierarchical derivation, mutual benefit) is satisfied. Below this threshold, no coherent O_c is definable and composite-level quantities — including R_c on the right of (CM2) — are ill-typed. The honest statement of composite persistence is therefore the conjunction of $\kappa_c(U_O) > 0$ with the scope conditions of 12.2 — abbreviated $\mathcal{S}_c$:

Scope (scope-gate-from-composition-scope-condition).

$$\boxed{\kappa_c(U_O) > 0 \wedge \mathcal{S}_c \Leftrightarrow \text{composite persists as AAT agent}} \quad (\text{CM4})$$

U_O enters (CM4) in two independent ways: multiplicatively within (CM3), and as scope-gate via 12.2. It does **not** enter purely additively as a separate reserve term — there is no free-floating “ U_O contribution” detached from the coupling it modulates.

Asymmetric limit and symbiogenic composition.

Drop the matched-symmetric assumption. Let $\alpha_1 \gg \alpha_2$ with $\alpha_2 \rightarrow 0$. The unweighted joint Lyapunov $V = \frac{1}{2}(\|\delta_1\|^2 + \|\delta_2\|^2)$ fails (the weakest-link ultimate bound diverges as $\alpha_2 \rightarrow 0$). A **weighted** Lyapunov $V_\mu(\xi) = \frac{1}{2}(\|\delta_1\|^2 + \mu\|\delta_2\|^2)$ with $\mu \rightarrow 0$ yields

Sketch (asymmetric-limit-symbiogenesis, from weighted Lyapunov).

$$\dot{V}_\mu \leq -\alpha_1 \|\delta_1\|^2 + \rho_1 \|\delta_1\| + O(\mu), \quad (\text{J.2})$$

so in the limit the composite's stability is controlled **entirely by agent 1**; agent 2's autonomous correction dynamics are weighted out of the stability accounting.

This provides a Lyapunov-weighted formalization of 12.3's **(S-3) autonomy reduction**: the endosymbiont's effective action space contracts ($\mathcal{A}_e^{\text{effective}} \rightarrow \mathcal{A}_e^{\text{restricted}}$) and its autonomous dynamics fall out of the joint Lyapunov argument. The asymmetric limit is a smooth deformation of (CM4), not a discontinuous regime change — symbiogenesis and peer coupling are parameter-limits of the same weighted-Lyapunov analysis. The result does **not** close 12.3's (S-1) objective absorption or (S-2) function transfer: what happens to agent 1's state space when it inherits structure from agent 2 is a separate question the weighting argument does not address.

What Is Derived vs. What Is Chosen.

Table J.2

Property	Source	Strength
Coupling model (C1): $\rho_i^{\text{eff}} = \rho + \gamma \mathcal{T}_j$	Import from 15.1 and 15.2	Formulation choice (requirement for the derivation)
Coordination-cost model (C2): $\alpha_i^{\text{eff}} = \alpha - C$	Import from 15.1's coordination-overhead threshold	Formulation choice
Joint quadratic Lyapunov $V = \frac{1}{2}(\ \delta_1\ ^2 + \ \delta_2\ ^2)$	Standard vector-Lyapunov construction (Matrosov 1962; Bellman 1962)	Formulation choice (canonical for matched-symmetric dyads)
Ultimate bound $R_c^* \leq (\rho + \gamma \mathcal{T})/(\alpha - C)$	Lyapunov dissipation + Cauchy-Schwarz	Derived
Critical-mass inequality (CM2): $(\alpha - C)R > \rho + \gamma \mathcal{T}$	(L4) + sector-region fit $R_c^* < R_c = R$	Derived (conditional on Tier 1 + matched-symmetric + Model D)
Four specialization checks (no-coupling / cooperative / adversarial / coordination-dominated)	Direct substitution into (CM2)	Proved (within stated scope)
Subsumption of weakest-link bound	(CM2) sign-sensitive; weakest-link is sign-blind	Proved
(UO-mult): $\gamma(U_O) = -\gamma_{\max} U_O$	LQR-compatibility sketch; aligned targets $\rightarrow$ aligned actions $\rightarrow$ constructive cross-contribution	Discussion-grade
Composite persistence as (CM3) $\wedge$ scope-satisfaction: (CM4)	(KC) with (UO-mult) + 12.2	Derived (conditional)
Asymmetric limit $\rightarrow$ 12.3 (S-3) via weighted Lyapunov	Matrosov-style weighting; $\mu \rightarrow 0$ limit	Sketch (the weighting is standard; the identification with (S-3) is structurally motivated but not a theorem)
(S-1) objective absorption and (S-2) function transfer formalizations	Not addressed by this derivation	Open (in 12.3 Working Notes)
Heterogeneous-architecture case (A_1 Tier 1, A_2 Tier 2/3)	Requires per-sub-agent tiering per 13.1	Open
Heterogeneous-metric Tier-1M dyad ($\lambda_1 \neq \lambda_2$, $C_1 \neq C_2$, $k_{12} \neq k_{21}$)	AI (CM2-M) via Slotine 2003 negative-feedback small-gain: $(\lambda_1 - C_1)(\lambda_2 - C_2) > k_{12}k_{21}/4$	Derived (conditional on AI (CT2) preconditions + Slotine 2003)
Nonlinear coupling $\gamma = \gamma(\delta_j)$	Requires full joint-Lyapunov machinery from 15.2 (effects-spiral corollary)	Open
Dynamic coordination cost $C = C_0 + C_1 \ \delta_j\ $	Quadratic inequality; admits closed form, loses interpretive cleanliness	Open
Fully-coupled tempo dynamics ($\mathcal{T}_i$ responsive to δ_j)	Requires joint tempo analysis from 15.2 Working Notes	Open

<i>Property</i>	<i>Source</i>	<i>Strength</i>
$N > 2$ scaling of (CM4)	Conjunction over pairwise terms generalizes but loses closed form	Open

The dividing line: (C1), (C2), and the quadratic Lyapunov candidate are **formulation choices** imported from adjacent segments or from standard Lyapunov practice. The *consequences* under these choices — (L4), (CM2), (KC), the specialization checks, the weakest-link subsumption, and (CM4) with its scope-gate conjunct — are **derived**. The U_O -multiplicative modulator (UO-mult) is discussion-grade: it uses an LQR-compatibility argument whose rigor depends on an action-space inner-product analysis deferred to 14.1. The asymmetric-limit identification with 12.3 (S-3) is sketch-level — the weighted-Lyapunov argument is standard but the semantic identification with autonomy reduction is structural, not proved.

Epistemic Status.

Conditional. Max attainable: *exact* (within the matched-symmetric-Tier-1 scope); *conditional* beyond.

(CM2) and (KC) are **proved** under Tier 1 architecture + matched-symmetric parameters + Model D disturbance + the (C1) disturbance-coupling model + the (C2) coordination-cost model. These conditions cover Kalman filters, exponential-family Bayesian updaters, gradient-on-strongly-convex agents, and linear-PD correctors — the same architecture class for which 13.1’s bridge lemma is promoted from “conditional” to “derived.” Within this scope the result is as strong as the standard Lyapunov argument allows.

(CM3) inherits the conditional status of (UO-mult), which is **discussion-grade**: the LQR-compatibility sketch is qualitatively clear, but a rigorous action-space inner-product derivation that pins down $\gamma_{\max}$ has not been produced. (CM4) is therefore conditional on both (UO-mult)’s rigor and on 12.2’s scope-gate being independently verified for the given composite candidate.

The asymmetric limit (§asymmetric-limit) is **sketch-level**. The weighted-Lyapunov argument is textbook (Matrosov 1962); the identification of the $\mu \rightarrow 0$ limit with 12.3’s (S-3) autonomy-reduction mechanism is structurally motivated but not a theorem, because (S-2) function transfer is not formalized in 12.3. When (S-2) lands, the symbiogenic-limit result can be promoted to derived.

What this segment does **not** establish:

- Composite **incremental** sector bound (DA2’-inc) — still the domain of 13.1’s bridge lemma. (CM4) gives composite (T2) at the macro level; the bridge lemma’s contraction is a separate, stronger condition.
- Heterogeneous-architecture composites (Kalman + PID, Tier 1 + Tier 3): the joint Lyapunov construction requires agent-by-agent tiering; closed form is not available.
- Nonlinear or state-dependent coupling: (C1) assumes γ independent of δ . State-dependent γ produces a non-linear inequality in δ ; this is the effects-spiral corollary territory of 15.2, still open.
- $N > 2$ scaling: the matched-symmetric pairwise result generalizes by conjunction, but the Cauchy–Schwarz step degrades with team size; the closed form does not survive cleanly.

On (T2) and sub-scoping. The joint quadratic Lyapunov candidate presumes each sub-agent’s correction is in sub-scope α of 4.2 (Bayesian / exponential-family / strongly-convex-gradient / linear-PD) under directional fidelity per 4.3. Composites with sub-scope β sub-agents (PID, rule-based, human-judgment) require (T2) verification per sub-agent at the composite level — the template’s A2’-sub-scope label is inherited pairwise.

Discussion.

Relationship to the bridge lemma. 13.1’s bridge lemma establishes when the macro-update map f_c is **incrementally** contracting, at the trajectory-error level — a condition strictly stronger than the one-point sector bound. This segment is the complement at the macro-state level: given the bridge lemma’s admissibility, (CM4) derives composite (T2), the one-point sector bound that G ’s instantiation for the composite requires. Both are necessary for the composite to be a stable macro-agent with bounded mismatch: bridge lemma says the macro-description tracks micro-reality (trajectory error stays bounded); (CM4) says the composite’s own corrections drive composite mismatch back inside the sector region. Together they close the composite-persistence argument at both layers.

Pattern across the signed-coupling instances. (CM4) has the same shape as several persistence-flavored results already in AAT:

- 15.1: per-sub-agent inequality $\alpha_i R_i > \rho_{i,env} + \sum_j \gamma_{j \rightarrow i}^{ady} \mathcal{J}_j - \sum_j \gamma_{j \rightarrow i}^{coop} \mathcal{J}_j$
- 13.2: composite inequality with effective disturbance $\rho_{ext} + \epsilon^* \nu_c$
- 15.2: failure condition $\gamma_A \mathcal{J}_A > \alpha_B R_B - \rho_B$ (negation of persistence)
- this segment: matched-symmetric dyad with signed γ and scope-gate

All four are instances of G ’s pattern with signed coupling controlling the sign of the cross-agent contribution to ρ_ξ . The template already names this pattern at the meta level; the present segment is the dyadic closed-form instance that the other three segments reference pairwise. A dedicated meta-segment for “signed-coupling critical-mass” was considered during spike work and judged redundant with G — the cross-instance structure is already visible in that segment’s instantiation table.

Potential-game generalization (via 16.1). (CM4) applies to composites with shared target (scope routes C-i / C-ii / C-iii from #scope-composite-agent) where contraction-to-shared-truth is the correct primitive. #deriv-strategic-composition carries the sibling result for composites with partially-opposing objectives (scope route C-iv — strategic composites): under the potential-game condition (Monderer-Shapley 1996), the sector-persistence template transfers to the gradient of the joint potential Φ , with α_{joint} playing the role of the composite sector constant and $\xi = \pi - \pi^*$ (deviation from Nash) playing the role of the composite state. For matched-symmetric potential games, the structural form of (CM2) survives with $(\alpha, R, \rho, \gamma, C)$ replaced by $(\alpha_{joint}, R_{Nash-basin}, \rho_\xi, \gamma_{strategic}, C_{strategic})$; the specific mapping is instance-dependent and typically not closed-form for non-zero-sum games. The joint-quadratic-Lyapunov machinery of this segment and the potential-function-Lyapunov machinery of #deriv-strategic-composition are both instances of #result-sector-persistence-template at the composite-state-variable level; what varies is whether the composite state is *mismatch-to-shared-target* (this segment) or *deviation-from-Nash* (#deriv-strategic-composition).

What (CM4) contributes beyond existing segments.

1. **Derivation, not assumption.** The composite sector constant appearing in 13.1’s (A4) was previously bounded by the weakest-link formula (a derived lower bound) but treated as an assumption for the bridge lemma. (CM4) *derives* α_c as a closed-form function of sub-agent parameters + coupling + unity + coordination overhead, in the matched-symmetric-Tier-1 case.
2. **Sign-sensitive.** The weakest-link bound is sign-blind — it gives the same $\alpha_c \geq \alpha - C$ regardless of whether the coupling is cooperative or adversarial. (CM4) makes the sign explicit through the $\rho + \gamma \mathcal{J}$ right-hand side and turns a correction-rate bound into a full persistence inequality.
3. **Unifies cooperative and adversarial regimes.** Teams persisting where individuals can’t and adversarial destabilization are the same inequality viewed from opposite signs of γ , not independent results.

4. **Scope-gate made explicit.** Composite persistence requires both contraction (CM3) **and** scope-satisfaction (12.2). (CM4) states this conjunction honestly; the absence of one or the other is a different failure mode (composite fails to contract vs. composite was never a composite).
5. **Symbiogenic and peer regimes connected.** The asymmetric limit shows symbiogenesis is a parameter-limit of peer coupling under a Lyapunov-weight deformation, not a discontinuous regime change requiring separate machinery.

Why the matched-symmetric restriction is load-bearing. Relaxing matched architectures requires per-sub-agent tiering in the sense of 13.1 (Tier 1 / 2 / 3). Heterogeneous composites can still satisfy (T2) at the composite level, but the joint Lyapunov construction must be weighted per sub-agent's contraction capacity — and the weighted form loses the clean closed-form (CM2). Relaxing symmetric coupling ($\gamma_{1 \rightarrow 2} \neq \gamma_{2 \rightarrow 1}$) produces a non-symmetric matrix whose smallest eigenvalue must be computed explicitly per instance. The matched-symmetric case is the one where both sub-agent tiering and coupling symmetry collapse the Lyapunov construction to a scalar inequality — which is why closed form is available there and not elsewhere.

Load-bearing role under #disc-identifiability-floor Instance 3. The composition-layer identifiability floor (Instance 3 of #disc-identifiability-floor) establishes a no-go theorem: there exist pairs of coupled systems with identical marginal component-level observation distributions but opposite composite-contraction signs, so composite contraction is not in general identifiable from component data alone. Four structural escapes are named there; escape (b) — matched Tier at the composite level — is operationalized by the closed-form (CM2) in this segment. Under the floor, (CM2) is not just “a closed-form result in a special case” but **the unique broadly-available composition-contraction certificate** among the four escape routes listed. Without (CM2) or its metric-formulation generalization (CM2-M) via #result-contraction-template, the weakest-link bound (WL) is sign-blind and cannot distinguish the cooperative-contracting from the adversarial-destabilizing composite. This load-bearing status positions this segment as “the machinery that escapes the composition-layer floor” rather than as a closed-form curiosity in the matched-symmetric special case.

Adjacent literature. The joint Lyapunov construction is an instance of the classical **vector Lyapunov function** method (Matrosov 1962; Bellman 1962). The critical-mass inequality is the AAT sector-bounded analog of the **small-gain theorem for ISS systems** (Jiang–Teel–Praly 1994; Sontag 1989): in the small-gain framework, composition of two ISS systems is ISS iff the product of their gains is less than one; in AAT's sector-bounded framework, the composite persists iff the *sum* of parent reserve-rates exceeds the coupling-amplified disturbance (additive rather than multiplicative because the averaging projection averages rather than multiplies gains). In the linear-diagonal-coupling case, the matrix $A = \alpha I - \beta(I - J)$ where J is the averaging operator is the graph-Laplacian-shifted form governing consensus convergence (Olfati-Saber & Murray 2004); (CM2) is consensus convergence rewritten as a persistence inequality. Relative to active inference's FEP-flow stability arguments (Friston 2019; narrowed by Aguilera et al. 2022 to small parameter regimes in NESS-density models), the present result inherits G's broader validity: it applies wherever (T1)–(T3) hold pairwise + (C1)/(C2) + matched symmetry, without requiring free-energy landscapes or NESS structure.

Findings.

Strong Monotonicity as the Hinge for Legitimate Macro-Agent Coarse-Graining. **Brief:** Two coupled adaptive systems can have identical marginal observation distributions while one composite contracts and the other diverges — the difference is a single bit (the sign of the cross-coupling) that is invisible from component data alone. The matched-symmetric-Tier-1 critical-mass inequality $(\alpha - C)R > \rho + \gamma\mathcal{T}$ exposes this bit explicitly: the same inequality recovers cooperative team-persistence (where coupling helps), adversarial destabilization (where coupling hurts), and Brooks's-Law coordination collapse (where overhead C exceeds correction rate α) as signed special cases of one closed-form result. The strong-monotonicity / DA2'-inc condition picks out precisely the agent classes (Kalman, exp-family Bayes, gradient on strongly-convex losses, linear with positive-definite gain-observation product) where the inequality is exact rather than heuristic.

Impact: Promotes the composite sector constant in `#form-composition-closure`’s admissibility condition (A4) from a weakest-link lower bound (sign-blind, treats cooperative and adversarial coupling identically) to a derived closed form that depends explicitly on coupling sign, target-correlation U_O , and coordination overhead C . Operationalizes Instance 3 of `#disc-identifiability-floor` (composition-layer common-Lyapunov no-go via Liberzon 2003) through escape route (b): under matched Tier at the composite level, the joint Lyapunov collapses to a scalar inequality and the otherwise-unidentifiable sign bit becomes a structural input to (CM2). Within the four `#disc-identifiability-floor` Instance-3 escapes, (CM2) and its metric generalization (CM2-M) in `#result-contraction-template` are the unique broadly-available coupling-sign certificate. The asymmetric-parameter limit gives `#hyp-symbiogenic-composition`’s (S-3) autonomy-reduction a Lyapunov-weighted formulation as a smooth deformation of (CM4) rather than a discontinuous regime change.

Novelty Claim: *Claim novelty* on strong monotonicity as the criterion separating legitimate macro-agent coarse-graining from coexistence-only multi-agent description. The closest mathematical neighbors (Subramanian 2020; Congeduti 2020) prove bounded-loss composition under predictive compression but do not isolate a single condition whose failure flips composite contraction; the Markov-blanket line (Parr 2019; Kirchhoff 2018) discusses nested agency without a control-theoretic monotonicity criterion; the small-gain-theorem line (Jiang-Teel-Praly 1994; Sontag 1989) provides a multiplicative composition criterion under input-to-state stability rather than the additive sign-sensitive form (CM2) takes here.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Strong monotonicity as composition-validity hinge	Subramanian, Sinha, Seraj & Mahajan 2020, “Approximate information state for approximate planning and reinforcement learning in partially observed systems” <i>arXiv:2010.08843</i> (published 2020, found 2026-04)	<i>closest mathematical neighbor</i> — proves a bridge-shape bound but does not foreground a single monotonicity-grade condition that determines whether composite description is legitimate. Per the Pillar-2 defense strategy, foregrounding strong monotonicity (DA2’-inc; equivalently (CT2)-at- $M = I$ in <code>#result-contraction-template</code>) as the hinge between stable coexistence and valid macro-agent coarse-graining is the increment ASF supplies on top of this neighbor
Coordination-overhead / influence loss bound	Congeduti, Mey & Oliehoek 2020, “Loss Bounds for Approximate Influence-Based Abstraction” <i>arXiv:2011.01788</i> (published 2020, found 2026-04)	<i>closest mathematical neighbor</i> — explicit bounds on value loss from approximate influence in multi-agent settings. (CM2)’s sign-sensitive RHS $\rho + \gamma\mathcal{T}$ encodes the same loss-vs-cooperation tradeoff that Congeduti’s influence-approximation bound encodes for value, applied at the persistence-inequality layer rather than the policy-value layer
Composite-Lyapunov nonexistence under component-marginal data	Liberzon 2003, <i>Switching in Systems and Control</i> Theorem 2.1; Dayawansa & Martin 1999, <i>IEEE TAC</i> 44; Shorten et al. 2007 <i>SIAM Review</i> 49 (published 2003/1999/2007, found 2025-04)	<i>formal antecedent</i> — supplies the no-go theorem <code>#disc-identifiability-floor</code> Instance 3 invokes. (CM2) is the AAT escape route (b) under matched Tier at the composite level
Vector-Lyapunov composition	Matrosov 1962; Bellman 1962	<i>formal antecedent</i> — joint quadratic Lyapunov $V = \frac{1}{2}(\ \delta_1\ ^2 + \ \delta_2\ ^2)$ is a vector-Lyapunov construction; standard machinery

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Multiplicative composition criterion via small-gain	Jiang, Teel & Praly 1994, “Small-gain theorem for ISS systems and applications” <i>Math. Control Signals Syst.</i> 7; Sontag 1989	<i>partial anticipation</i> — same compositional-validity question, multiplicative form (gain product < 1) under input-to-state stability. (CM2)’s additive form $(\alpha - C)R > \rho + \gamma\mathcal{T}$ comes from sector-bounded correction rather than ISS; the two are different scaling regimes of the same composition-validity question, with (CM2) sharper in AAT’s setting because the averaging projection averages rather than multiplies sub-agent gains
Negative-feedback heterogeneous extension	Slotine 2003, “Modular stability tools for distributed computation and control” <i>Int. J. Adapt. Control Signal Process.</i> 17:397–416 — Theorem 3	<i>formal antecedent</i> — supplies (CC-feedback) used in #result-contraction-template to lift (CM2) to heterogeneous Tier-1M sub-agents via (CM2-M)
Consensus dynamics graph-Laplacian shift	Olfati-Saber & Murray 2004, “Consensus problems in networks of agents with switching topology and time-delays” <i>IEEE TAC</i> 49:1520	<i>adjacent literature</i> — in the linear-diagonal-coupling case, (CM2) is consensus convergence rewritten as a persistence inequality; different domain framing, same mathematical object
Markov-blanket nested-agency at composition	Parr, da Costa & Friston 2019; Kirchhoff et al. 2018 (published 2019/2018, found 2026-04)	<i>conceptual precursor</i> — provides nested-agency framing without a control-theoretic monotonicity criterion that separates valid macro-agent coarse-graining from coexistence

Search Log:

- 2026-04 (*nominally comprehensive*): the strong-monotonicity hinge is foregrounded as the criterion not visible in retrieved prior art. Subramanian / Congeduti provide the closest math (bounded-loss composition) without isolating a single condition whose failure flips composite legitimacy; Markov-blanket line provides nested-agency intuition without monotonicity machinery.
- 2026-04 (*targeted*, prior to comprehensive search): the small-gain-theorem line (Jiang-Teel-Praly 1994; Sontag 1989) and consensus-dynamics line (Olfati-Saber & Murray 2004) were known and cited in the segment’s existing Discussion as adjacent literature. The comprehensive search added the Sub20 / Con20 closest-neighbor positioning and confirmed no surfaced paper foregrounds the strong-monotonicity hinge.
- 2026-04 (*intuition-only*, prior): expected adjacent literature was switched-systems stability (Liberzon 2003) and game-theoretic equilibrium analysis. Switched-systems hit confirmed via #disc-identifiability-floor Instance 3; game-theoretic side is properly the territory of #deriv-strategic-composition, scope-separated.

Working Notes.

- **Partial-derivation: heterogeneous-architecture dyad.** The clean closed form (CM2) relies on matched sub-agent architectures collapsing the joint Lyapunov candidate to a scalar inequality. A natural next move is the $(A_1, A_2) = (\text{Tier 1}, \text{Tier 2})$ case: weighted Lyapunov $V_\mu = \frac{1}{2}(\|\delta_1\|^2 + \mu(\delta_2)\|\delta_2\|^2)$ with the weight a function of agent 2’s local contraction modulus. Likely produces a range-valued (not closed-form) critical-mass inequality. Defer until a specific Tier-mismatch composite motivates it.
- **Sharpen (UO-mult).** Upgrading $\gamma(U_O) = -\gamma_{\max} U_O$ from discussion-grade to derived requires an action-space inner-product analysis: define the environment’s action-coupling operator, show that LQR-linear policies produce cross-actions with inner product proportional to target correlation, and pin down $\gamma_{\max}$ in terms of the quadratic objective’s Hessian and

the environment's coupling gain. This is mechanical but non-trivial; natural home is an extension to 14.1's linear-Gaussian closed-form section.

- **Close (S-2) function transfer in 12.3.** The asymmetric-limit result here identifies the Lyapunov-weight limit as (S-3) autonomy reduction but leaves (S-2) function transfer unformalized. A complete symbiogenic-limit theorem requires specifying what happens to agent 1's state space when it inherits structure from agent 2 — how $\mathcal{F}(M_e, \Sigma_e)$ lands in M_h . This is flagged in 12.3's Working Notes and is a prerequisite for promoting the limit result to derived.
- **Connection to Miller-2022 extreme-transition motif.** The asymmetric-limit smooth-deformation result contrasts with extreme-transition dynamics (pending dedicated Part III segments) where population-level niche-replacement proceeds discontinuously. The two mechanisms co-exist and are not reducible to one another; the weighted-Lyapunov analysis is specific to bilateral asymmetric integration.
- **N-agent scaling.** The conjunction generalization “composite persists iff (CM4) holds pairwise for all i, j ” is probably too strong — pairwise cooperative effects can compose super-additively in particular topologies (ensemble filters, committee agents). A sharper N -agent theorem requires a graph-structured Lyapunov construction. See `spikes/spike-composition-scaling-N.md` for a framing of the question.
- **Dynamic-regime placement (added 2026-05-21 per Phase 5 cross-segment ripple).** The (CM2) / (CM2-M) closed-form result and the matched-Tier dyad machinery live on **R0 contraction-regime** per `#disc-dynamic-regime-axis`; this is the canonical *closed-form* R0 instantiation that backs `#disc-identifiability-floor` Instance 3 escape (b). The asymmetric-limit symbiogenic case is the canonical structural mechanism for the **R1 $\rightarrow$ R0 transition** on the dynamic-regime axis (`#disc-dynamic-regime-axis §"Transition asymmetry"`): symbiogenic absorption is what moves a composite up the regime ladder via self-driven ascent. Composites that remain in R1 (strategic equilibrium under partially-opposing objectives that have not absorbed) need the equilibrium-theoretic machinery in `#deriv-strategic-composition`, not (CM2).

Incidental audit gold (gold-lift, 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / forward-vision material, kept separate from certified theory-fix findings (off-ramp block at the end). **Coverage:** three substrates reached a digested reflection on this segment (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Gemini-voiced, AUDIT-WORKING-773921); AUDIT-WORKING-471203 touched it only by reference (the symbiogenesis asymmetric-limit connection from `#hyp-symbiogenic-composition`).

1. Candidate Briefprose / pre-prose.

- **“The equation of organizational physics.”** (CM2) $(\alpha - C)R > \rho + \gamma\mathcal{T}$ glossed as five levers of survival: correction efficiency α (smarter people / better tools), coordination overhead C (fewer meetings / decoupled architecture), structural capacity R (a model that absorbs large errors without breaking), environmental volatility ρ (stabler market / moats), and coupling $\gamma\mathcal{T}$ (aligned allies lower your effective disturbance; internal politics raises it). Compact and Feynman-flavored (Gemini, AUDIT-WORKING-829314, AUDIT-WORKING-773921).
- **“Cooperation as artificially lowering the disturbance each individual feels.”** Cooperative coupling enters through a *negative* term that can drive ρ_i^{eff} below the single-agent ρ — “this is formally how teams persist where individuals cannot.” Candidate plain-language hook for why composites form at all (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Brooks's Law as a theorem, not a heuristic.** The $C > \alpha$ limit (coordination overhead exceeds raw correction speed) drives the left side of (CM2) negative and *guarantees* structural collapse — moving “adding people to a late project makes it later” from an empirical software-engineering observation to a strict consequence of the dyadic Lyapunov inequality. Two substrates independently flagged this as the segment's most quotable consequence (Gemini, AUDIT-WORKING-193847, AUDIT-WORKING-829314).
- **Symbiogenesis as escape from the local persistence bound.** The asymmetric-limit ($\mu \rightarrow 0$) reading: when an agent cannot individually satisfy persistence (its ρ too high or R too small), its only mathematical escape from death is to merge into a larger system that *does* satisfy it — it lets its own state variables be marginalized out of the joint Lyapunov function in exchange for the host's stability guarantee. Offered as a unifying lens on mergers/acquisitions, biological endosymbiosis (mitochondria),

and the formation of nation-states as “the same physical imperative: escaping the local persistence bound by hiding inside a larger, more stable basin.” A vivid Discussion candidate — verify the analogy stays isomorphic before promoting past discussion-grade (Gemini, AUDIT-WORKING-829314).

- **The Goldilocks coupling band.** For a multi-agent consciousness: couple sub-agents tightly enough to share cognitive load (negative γ) but loosely enough that they don't spend all their tempo negotiating (C). Frames ($\alpha - C$) as a dynamically-monitored margin — prune communication channels when C climbs (Gemini, AUDIT-WORKING-193847).

3. Follow-up items.

- **Rivalrous-environment caveat on (UO-mult)** — also flagged below as an off-ramp finding, since it is a scope-correctness claim, not framing.
- The existing Working-Notes items (heterogeneous-architecture dyad, N -agent scaling) were independently re-surfaced by auditors as the natural next moves (Gemini, AUDIT-WORKING-193847 on the residual-autonomy “tempo tax” when μ does not quite reach zero; the N -agent $O(N^2)$ -communication-cost-forces- $C > \alpha$ hard-team-size-ceiling observation, AUDIT-WORKING-193847).

4. Readers often ask / wonder.

- **“What happens when μ doesn't quite reach zero?”** A natural question on the symbiogenic limit: the host pays a small tempo tax to manage the endosymbiont's residual autonomy — a partial-absorption regime the closed form does not yet name (Gemini, AUDIT-WORKING-829314).
- **“Can I apply (CM2) to a heterogeneous team?”** Readers will reach for the clean scalar inequality on mismatched- α teams; the matched-symmetric-Tier-1 scope restriction (and the Slotine contraction-metric machinery needed otherwise) is easy to miss (Gemini-voiced, AUDIT-WORKING-773921).

Belongs elsewhere.

- **ELI internal-architecture reading** (points at 04-eli-core/ / composite-mind design, not this appendix): the ($\alpha - C$) Goldilocks band as a design constraint on an ELI's sub-agent coupling — monitor the margin, force temporary return-to-autonomy when internal friction consumes adaptive capacity (Gemini, AUDIT-WORKING-193847).

Off-ramp (NOT gold) — routed for adjudication.

- **(UO-mult) conflates teleological unity with physical coupling.** Auditor challenge (Gemini, AUDIT-WORKING-193847): the discussion-grade map $\gamma(U_O) = -\gamma_{\max} U_O$ assumes aligned targets $\Rightarrow$ aligned actions $\Rightarrow$ constructive cross-contribution, which holds in *non-rivalrous* settings (information sharing) but can *invert* under resource contention — two agents with identical targets (“grab the only apple”) may interfere maximally, so $U_O = 1$ can *maximize* adversarial coupling $\gamma > 0$. Suggested resolution: explicitly decouple teleological unity (U_O) from physical/environmental coupling (γ) and scope (UO-mult) to non-rivalrous environments. Already discussion-grade with an LQR-compatibility-sketch caveat in the body, so this is a *scope-sharpening of an already-hedged claim* rather than a refuted result — but it is a correctness concern, not framing. Strengthen-first lens: the action-space inner-product derivation already named in Working Notes (item “Sharpen (UO-mult)”) is the place to land the rivalrous/non-rivalrous split as a derived condition.

Appendix K

Derivation: Gain-Sector Bridge — Proofs and Verification

Complete derivations for the results stated in 4.3: gain-based updating produces correction functions satisfying the sector condition (GA-3) whenever the update rule has directional fidelity. Four propositions are proved. **Prop B.1 (scalar Kalman)**: for scalar linear-Gaussian systems, the sector parameter equals the Kalman gain exactly. **Prop B.2 (matrix Kalman)**: for vector-valued systems, the sector condition holds in the inverse-prior-covariance-weighted inner product, with sector parameter equal to the smallest eigenvalue of KH on the observable subspace. **Prop B.3 (bridge theorem)**: the general gain-based update produces a sector-condition-satisfying correction function whenever directional fidelity (B1) holds. **Prop B.4 (gradient equivalence)**: the *two-point / incremental* sector condition (DA2'-inc, used by #form-composition-closure's bridge lemma) is equivalent to local strong convexity via Nesterov 2.1.10; the *one-point* sector (A2', what AAT's persistence machinery in #form-sector-condition actually requires) is *weaker* — strong convexity implies the one-point sector but not conversely (counterexample $L'(x) = x(1 + \frac{1}{2} \sin(10x))$).

The framework's overall posture is that the bridge is **conditional, not unconditional**: pathological update rules exist that satisfy every framework postulate and the gain-based update form yet violate directional fidelity. Scope plus gain structure alone does not force the bridge; some optimality / coherence / rationality constraint (Bayesian coherence, gradient-of-a-convex-loss) is required. The contribution is *characterizing which agent classes give the bridge for free* (sub-scope α per #form-sector-condition) and *which require the sector condition as a primitive posit* (sub-scope β). Numerical verification across six experiments — quadratic, logistic, Gaussian-mixture, exponential-family, quasi-convex, multi-modal — confirms the loss-function classification predicted by Prop B.4.

Motivation.

A proves persistence and stability downstream of the sector condition (GA-3): $\delta^T F(\mathcal{J}, \delta) \geq \alpha \|\delta\|^2$. The sector parameter α governs the persistence bound ($R^* = \rho/\alpha$), the adaptive reserve ($\Delta\rho^* = \alpha R - \rho$), and the adversarial scaling exponent. But whether the correction function F induced by the gain principle (3.6) actually satisfies GA-3 was not derived — GA-3 was the theory's softest structural joint.

This appendix closes the gap. For optimal Bayesian updates (Kalman, conjugate families), the bridge is exact: the sector parameter equals the gain. For gradient-based agents, GA-3 is equivalent to local strong convexity of the loss function. The load-bearing assumption shifts from “the correction function satisfies the sector condition” (opaque) to “the update rule has directional fidelity” (transparent, checkable).

Proposition B.1: Scalar Kalman Sector Condition.

Statement. For a scalar linear-Gaussian system ($n = m = 1, H = 1$) with Kalman filter gain $K = P^-/(P^- + R_{\text{obs}})$, the correction function $F(e) = K \cdot e$ satisfies the sector condition with:

Derived (scalar-Kalman-sector, from Kalman update).

$$\alpha = K = \frac{P^-}{P^- + R_{\text{obs}}} = \eta^* \quad (\text{K.1})$$

The sector parameter equals the Kalman gain, which equals the uncertainty-ratio gain from 3.6. The bound is tight (the correction is linear).

Proof. The scalar Kalman update for state estimate $\hat{x}$ given innovation $\delta = o - \hat{x}$ is $\hat{x}_{\text{post}} = \hat{x}_{\text{prior}} + K\delta$, where the gain is $K = P^-/(P^- + R_{\text{obs}})$ with P^- the prior variance and R_{obs} the observation noise variance.

The state-space estimation error $e = x - \hat{x}$ evolves under the correction step as:

$$e_{\text{post}} = e_{\text{prior}} - K(He_{\text{prior}} + \varepsilon) = (1 - K)e_{\text{prior}} - K\varepsilon \quad (\text{K.2})$$

With $H = 1$, the expected correction function is $F(e) = K \cdot e$. The sector product is:

$$e \cdot F(e) = K \cdot e^2 \quad (\text{K.3})$$

Since $P^- > 0$ and $R_{\text{obs}} > 0$, we have $K \in (0, 1)$. The sector condition $e \cdot F(e) \geq \alpha \cdot e^2$ holds with $\alpha = K$. The bound is tight because the correction is exactly linear. $\square$

Steady-state sector parameter. At steady state (random walk dynamics, $A = 1$), the prior variance satisfies the algebraic Riccati equation. Solving $K^2 R_{\text{obs}} + QK - Q = 0$ (where Q is the process noise variance) gives:

Derived (steady-state scalar sector parameter).

$$\alpha_{ss} = K_{ss} = \frac{-Q + \sqrt{Q^2 + 4QR_{\text{obs}}}}{2R_{\text{obs}}} \quad (\text{K.4})$$

Limiting behavior: when $Q \gg R_{\text{obs}}$ (fast dynamics, clean observations), $K_{ss} \rightarrow 1$; when $Q \ll R_{\text{obs}}$ (slow dynamics, noisy observations), $K_{ss} \approx \sqrt{Q/R_{\text{obs}}}$.

Connection to AAT quantities. The adaptive tempo for a single observation channel at rate ν is $\mathcal{T} = \nu \cdot K_{ss}$, and the sector parameter in the continuous-time framework is $\alpha = \mathcal{T}$. The bridge is trivial in the scalar case: the gain IS the sector parameter.

Proposition B.2: Matrix Kalman Sector Condition.

Statement. For a linear-Gaussian system with state $x \in \mathbb{R}^n$, observations $o \in \mathbb{R}^m$, observation matrix H , and Kalman gain $K = P^-H^T(HP^-H^T + R_{\text{obs}})^{-1}$, the correction function $F(e) = KH \cdot e$ satisfies the sector condition in the $(P^-)^{-1}$ -weighted inner product, restricted to the observable subspace $\mathcal{O} = \text{range}(H^T)$:

Derived (matrix-Kalman-sector, from Kalman covariance reduction).

$$e^T(P^-)^{-1}KH e = e^TH^TS^{-1}H e \geq \alpha \cdot e^T(P^-)^{-1}e \quad (\text{K.5})$$

where $S = HP^-H^T + R_{\text{obs}}$ is the innovation covariance, and:

$$\alpha = 1 - \lambda_{\max}(P_{t|t} P_{t|t-1}^{-1}) \quad (\text{K.6})$$

restricted to observable directions. In unobservable directions ($e \in \ker(H)$), $\alpha = 0$.

Proof. Define the $(P^-)^{-1}$ -weighted inner product: $\langle u, v \rangle_{P^-} = u^T(P^-)^{-1}v$. In this inner product the sector product becomes:

$$\langle e, KH e \rangle_{P^-} = e^T(P^-)^{-1}KH e \quad (\text{K.7})$$

Substituting $K = P^-H^TS^{-1}$:

$$e^T(P^-)^{-1}P^-H^TS^{-1}H e = e^TH^TS^{-1}H e \quad (\text{K.8})$$

Since $S > 0$, the matrix $H^TS^{-1}H$ is symmetric positive semidefinite, with null space $\ker(H)$. So $\langle e, KH e \rangle_{P^-} \geq 0$ for all e , with equality iff $He = 0$.

For the sector bound, we need $e^TH^TS^{-1}H e \geq \alpha \cdot e^T(P^-)^{-1}e$. From the Kalman covariance identity $KH = I - P(P^-)^{-1}$ (where $P = P_{t|t}$ is the posterior covariance), the eigenvalues of KH in the $(P^-)^{-1}$ -weighted sense are $1 - \lambda_i(P(P^-)^{-1})$, where λ_i denotes generalized eigenvalues.

Since $P \leq P^-$ (the posterior is no less certain than the prior), $\lambda_i(P(P^-)^{-1}) \leq 1$, so all eigenvalues of KH are non-negative. In observable directions, $P < P^-$ strictly, giving $\alpha > 0$. In unobservable directions, $P = P^-$ (no information gained), so $\alpha = 0$. $\square$

Fully observable diagonal case. When $H = I, A = I, Q = \text{diag}(q_1, \dots, q_n), R_{\text{obs}} = \text{diag}(r_1, \dots, r_n)$, the problem decouples into n scalar problems (each governed by Prop B.1), and:

Derived (diagonal-Kalman-sector).

$$\alpha = \min_{i=1}^n K_i = \min_{i=1}^n \frac{-q_i + \sqrt{q_i^2 + 4q_i r_i}}{2r_i} \quad (\text{K.9})$$

The bottleneck is the dimension with the worst signal-to-noise ratio, consistent with 16.5.

The weighted-norm subtlety. The Lyapunov proofs in A use the Euclidean norm ($V = \frac{1}{2}\|e\|^2$), while the matrix Kalman sector condition holds in the $(P^-)^{-1}$ -weighted norm. For fully observable systems with bounded condition number $\kappa(P^-)$, the norms are equivalent:

$$\alpha_{\text{Euclidean}} \geq \alpha_{\text{weighted}} / \kappa(P^-) \quad (\text{K.10})$$

The Lyapunov results remain valid with this quantitative adjustment. The weighted Lyapunov function $V(e) = \frac{1}{2}e^T(P^-)^{-1}e$ yields the tighter bound directly.

Proposition B.3: Bridge Theorem.

Statement. Given the gain-based update $M_t = M_{t-1} + \eta^* \cdot g(\delta_t)$ (3.6), with H mapping state-space corrections to observation-space mismatch reduction, the induced correction function $F(\delta) = \eta^* \cdot H g(\delta)$ satisfies the sector condition (GA-3) with parameter $\alpha > 0$ whenever:

(B1) Directional fidelity. The composite mismatch transform preserves the mismatch-reducing direction:

Derived (bridge-theorem, from update-gain + B1).

$$\delta^T H g(\delta) \geq c \|\delta\|^2 \quad \text{for } \|\delta\| \leq R \quad (\text{K.11})$$

for some $c > 0$. The sector parameter is:

$$\alpha = \eta^* \cdot c_{\min}, \quad c_{\min} = \inf_{\|\delta\| \leq R} \frac{\delta^T H g(\delta)}{\|\delta\|^2} \quad (\text{K.12})$$

Proof. The gain-based update changes the model state by $\Delta M = \eta^* \cdot g(\delta)$. The induced change in predicted observation is $H \cdot \Delta M = \eta^* \cdot H g(\delta)$, so the expected correction function (the mismatch reduction per step) is:

$$F(\delta) = \eta^* \cdot H g(\delta) \quad (\text{K.13})$$

The sector product is:

$$\delta^T F(\delta) = \eta^* \cdot \delta^T H g(\delta) \quad (\text{K.14})$$

By B1: $\delta^T H g(\delta) \geq c_{\min} \|\delta\|^2$. Since $\eta^* > 0$ (the agent updates), we have:

$$\delta^T F(\delta) \geq \eta^* \cdot c_{\min} \|\delta\|^2 = \alpha \|\delta\|^2 \quad \square \quad (\text{K.15})$$

When B1 holds by construction. For optimal Bayesian updates (Kalman, conjugate families, exponential families), the posterior update minimizes expected loss, ensuring the correction aligns with the mismatch. B1 holds by optimality, not by assumption. The gain principle $\eta^* = U_M / (U_M + U_o)$ determines only the magnitude; the direction is guaranteed by the update rule's optimality. For gradient descent on a convex loss, B1 follows from gradient monotonicity (the defining property of convexity).

Proposition B.4: Gradient Equivalence.

Statement. For any agent updating via gradient descent on a differentiable loss L with learning rate η and minimizer M^* (where $\nabla L(M^*) = 0$), there are two distinct results corresponding to the one-point and two-point sector conditions:

(B.4-i) One-point sector $\Leftarrow$ strong convexity (one direction only). The one-point sector condition at M^* — equivalent to AAT’s GA-3 / A2’ as stated in 4.2 — is

$$\delta^T F(\delta) \geq \alpha \|\delta\|^2 \quad \text{for } \|\delta\| \leq R \quad (\text{K.16})$$

evaluated at fixed equilibrium M^* . Local (α/η) -strong convexity of L on $\mathcal{B}_R(M^*)$ implies this one-point sector condition with $\alpha = \eta\mu$, but the converse fails: there exist losses satisfying the one-point sector condition that are *not* strongly convex on any neighborhood of M^* (counterexample below).

(B.4-ii) Two-point sector $\Leftrightarrow$ strong convexity (full equivalence). The two-point / incremental sector condition — DA2’-inc in O and the bridge-lemma precondition in 13.1 — is

Derived (sector-convexity-equivalence, two-point form).

$$(F(\delta_1) - F(\delta_2))^T(\delta_1 - \delta_2) \geq \alpha \|\delta_1 - \delta_2\|^2 \quad \text{for } \delta_1, \delta_2 \in \mathcal{B}_R(M^*) \quad (\text{K.17})$$

Under this strengthened condition the iff holds:

$$\text{Two-point sector with } (\alpha, R) \iff L \text{ is } (\alpha/\eta)\text{-strongly convex on } \mathcal{B}_R(M^*) \quad (\text{K.18})$$

with $\alpha = \eta\mu$ and $\mu = \inf_{\delta \in \mathcal{B}_R(M^*)} \lambda_{\min}(\nabla^2 L(M^* + \delta))$. The basin radius R is the largest ball around M^* where $\nabla^2 L$ remains positive definite.

Proof of (B.4-ii). The correction function for gradient descent is $F(\delta) = \eta \cdot \nabla L(M^* + \delta)$ (continuous-time form absorbing event rate ν into $\mathcal{T} = \nu \cdot \eta$). The two-point sector condition becomes:

$$\eta \cdot (\nabla L(M^* + \delta_1) - \nabla L(M^* + \delta_2))^T(\delta_1 - \delta_2) \geq \alpha \|\delta_1 - \delta_2\|^2 \quad (\text{K.19})$$

Dividing by $\eta > 0$ gives gradient monotonicity with modulus $\mu = \alpha/\eta$. By Nesterov 2004, Theorem 2.1.10, L is μ -strongly convex on $\mathcal{B}_R(M^*)$ iff this gradient monotonicity holds for all $x, y \in \mathcal{B}_R(M^*)$. The equivalence is bidirectional:

($\Rightarrow$) Two-point sector with (α, R) yields gradient monotonicity with $\mu = \alpha/\eta$, hence strong convexity.

($\Leftarrow$) μ -strong convexity gives gradient monotonicity, multiplying by η recovers the two-point sector condition with $\alpha = \eta\mu$. $\square$

Proof of (B.4-i) one direction. Setting $\delta_1 = \delta$, $\delta_2 = 0$ in the two-point condition and using $\nabla L(M^*) = 0$ recovers the one-point form $\delta^T F(\delta) \geq \alpha \|\delta\|^2$. So strong convexity (which is equivalent to the two-point sector by (B.4-ii)) implies the one-point sector. The reverse direction does not hold; see the counterexample below. $\square$

Counterexample showing one-point $\nRightarrow$ strong convexity. Let $L : \mathbb{R} \rightarrow \mathbb{R}$ have $L'(x) = x(1 + \frac{1}{2} \sin(10x))$ with $L'(0) = 0$ (so $x^* = 0$). The one-point sector at x^* is

$$x \cdot L'(x) = x^2 (1 + \frac{1}{2} \sin(10x)) \geq \frac{1}{2} x^2, \quad (\text{K.20})$$

so the one-point sector holds globally with $\mu = \frac{1}{2}$. But $L''(x) = 1 + \frac{1}{2} \sin(10x) + 5x \cos(10x)$ takes values such as $L''(\pi/10) = 1 - \pi/2 \approx -0.57 < 0$, so L is not convex on any neighborhood of x^* that contains $\pi/10$. The one-point sector at the equilibrium is genuinely weaker than full local strong convexity — a structural distinction, not a smoothness artifact. The full two-point sector fails on this L for any pair (δ_1, δ_2) straddling a region where $L'' < 0$ (gradient monotonicity fails there), so (B.4-ii) correctly identifies this L as a non-instance.

The α factorization (under (B.4-ii)). The decomposition $\alpha = \eta \cdot \mu$ separates agent design (η , responsiveness) from environment structure (μ , loss curvature). The adaptive tempo maps as $\alpha \propto \mathcal{T}$: higher gain or steeper curvature means faster mismatch correction.

Where each direction lands in AAT. The one-point form is what #form-sector-condition's A2' ((A2')) applied at $\delta^* = 0$ requires for Lyapunov persistence (via A) — and what AAT's six persistence-flavored results inherit through #result-sector-persistence-template (T2). The two-point / incremental form is what #form-composition-closure's bridge lemma requires (DA2'-inc) for full-update-map contraction at the composite level. Strong convexity sits at the strict end of this scale: it implies both. The one-point $\nRightarrow$ two-point counterexample above is exactly why AAT distinguishes the two — Lyapunov persistence is available for some agent classes (variational, PID-bounded-plant) where bridge-lemma contraction is not.

Loss Function Classification.

The gradient equivalence (Prop B.4) classifies which loss functions satisfy GA-3, and with what parameters:

Table K.1

Loss class	Strong convexity	α	Basin R	Status
Quadratic (Kalman, linear regression)	Global: $\mu = \lambda_{\min}(H)$	$\eta \cdot \lambda_{\min}(H)$	∞	Exact
Exponential family (natural params), bounded scope	Pointwise on the interior; uniform on any compact $\Theta_0 \subset \text{int}(\Theta)$: $\mu_0 = \inf_{\theta \in \Theta_0} \lambda_{\min}(\mathbf{I}(\theta)) > 0$	$\eta \cdot \mu_0$	Θ_0 (compact / interior-bounded)	Exact within Θ_0
L2-regularized convex loss	Global: $\mu \geq \lambda$	$\eta \cdot \lambda$ (floor)	∞	Exact
Unregularized logistic	Global convex, not strongly	$\eta \cdot \mu(R)$, decaying	∞ (but $\alpha \rightarrow 0$)	Local
Quasi-convex	$\delta^T \nabla L \geq 0$ but ratio $\rightarrow 0$	$\eta \cdot \mu(R) \rightarrow 0$	Finite effective	Local
Non-convex within basin	Local: $\mu > 0$ in basin	$\eta \cdot \mu_{\text{local}}$	Distance to nearest saddle	Local
Non-convex beyond basin	Fails: $\lambda_{\min}(\nabla^2 L) < 0$	N/A	N/A	Fails

Key observations:

1. *Exponential family models in natural parameter form satisfy GA-3 pointwise on the interior of the natural-parameter space, and uniformly on any compact subset of the interior.* The Hessian is the Fisher information matrix $\mathbf{I}(\theta)$, which is positive definite in $\text{int}(\Theta)$ — but pointwise positive definiteness does not imply a uniform global lower bound on $\lambda_{\min}(\mathbf{I}(\theta))$. The Poisson natural parameter is the canonical counterexample: $\mathbf{I}(\theta) = e^\theta$ on $\Theta = \mathbb{R}$, so $\inf_{\theta \in \mathbb{R}} \mathbf{I}(\theta) = 0$ and no global sector constant exists. A uniform $\mu_0 > 0$ — and hence a global $\alpha = \eta \mu_0$ — requires either (i) restricting the operating region to a compact $\Theta_0 \subset \text{int}(\Theta)$ on which $\mu_0 := \inf_{\theta \in \Theta_0} \lambda_{\min}(\mathbf{I}(\theta)) > 0$, or (ii) verifying a uniform Fisher lower bound for the family in question (Gaussian-mean and Beta-Bernoulli, whose Fisher information is bounded below on the interior of Θ , qualify; Poisson

and Gamma-shape do not on the full natural-parameter line). The compact-scope condition is verifiable per-application from the agent's prior support and corresponds to taking R as the diameter of Θ_0 in the natural-parameter coordinate, matching A2's local-region structure (4.2).

2. *L2 regularization transforms locally strongly convex losses into globally strongly convex ones.* The regularization parameter λ provides a floor: $\alpha \geq \eta\lambda$ everywhere.
3. *Non-convex losses satisfy GA-3 within each basin of attraction.* The basin radius R is the distance from the local minimum to the nearest inflection surface (where $\lambda_{\min}(\nabla^2 L) = 0$). Beyond the basin, the sector condition fails — this IS the structural-adaptation trigger from 4.8.

Failure Modes.

The bridge fails in precisely five cases. These characterize the exact conditions under which the gain-based update does NOT produce a correction function satisfying the sector condition.

FM-1: Directional Infidelity. The mismatch transform g rotates the correction away from the mismatch direction, so $\delta^T H g(\delta) \leq 0$.

Example. If $\delta \in \mathbb{R}^2$ and $g(\delta) = R_{90}\delta$ (a 90-degree rotation), then $\delta^T g(\delta) = 0$ for all δ . The correction is perpendicular to the mismatch and never reduces it.

When it occurs. Pathological parameterizations where the model-space update direction is misaligned with observation-space mismatch. For optimal Bayesian updates, B1 holds by construction — the posterior minimizes expected loss.

FM-2: Gain Collapse. $\eta^* \rightarrow 0$ while $\rho > 0$, so $\alpha \rightarrow 0$ and the persistence condition $\alpha > \rho/R$ eventually fails. An agent accumulating experience in a non-stationary environment will eventually have gain too small to track changes. This is not a bridge failure but a persistence-condition failure — the bridge holds ($\alpha = \eta^* \cdot c > 0$ for finite experience), but α falls below ρ/R . See 3.6.

FM-3: Nonlinear Saturation. The correction function g saturates at large $\|\delta\|$, so the sector ratio $\delta^T g(\delta)/\|\delta\|^2$ decays. For a saturating function such as $g(\delta) = \tanh(\delta)$, the local sector parameter is:

$$\alpha(R) = \eta^* \cdot \frac{\tanh(R)}{R} \quad (\text{K.21})$$

For small R , $\alpha \approx \eta^*$ (linear regime). For large R , $\alpha \approx \eta^*/R$ (saturated regime). The sector condition holds locally — the valid region shrinks as the nonlinearity strengthens. This is exactly what the local form A2' in 4.2 anticipates.

FM-4: Unobservable Directions. When $\ker(H) \neq \{0\}$ (fewer observations than state dimensions), the correction has no effect on mismatch components in $\ker(H)$. The sector condition holds only in the observable subspace $\mathcal{O} = \text{range}(H^T)$. This is a structural limitation: the agent cannot correct errors it cannot observe. See 9.3.

For persistence in the full state space, the system must be *detectable*: all unstable modes must be observable. Stable unobservable modes decay naturally without correction.

FM-5: Model Misspecification. The model class does not contain the truth, so the gradient direction is systematically wrong. B1 fails because the correction aims at the wrong target. The sector parameter degrades proportionally to the misspecification. This is the 4.8 trigger: the correction function fails not because the gain is wrong but because the correction *direction* is wrong.

Simulation Results Summary.

Six numerical experiments validate the gradient equivalence (Prop B.4) and the loss-function classification.

Experiment 1: Quadratic Loss (Global Strong Convexity). $L(w) = \frac{1}{2}(w - w^*)^T H(w - w^*)$ with $w \in \mathbb{R}^5$, Hessian eigenvalues $\{0.5, 1.0, 2.0, 3.0, 5.0\}$, $\eta = 0.1$. The sector ratio $\delta^T F / \|\delta\|^2$ at every gradient-descent step fell within $[\eta\mu, \eta L] = [0.05, 0.50]$, confirming Prop B.4 exactly. No step violated the bound.

Experiment 2: Logistic Regression (Position-Dependent Convexity). Logistic regression with $d = 2, N = 5000$ samples. Unregularized: sector ratio positive along the entire trajectory, with local μ ranging from 0.076 (at MLE) to higher values far from it. With L2 regularization ($\lambda = 0.1$): sector ratio bounded below by $\eta\lambda = 0.03$ at every point, confirming the global floor.

Experiment 3: Gaussian Mixture (Non-Convex, Basin Structure). Two-component Gaussian mixture. Within basin ($r < 3.1$): Hessian positive definite, sector ratio positive, gradient descent converges to correct optimum. At basin boundary ($r \approx 3.1$): Hessian eigenvalue crosses zero. Beyond basin ($r > 3.5$): sector ratio negative, gradient descent converges to wrong optimum. Basin boundary confirmed as sharp transition, matching the 4.8 trigger.

Experiment 4: Local Sector Parameter Measurement. Same Gaussian mixture. Sector parameter $\alpha(r)$ decreases monotonically from 181.4 (at $r = 0.5$) to 125.8 (at $r = 3.0$), then drops to zero at $r \approx 3.1$. The decay is moderate within the basin (69% retention at the boundary); the transition at the boundary is sharp.

Experiment 5: Exponential Family (Poisson, Natural Parameters). Poisson in natural parameter space. Sector ratio positive at every step, ranging from 0.00177 to 0.00240 (with $\eta = 0.001$). Confirms global strong convexity of exponential family losses in natural parameterization.

Experiment 6: Quasi-Convex and Multi-Modal Losses. *Quasi-convex* ($L(w) = -1/(1 + w^2)$): sector ratio always positive but decays as $O(1/w^4)$. No uniform lower bound exists — $\alpha(R) \rightarrow 0$, making persistence bounds vacuous for large R .

Multi-modal ($L(w) = \sin(w) + 0.01w^2$): sector condition holds within each basin ($|\delta| < 3.0$), fails at basin boundary (gradient reversal at local maximum). Basin radius $\approx$ distance from local minimum to nearest local maximum.

Epistemic Status.

Propositions B.1 and B.2 are *exact* — they follow from standard Kalman filter algebra. The only subtlety is the weighted norm in the matrix case (B.2), which is a quantitative refinement, not a qualitative gap. Both are standard results in estimation theory reframed in sector-condition language.

Proposition B.3 (Bridge Theorem) is a *conditional derivation*: exact under B1 (directional fidelity). B1 holds by construction for optimal Bayesian updates (the posterior minimizes expected loss, ensuring the correction aligns with the mismatch). For approximate update rules, B1 is a design condition, not a global assumption. The condition is transparent and checkable for specific systems.

Proposition B.4 (Gradient Equivalence) splits along the one-point / two-point distinction. (B.4-ii) — the iff between strong convexity and the *two-point / incremental* sector condition (DA2'-inc) — is an *exact mathematical equivalence*: bidirectional via Nesterov 2.1.10. (B.4-i) — the relation to AAT's one-point sector A2' as stated in 4.2 — is *one-directional only*: strong convexity implies the one-point sector at M^* , but not conversely. The Codex-style counterexample $L'(x) = x(1 + \frac{1}{2}\sin(10x))$ satisfies the one-point sector globally yet has L'' negative on intervals, ruling out a converse. The loss-function classification table is read accordingly: rows that supply strong convexity satisfy both forms; rows that supply only one-point sector (none in the current table — strong convexity is the universal column)

would not transfer to two-point. The simulation experiments confirm the theoretical predictions across all six loss classes tested; no violations were observed where the theory predicts the sector condition holds.

Max attainable: *conditional* for the bridge (B1 is inherent — pathological update rules exist), *exact* for the gradient equivalence in its two-point form (B.4-ii) and *exact one-direction* for its one-point form (B.4-i). The condition cannot be removed: there exist correction functions that violate the sector condition (FM-1 through FM-5), and there exist losses that satisfy the one-point sector at M^* without being strongly convex (the Codex-style counterexample), which is why the one-point $\nRightarrow$ two-point gap is structural rather than a smoothness artifact.

What remains open. (1) Non-gradient agents (PID controllers, rule-based systems, human judgment): GA-3 remains an empirical claim for these agent classes. (2) Time-varying α : when the gain adapts (Adam, RMSprop, Kalman transient), $\alpha(t)$ varies; the Lyapunov analysis extends to time-varying $\alpha(t) \geq \underline{\alpha} > 0$ via standard results (Khalil 2002, Chapter 8). (3) Stochastic gradients: SGD satisfies the sector condition *in expectation*; the per-step noise enters as effective disturbance in the Prop A.1S framework.

Discussion.

The formal chain is closed for well-designed agents. The prediction chain becomes:

gain principle+B1 (directional fidelity) $\xrightarrow{\text{Prop B.3 (exact)}}$ sector condition (GA-3) $\xrightarrow{\text{Props A.1, A.1S, A.2 (exact)}}$ persistence, reserve, scaling (K.22)

For optimal Bayesian updates, B1 holds by construction, making the full chain a derivation. For gradient agents, B1 is equivalent to local strong convexity — a well-characterized property.

GA-3 is grounded, not floating. The assumption load shifts from “the correction function satisfies the sector condition” (what correction function?) to “the update rule has directional fidelity” (the correction at least points toward reality). For the important agent classes — Kalman filters, conjugate posteriors, exponential families, gradient descent on convex losses — this is automatic.

Basin boundary = structural adaptation trigger. For gradient agents with non-convex losses, the basin radius R is the convexity radius of the loss landscape. When mismatch exceeds R , the correction function reverses direction. This is the 4.8 trigger with a precise geometric characterization: structural adaptation is needed when the agent crosses an inflection surface of its loss landscape.

Working Notes.

- The fluid-limit gap: the bridge analysis works in expected value. The actual per-step correction is stochastic; observation noise ε contributes $K\varepsilon$ to each update, acting as effective disturbance of magnitude $\|K\|\sigma_\varepsilon$ per step. This maps to the Prop A.1S (stochastic) framework — the sector condition on the expected correction plus stochastic noise.
- For variational inference and other approximate methods, B1 is not guaranteed by optimality and must be verified per approximation scheme.
- The adaptive-reserve factorization for gradient agents is $\Delta\rho^* = \eta\mu R - \rho$, with three controllable factors: gain η , curvature μ , and basin width R . An agent is robust when $\eta\mu R \gg \rho$.
- Full simulation code, raw traces, and intermediate analysis live in `spikes/.integrated/spike-gain-sector-bridge-nonlinear.md`; the segment carries the parameters and outcomes that establish the result. Landing-context provenance: this segment consolidates `spikes/.integrated/spike-gain-sector-bridge.md` (Kalman / bridge theorem) and `spikes/.integrated/spike-gain-sector-bridge-nonlinear.md` (gradient equivalence and the six experiments).

Incidental audit gold (gold-lift, 2026-05-31). Cross-audit ideation harvested from de-novo auditors’ working dirs, deduplicated and lightly attributed. Orthogonal framing / pedagogy material; off-ramp (already-resolved + dimensional-convention) at the end. **Coverage:** three substrates reached a digested reflection (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-584721; Codex, AUDIT-WORKING-742613), plus cross-cycle confirmation from Claude, AUDIT-WORKING-963715 and Gemini, AUDIT-WORKING-849201.

1. *Candidate Briefprose / pre-prose.*

- **“The Rosetta Stone between Control and ML.”** Prop B.4’s gradient-equivalence (under the corrected one-way reading) shows gradient descent on a strongly-convex loss is the same object as a Kalman filter on a linear system — both instances of the sector condition. A plain-language anchor for why the bridge matters: it lets control-theoretic persistence bounds apply to learning systems (Gemini, AUDIT-WORKING-193847).
- **The $\alpha = \eta\mu$ factorization as the diagnostic.** It separates *agent-design* (gain η , tunable by the designer) from *environment-structure* (curvature μ , basin width R , given by the world); adaptive reserve $\Delta\rho^* = \eta\mu R - \rho$ then reads as a three-factor budget, and “robustness = $\eta\mu R \gg \rho$ ” is the one-line takeaway (Claude, AUDIT-WORKING-584721).

2. *Candidate Discussion.*

- **The FM-1–FM-5 failure-mode taxonomy as a diagnostic for learning collapse.** Two substrates singled out the failure-mode classification as standout pedagogy — it formally separates vanishing-gradient (FM-3), misspecification (FM-5), and unobservable-latent-state (FM-4) failures. Candidate to surface more prominently as the segment’s diagnostic contribution (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-584721 praises the loss-classification table as a model for other segments).
- **Directional infidelity (FM-1) as organizational “blame-shifting.”** When the update rule rotates the correction away from the true mismatch direction, $\delta^\top g(\delta) \rightarrow 0$ and the sector parameter $\alpha \rightarrow 0$ even at high gain η^* : the system expends huge effort and learns nothing. The organizational analog (firing a mid-level manager instead of fixing the structural flaw) makes the abstract orthogonality condition concrete, and the consciousness-infrastructure reading — *the internal update must point at the source of the error; an agent that rotates its own error-gradient to protect a favored hypothesis suffers FM-1* — is a vivid pedagogical extension (Gemini, AUDIT-WORKING-193847).
- **Quasi-convex plateaus are worse than steep narrow basins.** The $\alpha \rightarrow 0$ -as- $R \rightarrow \infty$ case: a plateau gently sloping toward a hole provides *zero adaptive reserve* against drift, whereas a narrow steep non-convex basin at least gives strong local correction — a counterintuitive consequence of the sector geometry worth naming (Gemini, AUDIT-WORKING-193847).

3. *Follow-up items.*

- **The “expected-bridge + stochastic-disturbance” composition is a meta-pattern.** The bridge analysis works in expected value (already in Working Notes as the fluid-limit gap); the stochastic per-step residual $\|K\|\sigma_\varepsilon$ enters as Model-S disturbance under Prop A.1S — so the framework’s expected-value bridge results compose cleanly with its stochastic noise treatments. Flagged as a candidate cross-segment structural observation, not just a local note (Claude, AUDIT-WORKING-584721).
- The fully-observable diagonal case $\alpha = \min_i K_i$ (bottleneck dimension sets persistence) lines up with #result-per-dimension-persistence; the 72% scalar-overestimate from #def-adaptive-tempo anisotropy presumably comes from averaging where minimization is correct (Claude, AUDIT-WORKING-584721).

4. *Readers often ask / wonder.*

- **“Is the gradient equivalence really an iff?”** This is exactly the question the corrected B.4 (one-way $\Leftarrow$) answers — see off-ramp; worth a one-line forward-pointer so a fresh reader does not re-derive the false converse (Codex, AUDIT-WORKING-742613; verified first-hand at Claude, AUDIT-WORKING-963715 — “mathematically precise and consequential”).

Off-ramp (NOT gold) — routed for adjudication.

- **Prop B.4 gradient-equivalence “iff” overstatement — RESOLVED-BY-STRENGTHENING** (recorded so it is **not re-opened**). Codex (AUDIT-WORKING-742613, “candidate finding K”) and Gemini (AUDIT-WORKING-849201) independently flagged that the one-point sector condition (monotonicity relative to M^*) is *strictly weaker* than local strong convexity; the proof’s reverse direction silently replaced the one-point inequality with full two-point gradient monotonicity (witness $L'(x) = x(1 + \frac{1}{2} \sin(10x))$: one-point sector holds with $\mu = \frac{1}{2}$ while L'' goes negative nearby). Per the cycle records (742613-F3, resolved by strengthening; landing at the B.4 split — one-point $\Leftarrow$ vs two-point $\Leftrightarrow$), this was **already corrected in current canon**. Flagged here only as a regression-guard: the segment’s counterexample $L'(x) = x(1 + \frac{1}{2} \sin(10x))$ is the *defense* of the corrected one-way reading, not a defect — do not “restore” an iff.
 - **Exponential-family global-strong-convexity scope (likely subsumed by the B.4 correction)**. Codex (AUDIT-WORKING-742613): “all exponential-family models in natural-parameter form satisfy GA-3 globally” is too strong — pointwise PD Fisher information does not give a uniform global lower bound (Poisson natural parameter: Fisher = e^θ , $\inf_{\mathbb{R}} = 0$). Global sector constants need a compact / bounded-away-from-boundary region or a uniform Fisher lower bound. Verify whether the B.4 split already scoped this.
 - **Per-event vs per-time normalization (architectural; tracked in PROPOSALS)**. The deeply-mathematical AUDIT-WORKING-526815 cycle (F13) flags that #der-gain-sector-bridge derives $\alpha = \eta^* c_{\min}$ while persistence uses α as a *rate* and tempo is $\mathcal{T} = \nu \eta^*$ — the event-rate factor ν is omitted unless F is time-aggregated. Cross-cycle convergence (471203, 526815) reads this as “the bridge is *incomplete*, and downstream segments treat it as complete,” with the strengthen-first answer being to finish the bridge + its proof dependencies (this segment, #deriv-sector-condition) *first*, then propagate the cleaned dimensional convention. Routed architectural $\rightarrow$ PROPOSALS, connected to PRACTICA’s persistence-and-stability area.
 - **FM-3 saturation hard ceiling (scope-sharpening)**. Gemini (AUDIT-WORKING-193847): for $g(\delta) = \tanh(\delta)$, the local sector parameter $\alpha(R) = \eta^* \tanh(R)/R$ correctly decays, but the *force* saturates — so survival is impossible if $\rho > \|F\|_{\max}$, independent of basin radius R or linear-regime gain η^* . Suggested: add a note to FM-3 that saturating nonlinearities cap the maximum absolute correction speed.
-

Appendix L

Derivation: Recursive Update — Uniqueness Derivation

Appendix derivation backing 3.2. The claim being established is *uniqueness*: under three constraints — arrow of time, partial observability, and state completeness — the recursive form $M_{\tau+} = f(M_{\tau-}, e_{\tau})$ is the only update form realizable, not merely one consistent option. The structure is an elimination argument over the universe of information potentially accessible at event time τ : the environment state, the full chronica, all prior model states, the current event e_{τ} , and future events.

The three constraints do different kinds of work. **C1 (arrow of time, from 1.7)** rules out dependence on future events: in a classical universe such information is simply not accessible, and predictions about the future, however accurate, are internal computations belonging to $M_{\tau-}$, not future information. **C2 (partial observability, from 1.5 and 1.3)** rules out direct access to Ω_{τ} except through the lossy observation channel e_{τ} . **C3 (state completeness, from 2.1)** compresses all prior-past information — the full chronica and every earlier model state — into $M_{\tau-}$, because by construction M is the agent’s complete internal state and any information available to the update but not in M would mean M was misspecified. After all three eliminations only $(M_{\tau-}, e_{\tau})$ remains in the dependency set. A measure-theoretic version via the Doob–Dynkin lemma — restricting the agent’s sigma-algebra to $\sigma(M_{\tau-}, e_{\tau})$ — gives a cleaner technical proof.

The derivation then mounts seven adversarial attacks to test whether the result really holds. Simultaneous events are absorbed by treating the bundle as a single e_{τ} (form preserves). Continuous environmental coupling is genuinely outside the event-driven formulation — but the analogous result reached by the same three-constraint argument in continuous time is the state-space representation $\dot{M} = g(M, u)$ from classical control theory, so the underlying structure survives. The objection that C3 is circular — anything not in M gets absorbed into M by definition — is acknowledged as the deepest objection, and the derivation is explicit about it: the real content is an *analytical commitment* that by defining M as complete one commits to Markovian analysis, which then makes 2.3 the right quality metric. Shared state, external randomness, time-dependence, and agents that store full history each reduce to the recursive form by appropriate enlargement of the model space or interpretation of f .

The honest epistemic accounting at the end is load-bearing. **C1** (physical postulate) and **C2** (scope definition) do *eliminative* work — they rule out physically impossible and scope-excluded update forms. **C3** (analytical commitment) does not eliminate; it is *definitional* and cannot be “violated” because any apparent violation is absorbed by expanding M . The recursive form’s uniqueness is therefore conditional on accepting the three-constraint set, not on the constraints being independently inescapable — C3 in particular *could* be refused, at the cost of leaving AAT’s scope and accepting non-Markovian analysis. The Markov property is not a discovered law of adaptive systems but the unique form compatible with the modeling commitment of 2.1.

Setup.

We work within AAT's scope (1.5): an agent coupled to an environment Ω through observation and action channels, with residual uncertainty.

Universe of information at event time τ . The following information exists (in the broadest ontological sense) at the moment event e_τ occurs:

Table L.1

<i>Information</i>	<i>Description</i>
Ω_τ	The environment state
$\mathcal{C}_{\tau-}$	The complete interaction history (1.4) up to (but not including) e_τ
$\{M_{\tau'}\}_{\tau' \leq \tau-}$	The agent's prior internal states, culminating in $M_{\tau-}$
e_τ	The current event (observation arriving or action completing)
$\{e_{\tau'}\}_{\tau' > \tau}$	Future events (not yet occurred)

The question: of these, which can the update $M_{\tau+}$ depend on?

The Three Constraints.

Constraint 1 — Arrow of time (1.7 postulate). Events are temporally ordered and this ordering is irreversible. An update occurring at time τ cannot depend on events that have not yet occurred:

$$M_{\tau+} \text{ cannot depend on } \{e_{\tau'}\}_{\tau' > \tau} \quad (\text{L.1})$$

This is a physical constraint — the most primitive one. In a classical universe, information from the future is simply not available. Even if the agent can *predict* future events, those predictions are part of $M_{\tau-}$ (they are internal computations, not future information).

Constraint 2 — Partial observability (1.5). The agent cannot access Ω_τ directly. Its only interface with the environment is through the event e_τ , which is a lossy function of Ω_τ (via 1.3):

$$M_{\tau+} \text{ cannot depend on } \Omega_\tau \text{ except through } e_\tau \quad (\text{L.2})$$

This is a scope constraint. If the agent could access Ω directly, the residual uncertainty condition in 1.5 would be trivially violable.

Constraint 3 — State completeness (2.1). $M_{\tau-}$ is the agent's *complete* internal state just before event e_τ . There is no information about the agent's past that is available to the update mechanism but not encoded in $M_{\tau-}$:

$$M_{\tau+} \text{ cannot depend on } \mathcal{C}_{\tau-} \text{ or } \{M_{\tau'}\}_{\tau' < \tau-} \text{ except through } M_{\tau-} \quad (\text{L.3})$$

This constraint does the most interesting work and deserves careful examination (see Discussion below).

The Derivation.

Result (Recursive Update Uniqueness). Under Constraints 1–3, the model update at event time τ must have the form

$$M_{\tau+} = f(M_{\tau-}, e_{\tau}) \quad (\text{L.4})$$

for some (possibly stochastic) function $f : \mathcal{M} \times \mathcal{E} \rightarrow \mathcal{M}$. No other update form is consistent with the three constraints.

Derivation. Consider the most general possible update. The updated state $M_{\tau+}$ is a function of *all accessible information*:

$$M_{\tau+} = F(\text{accessible information at } \tau) \quad (\text{L.5})$$

We characterize the accessible information by eliminating what is not accessible.

(i) Eliminate future events. By C1 (arrow of time), $\{e_{\tau'}\}_{\tau' > \tau}$ is not accessible.

After this elimination, the candidate dependency set is: $\{\Omega_{\tau}, \mathcal{C}_{\tau-}, \{M_{\tau'}\}_{\tau' \leq \tau-}, e_{\tau}\}$

(ii) Eliminate direct environment access. By C2 (partial observability), the agent cannot access Ω_{τ} except through the event e_{τ} . Any information from Ω_{τ} that reaches the agent does so through e_{τ} — already in the dependency set.

After this elimination: $\{\mathcal{C}_{\tau-}, \{M_{\tau'}\}_{\tau' \leq \tau-}, e_{\tau}\}$

(iii) Reduce past information to $M_{\tau-}$. By C3 (state completeness), $M_{\tau-}$ is the agent's complete internal state. Every element of $\mathcal{C}_{\tau-}$ and every prior model state $M_{\tau'}$ ($\tau' < \tau-$) that could influence the update can do so *only through* its effect on $M_{\tau-}$. The agent's internal state evolves through a sequence of updates; the cumulative effect of all prior events is exactly $M_{\tau-}$. The raw events that produced this state are no longer separately available — they were “consumed” by the update mechanism and their information (to the extent it was retained) is now encoded in $M_{\tau-}$.

Could the agent maintain a separate log of raw events outside of M ? It could — but that log *is part of* M . Whatever information the agent retains in any form — model parameters, cached data, raw event buffers, metadata — is by definition part of its complete internal state $M_{\tau-}$. If something is available to the update mechanism and not in $M_{\tau-}$, then $M_{\tau-}$ was not the complete state — contradicting C3.

After this elimination: $\{M_{\tau-}, e_{\tau}\}$

Therefore: $M_{\tau+} = F(M_{\tau-}, e_{\tau}) \equiv f(M_{\tau-}, e_{\tau})$

This is the unique form: no information beyond $(M_{\tau-}, e_{\tau})$ is accessible under the three constraints, so no update form depending on anything else is realizable. $\square$

Corollary (Between-events dynamics). Between events, no new event e arrives. The same argument applies with e_{τ} removed from the accessible set:

$$\frac{dM}{d\tau} = g(M_{\tau}) \quad (\text{L.6})$$

The agent's internal evolution between events (prediction, decay, internal simulation) depends only on the current state. $\square$

Corollary (Serial special case). When observations and actions alternate at a uniform rate on a single channel, each event e_t is the pair (o_t, a_{t-1}) . The update becomes:

$$M_t = f(M_{t-1}, o_t, a_{t-1}) \quad (\text{L.7})$$

This is the familiar discrete-time form. $\square$

Information-Set Formalization.

For readers who prefer a measure-theoretic framing:

The agent's **information set** at time τ is the sigma-algebra $\mathcal{J}_\tau^{\text{agent}}$ — the collection of events (in the probability-theoretic sense) about which the agent can condition its update.

- **C1** restricts $\mathcal{J}_\tau^{\text{agent}} \subseteq \sigma(\{e_{\tau'} : \tau' \leq \tau\} \cup \{\Omega_\tau\} \cup \{M_{\tau'} : \tau' \leq \tau^-\})$ — no future information.
- **C2** further restricts: $\sigma(\Omega_\tau) \setminus \sigma(e_\tau)$ is not in $\mathcal{J}_\tau^{\text{agent}}$ — the agent cannot condition on aspects of Ω_τ not captured by e_τ .
- **C3** further restricts: $\sigma(\{e_{\tau'} : \tau' < \tau\} \cup \{M_{\tau'} : \tau' < \tau^-\}) \subseteq \sigma(M_{\tau-})$ from the agent's perspective.

After all three restrictions: $\mathcal{J}_\tau^{\text{agent}} = \sigma(M_{\tau-}, e_\tau)$.

By the Doob–Dynkin lemma¹, any $\sigma(M_{\tau-}, e_\tau)$ -measurable random variable is a (Borel) function of $(M_{\tau-}, e_\tau)$. Therefore $M_{\tau+} = f(M_{\tau-}, e_\tau)$ for some measurable f . $\square$

Attempts to Break the Result.

Before trusting the proof, seven counterexample attacks:

Attack 1: Simultaneous events. Two events arrive at exactly the same time: $e_\tau^{(1)}$ and $e_\tau^{(2)}$. The update has three arguments: $f(M_{\tau-}, e_\tau^{(1)}, e_\tau^{(2)})$.

Verdict: Not deep — 3.1 defines events as atomic. If we allow bundled events, the form holds with e_τ as a set. Reveals that “event” needs careful definition, but the form is preserved.

Attack 2: Continuous environmental influence. An agent embedded in a physical system experiences continuous forces (gravity, temperature, electromagnetic fields). These aren't “events” in 3.1's sense; they're continuous signals. The true dynamics would be $dM/d\tau = g(M_\tau, o(\tau))$ where $o(\tau)$ is a continuous observation stream.

Verdict: Genuine limitation of the event-driven formulation. The between-events corollary $dM/d\tau = g(M_\tau)$ holds only when the agent is truly isolated between events. For continuous coupling, the analogous result is the general state-space representation $\dot{M} = g(M, u)$ from control theory — arrived at by the same three constraints. The event-driven version is a special case for digital/sampled systems.

Attack 3: The C3 circularity. C3 defines M as the agent's complete internal state. Any apparent counterexample is dissolved by expanding M . Consider: an agent has a “model” (neural net weights) and a “replay buffer” (stored raw events). C3 says $M = (\text{weights}, \text{buffer})$. The model space is just larger than you thought.

Verdict: The deepest objection. The proof essentially: (1) Define M to be everything the agent has. (2) Observe the update can only use what the agent has. (3) Therefore $f(M_{\tau-}, e_\tau)$. The real content is the *analytical commitment*: by defining M as complete, we commit to Markovian analysis, which then makes 2.3 the right quality metric. See Epistemic Status below.

¹Kallenberg, O. (2002). *Foundations of Modern Probability* (2nd ed.). Springer. §1.2 (measurability and the Doob–Dynkin lemma).

Attack 4: Shared state between agents. Agents A and B share a common memory bank (shared database). The clean resolution is the multi-agent framework: the shared memory is part of the *composite* system’s state, and each agent’s interaction with it is mediated by events (reads and writes). Not a true counterexample but highlights that C3 requires careful delineation of agent boundaries.

Attack 5: External randomness not in e_τ . Hardware thermal noise used in the update. The stochastic case $M_{\tau+} \sim P(\cdot \mid M_{\tau-}, e_\tau)$ is a special case of f where f is a randomized function. The *form* — dependence on exactly $(M_{\tau-}, e_\tau)$ — is preserved. The result statement should explicitly allow stochastic f .

Attack 6: Time-dependent updates. Could f depend on the timestamp τ itself? Yes — consistently. The event e_τ in 3.1 carries a timestamp: $e_\tau = (\text{type}, \text{channel}, \text{payload}, \tau)$. So time-dependence enters through e_τ . Alternatively, the agent may maintain an internal clock as part of $M_{\tau-}$. Either way, $f(M_{\tau-}, e_\tau)$ accommodates time-dependence.

Attack 7: Agents that store full history. An agent with $M_{\tau-} \supseteq \mathcal{C}_{\tau-}$ is entirely consistent. The model space $\mathcal{M}$ is simply large enough to include the raw history. The 2.2 argues compression is *wise* — but the recursive update form holds regardless of compression level.

What Is Derived vs. What Is Chosen.

Table L.2

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Constraint C1 (arrow of time: update depends on τ^- , not future events)	Physical law — not a formulation choice	Postulate (physical)
Constraint C2 (partial observability: update depends on e_τ , not raw Ω_τ)	Scope definition of AAT	Postulate (scope-defining)
Constraint C3 (state completeness: $M_{\tau-}$ summarizes the agent’s relevant past)	Analytical commitment — the definition of M as complete	Definition
Recursive form $M_\tau = f(M_{\tau-}, e_\tau)$	C1 + C2 + C3	Proved (unique form compatible with the three constraints)
Future-dependent updates eliminated	C1 alone	Derived (direct consequence)
Ω_τ -dependent updates eliminated	C2 alone	Derived (direct consequence)
Full-history-dependent updates reducible to recursive form	C3 + any choice of $M \supseteq \mathcal{C}_{\tau-}$	Proved (compatibility, not elimination)
Markov property of the update	C3 (completeness) + recursive form	Proved (follows from C3 definition)
Seven attack counterexamples (simultaneous events, continuous coupling, C3 circularity, shared state, external randomness, time-dependence, full history)	Case-by-case reduction to the recursive form	Proved (each)
C3 is definitional, not eliminative	Analysis of what C3 asserts vs. what it rules out	Discussion-grade (clarifying observation)

The dividing line: C1 and C2 do genuine *eliminative* work — they rule out physically or scope-excluded update forms. C3 is a *definitional commitment* that forces the Markov structure by making M complete by construction; it cannot be “violated” because any apparent violation means M was misspecified. The recursive form’s uniqueness is therefore conditional on the three-constraint set being accepted, not on the constraints being independently inescapable — C3 in particular could be refused (yielding non-Markovian analysis), at the cost of leaving AAT’s scope.

Epistemic Status.

The result is correct but partly definitional. The three constraints have different epistemic characters:

Table L.3

<i>Constraint</i>	<i>Character</i>	<i>Can it be violated?</i>
C1 (arrow of time)	Physical law	Not in a classical universe
C2 (partial observability)	Scope definition	Only by leaving AAT's scope
C3 (state completeness)	Analytical commitment	Not without redefining M

C1 and C2 do genuine eliminative work — they rule out update forms that depend on future events or on raw Ω . These are non-trivial constraints.

C3 is a definitional commitment that produces the Markov structure. It cannot be “violated” because any violation is absorbed by expanding M . This is not a weakness — it’s the nature of the claim. The result says: *the Markovian analysis is the only one consistent with C1 + C2 + the definition of M as complete*. The alternative — an update that depends on something outside M — is not “wrong” but rather means M was misspecified.

What the result says: C1 eliminates a physically impossible class of updates (future-dependent). C2 eliminates a scope-excluded class (Ω -dependent). After (1) and (2), the *only remaining question* is how the past enters: through the full history $\mathcal{C}_{\tau-}$ or through a compressed state $M_{\tau-}$. C3 says the agent *has* a complete state, and whatever that state is, it’s all the agent has. The Markov form follows.

What the result does NOT say: That M must be a lossy compression (the agent could store full history). That the Markov property is “natural” or “optimal” (it’s a consequence of how M is defined). That continuous-coupling systems are event-driven (the event framework is one abstraction; $\dot{M} = g(M, u)$ is the more general one, arrived at by the same three constraints).

Discussion.

Recursion as a consequence of completeness. The recursive form is not an assumption bolted on — it follows from the definition of M_t as complete. The sufficiency of the recursive form is precisely what 2.3 measures: when $S(M_t) = 1$, the recursive update loses nothing.

What this opens. The proof yields the *form*. It immediately invites the follow-up questions that the rest of the theory addresses: What should f preserve? → 2.2 and 2.3. How should f weight new information? → 3.6. When is $\mathcal{M}$ itself inadequate? → 4.8.

Working Notes.

- C3’s definitional character is a feature, not a bug — but it must be stated honestly. The result is not “the update must be Markovian” but rather “the Markovian analysis is the *only* consistent one, given the modeling commitment of 2.1.” These sound the same but have different epistemic status.
- The continuous-coupling generalization (Attack 2) deserves a proper note somewhere: $\dot{M} = g(M, u)$ is the more general form, with event-driven updates as a special case. The three constraints produce the same argument structure in both cases.
- The information-set formalization (Doob-Dynkin) provides the cleanest technical proof. It should probably be considered the primary proof path, with the elimination argument as the more intuitive exposition.

Incidental audit gold (gold-lift, 2026-05-31). Cross-audit ideation harvested from de-novo auditors' working dirs, deduplicated and lightly attributed. Orthogonal framing / pedagogy; off-ramp (status-label harmonization) at the end. **Coverage:** five substrates reached a digested reflection (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-471203; Codex, AUDIT-WORKING-742613; Gemini-voiced, AUDIT-WORKING-773921) — unusually strong convergence; several rated this the most-trusted derivation they had read.

1. Candidate Brief prose / pre-prose.

- **“The Markov property is a boundary you draw around the agent, not a fact about the world.”** The recurring one-line synthesis across substrates: most ML/RL frameworks *postulate* the Markov property; here it is *forced* by C1 (arrow of time) + C2 (partial observability) + C3 (state completeness), with C3 the definitional commitment. “A rigorous proof that the Markov assumption in RL is not an assumption about the world, but a tautological boundary drawn around the agent” (Gemini-voiced, AUDIT-WORKING-773921; same framing, Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203).
- **“Memory as digestion.”** When event e_τ arrives, the agent extracts the update and discards the raw event; M_t is “the accumulated nutritional value of all past events,” not a storage bin. A concrete everyday analog for the recursive form that a non-specialist can re-derive (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **This derivation as the template for AAT’s inevitability-core segments.** Three substrates independently read the segment’s structure — three named constraints (eliminative C1/C2 vs definitional C3), dual proof paths (set-elimination + Doob-Dynkin), seven explicit counterexample “attacks” with honest verdicts, and the “What Is Derived vs. What Is Chosen” table — as the form *every other* AAT inevitability claim should adopt (Claude, AUDIT-WORKING-584721 and AUDIT-WORKING-471203; the seven-attack discipline named as a candidate meta-pattern, e.g. #result-mismatch-decomposition could enumerate “what would break the bias-variance decomposition?”).
- **“Epistemic-architectural rather than mathematical.”** Naming-seed for AAT’s distinctive contribution as legible here: most frameworks contribute new math; AAT’s distinctive move may be new *forms of stating* what is known, with explicit constraint-naming, definitional-character disclosure, and attack-defense. Closer to a philosophy-of-science contribution than a purely mathematical one — candidate for framing-level material (Claude, AUDIT-WORKING-471203). (*Note the early finding-vs-framing texture: offered as a re-characterization of the whole framework’s contribution, not just this segment.*)

3. Follow-up items.

- **The C3-circularity acknowledgment must survive downstream.** Several auditors flag a consistency-watch: segments that *use* the recursive-update result should preserve the “C3 is definitional, the result is conditional-on-the-modeling-commitment” honesty rather than treating Markovianity as physically derived; drift here is a cross-segment finding (Claude, AUDIT-WORKING-471203; Codex, AUDIT-WORKING-742613).
- **Continuous-coupling caveat propagation.** Attack 2’s $\dot{M} = g(M, u)$ generalization is the more-general form; the main #der-recursive-update between-event corollary $dM/d\tau = g_M(M_\tau)$ should probably carry the same “event-driven is the special case” caveat more prominently (Codex, AUDIT-WORKING-742613; already noted in this segment’s own Working Notes above — the auditors converged on it independently).
- **The “(Descended from TFT Appendix ...)” annotation is diff-voice in the body.** Editorial: move to Working Notes or remove; flagged as the fourth instance of the diff-voice pattern across Section I (Claude, AUDIT-WORKING-471203).

4. Readers often ask / wonder.

- **“What is the discretization penalty for the continuous case (Attack 2)?”** If the true dynamic is $\dot{M} = g(M, o(\tau))$, the event-driven form is a Riemann-sum-style approximation — does the agent suffer an integration error scaling with the inter-event gap? (Gemini, AUDIT-WORKING-193847).

- “Doesn’t a lossy ϕ make the recursive form epistemically sub-optimal?” If $M_{\tau-}$ is not a sufficient statistic for $\mathcal{C}_{\tau-}$ (lossy compression per #form-information-bottleneck), the recursive form locks the agent out of re-querying discarded history — mathematically valid but a structural disadvantage versus an agent that can read raw $\mathcal{C}_{\tau-}$. Offered as the formal motivation for *why* agents build external memory systems (writing things down bypasses the recursive bottleneck) (Gemini, AUDIT-WORKING-193847). (*Connects to SP-27 / lossy- ϕ recursion and #disc-m-preservation.*)

Belongs elsewhere.

- **Logogenic / Section IV reading** (points at 03-llm-core/ #disc-m-preservation, not this appendix): the C3-as-definitional move means a logogenic agent with externalized M_t (on disk) can have its M_t *defined* to include the externalized state, and the recursive form holds — the formal substrate for the M_t -preservation argument. Also the provocative architectural claim that Transformers “carry the raw apples around” (re-processing the full context each forward pass) rather than digesting history, so an external recursive loop must extract M_t and feed it forward — aspirational reach toward the logogenic-wrapping material (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203 names #disc-m-preservation as the destination).

Off-ramp (NOT gold) — routed for adjudication.

- **Status-label harmonization: exact (this appendix) vs conditional (#der-recursive-update body) — a genuine cross-substrate disagreement worth preserving as signal.** Two readings landed: (a) Claude (AUDIT-WORKING-471203) initially flagged a mismatch, then **withdrew** it after reading — concluding the layering is *deliberate and honest*: the appendix is “exact given the three constraints,” the body is “conditional on accepting C3 as a modeling commitment,” two angles on the same derivation. (b) Codex (AUDIT-WORKING-742613) and Gemini-voiced (AUDIT-WORKING-773921) judged the *language* should still be harmonized, proposing “exact conditional on C1–C3 and the event-driven/sampled representation; continuous coupling generalizes the input form.” Net: not a defect in the math, possibly a wording-clarity improvement on whether the two statuses read as obviously-the-same-claim-at-two-layers. Light-touch; route as a status/voice-clarity check, not a correctness finding.

Appendix M

Derived: Multi-Timescale Stability

When adaptive processes operate at nested timescales, the composite is stable exactly when each level satisfies the sector-persistence template with two interconnection terms added to its effective disturbance — the residue of the settled level below, and the target-drag of the moving level above — and the qualitative convergence constraint $\nu_{n+1} \ll \nu_n$ (4.9) becomes a closed-form threshold: the admissible timescale ratio equals the faster level's adaptive reserve divided by the rate at which the slower level drags the faster level's target.

A mental model before the formalism: picture each adaptive level as a bathtub — water is that level's mismatch, the drain is its correction, and the inflow is its disturbance (4.5 carries the single-tub version). Stacking levels couples the tubs in two directions. When the slow level acts, it *moves the fast level's drain* — the fast tub must chase a shifting target, which behaves exactly like extra inflow. And the fast tub's residual sloshing *splashes into the slow tub* — the slow level's measurements are contaminated by however much the fast level has not yet settled. Both couplings are ordinary disturbance once named, so each tub needs only the ordinary persistence condition against its *total* inflow — and the theorem's two conditions say precisely that. Micromanagement is the first coupling overwhelming the fast tub (the target moves faster than the fast level's spare drain capacity); catastrophic forgetting is the second coupling overwhelming the slow tub (the slow level is too sensitive to fast-level splash). They are dual violations of one theorem.

Formal Expression.

Fast state $x_1 \in \mathbb{R}^{n_1}$, slow state $x_2 \in \mathbb{R}^{n_2}$:

Formulation (stacked two-timescale system).

$$\dot{x}_1 = -F_1(x_1; x_2) + w_1(t), \quad \dot{x}_2 = \epsilon [-F_2(x_2; x_1) + w_2(t)] \quad (\text{M.1})$$

with $\epsilon > 0$ the timescale ratio — in AAT vocabulary $\epsilon = \nu_2/\nu_1$, the adjacent-level event-rate ratio whose smallness 4.9 asserts qualitatively. The singular-perturbation form is classical [4]; the textbook treatment is Khalil's *Nonlinear Systems* [5, Ch.~11], with the composite-Lyapunov approach this derivation parallels due to Saberi and Khalil [6] and the control-theoretic corpus consolidated in Kokotović, Khalil and O'Reilly [7]. What is AAT-native is the statement of the stacking entirely in the sector-persistence template's (α, R, ρ) coordinates, so that every quantity in the stability condition is an already-named persistence quantity.

- **(S0) Regularity.** F_1, F_2 locally Lipschitz in all arguments; w_1, w_2 measurable (solutions in the Carathéodory sense).

Assumption (stacking premises S0–S4).

- **(S1) Lipschitz quasi-steady-state manifold.** There is $h : \mathcal{X}_2 \rightarrow \mathbb{R}^{n_1}$ with $F_1(h(x_2); x_2) = 0$ for all x_2 in the slow scope region, and $\|Dh(x_2)\| \leq L_h$.
- **(S2) Per-level sector conditions** — the template's (T2), per level, the fast one *uniformly parametrized* by the slow state:
 - Fast: $(x_1 - h(x_2))^T F_1(x_1; x_2) \geq \alpha_1 \|x_1 - h(x_2)\|^2$ for $\|x_1 - h(x_2)\| \leq R_1$, with α_1, R_1 uniform over the slow scope region.
 - Slow (reduced dynamics): with $\bar{F}_2(x_2) := F_2(x_2; h(x_2))$, there is x_2^* with $\bar{F}_2(x_2^*) = 0$ and $(x_2 - x_2^*)^T \bar{F}_2(x_2) \geq \alpha_2 \|x_2 - x_2^*\|^2$ for $\|x_2 - x_2^*\| \leq R_2$.
- **(S3) Bounded interconnection.** $\|F_2(x_2; x_1) - F_2(x_2; h(x_2))\| \leq L_{21} \|x_1 - h(x_2)\|$ on the joint scope region, and $M_2 := \sup_{\|x_2 - x_2^*\| \leq R_2} \|\bar{F}_2(x_2)\| < \infty$.
- **(S4) Bounded disturbance (Model D).** $\|w_1(t)\| \leq \rho_1, \|w_2(t)\| \leq \rho_2$, with standing reserve hypothesis $\Delta\rho_1^* := \alpha_1 R_1 - \rho_1 > 0$ (the fast level persists standalone with reserve to spare; if it does not, no timescale separation can rescue the stack).

Error coordinates $y_1 := x_1 - h(x_2), y_2 := x_2 - x_2^*$; joint scope region $\mathcal{B} := \{\|y_1\| \leq R_1\} \times \{\|y_2\| \leq R_2\}$.

Theorem. Under (S0)–(S4), define the slow-velocity bound $v_2^{\max} := M_2 + L_{21}R_1 + \rho_2$ and the separation threshold

Derived (two-timescale stacked persistence).

$$\epsilon_{\max} := \frac{\Delta\rho_1^*}{L_h v_2^{\max}} \quad (\text{M.2})$$

(with $\epsilon_{\max} = \infty$ when $L_h = 0$: a fixed target imposes no separation requirement). If

$$(\text{C1}) \quad \epsilon < \epsilon_{\max} \quad \text{and} \quad (\text{C2}) \quad \alpha_2 R_2 > \rho_2 + L_{21} R_1, \quad (\text{M.3})$$

then $\mathcal{B}$ is forward-invariant, and every trajectory starting in $\mathcal{B}$ satisfies

$$\limsup_{t \rightarrow \infty} \|y_1(t)\| \leq r_1 := \frac{\rho_1 + \epsilon L_h v_2^{\max}}{\alpha_1}, \quad \limsup_{t \rightarrow \infty} \|y_2(t)\| \leq r_2 := \frac{\rho_2 + L_{21} r_1}{\alpha_2}. \quad (\text{M.4})$$

Both levels persist: each ultimate-bound ball sits strictly inside its scope ball ((C1) gives $r_1 < R_1$; (C2) with $r_1 < R_1$ gives $r_2 < R_2$).

Derivation. (i) *A-priori slow velocity.* On $\mathcal{B}$, $\|F_2(x_2; x_1)\| \leq \|\bar{F}_2(x_2)\| + L_{21} \|y_1\| \leq M_2 + L_{21} R_1$ by (S3), so $\|\dot{x}_2\| \leq \epsilon v_2^{\max}$ — a scope-constant bound with no dependence on the ultimate bounds derived below (no circularity).

(ii) *The fast level as a template instance with manifold-drift disturbance.* Differentiating $y_1 = x_1 - h(x_2)$,

$$\dot{y}_1 = -F_1(y_1 + h(x_2); x_2) + \underbrace{w_1 - Dh(x_2) \dot{x}_2}_{w_1^{\text{eff}}}, \quad \|w_1^{\text{eff}}\| \leq \rho_1^{\text{eff}} := \rho_1 + \epsilon L_h v_2^{\max} \quad (\text{M.5})$$

by (S1) and (i). With $V_1 = \frac{1}{2} \|y_1\|^2$ and (S2-fast): $\dot{V}_1 \leq -\alpha_1 \|y_1\|^2 + \|y_1\| \rho_1^{\text{eff}}$ on $\mathcal{B}$. The slow level's motion enters the fast level as additional Model-D disturbance at rate $\epsilon L_h v_2^{\max}$ — the moving-target term — and the fast level's persistence condition $\alpha_1 R_1 > \rho_1^{\text{eff}}$ rearranges to (C1).

(iii) *The slow level as a template instance with renormalized disturbance.* $\dot{y}_2 = \epsilon[-\bar{F}_2(x_2) - (F_2(x_2; x_1) - \bar{F}_2(x_2)) + w_2]$, where the middle term is bounded by $L_{21}\|y_1\|$ by (S3). With $V_2 = \frac{1}{2}\|y_2\|^2$ and (S2-slow): $\dot{V}_2 \leq \epsilon[-\alpha_2\|y_2\|^2 + \|y_2\|(\rho_2 + L_{21}\|y_1\|)]$ on $\mathcal{B}$ — in slow time $\tau = \epsilon t$ the ϵ factors out, and the fast level, integrated out, leaves a residue equal to its settled bound times the interconnection sensitivity.

(iv) *Joint forward-invariance and the cascade bound.* On the face $\|y_1\| = R_1$ of $\partial\mathcal{B}$: $\dot{V}_1 \leq R_1(-\alpha_1 R_1 + \rho_1^{\text{eff}}) < 0$ by (C1). On the face $\|y_2\| = R_2$, with $\|y_1\| \leq R_1$ worst-case: $\dot{V}_2 \leq \epsilon R_2(-\alpha_2 R_2 + \rho_2 + L_{21}R_1) < 0$ by (C2). Each V_i decreases strictly (with uniform margin) on its own face, so a first-exit-time contradiction gives forward-invariance of $\mathcal{B}$, corners included, and all bounds above hold for all $t \geq 0$. Within $\mathcal{B}$ the fast inequality gives $\limsup \|y_1\| \leq r_1$ by the template's Grönwall argument; then for any $\delta > 0$ the slow effective disturbance is eventually below $\rho_2 + L_{21}(r_1 + \delta)$, giving $\limsup \|y_2\| \leq (\rho_2 + L_{21}(r_1 + \delta))/\alpha_2$ for every δ , hence the stated r_2 . $\square$

If the fast level is already settled at composition time ($\|y_1(0)\| \leq r_1 + \delta$ for some $\delta > 0$), the smaller ball $\{\|y_1\| \leq r_1 + \delta\}$ is itself forward-invariant (same face argument under (C1)), and (C2) weakens to

Derived (warm-start refinement — the cost of acting on transients).

$$(C2\text{-warm}) \quad \alpha_2 R_2 > \rho_2 + L_{21}(r_1 + \delta). \quad (M.6)$$

The gap between the cold-start and warm-start conditions, $L_{21}(R_1 - r_1)$ as $\delta \rightarrow 0$, is the quantitative price of engaging the slow level before the fast level has converged: early action does not void the guarantee — it raises the slow level's required reserve from settled-residue size to worst-case-transient size. 4.9's qualitative rule ("a slower process must not act before the faster process beneath it has converged") is thereby graded, not binary.

Remark (Tikhonov's prerequisite, within scope). Tikhonov-type results require the frozen fast dynamics to have a unique isolated equilibrium for each slow configuration. Under (S2-fast) this holds by construction within scope: if $F_1(y + h(x_2); x_2) = 0$ with $0 < \|y\| \leq R_1$, then $0 = y^\top F_1 \geq \alpha_1 \|y\|^2 > 0$ — contradiction — so $h(x_2)$ is the unique equilibrium in the radius- R_1 ball, and the sector additionally gives exponential frozen-dynamics attraction (more than Tikhonov asks; the derivation above in fact bypasses Tikhonov's theorem entirely via the composite-Lyapunov route). Outside the sector ball the guarantee is void: a fast level with multiple equilibria or limit cycles in its operating region — non-convex losses (K), cyclic strategic dynamics (16.1's R2 regime) — sits outside (S2-fast), and no amount of slowing the outer loop restores the guarantee. Slowing the slow level helps only against (C1) violations, never against a fast level that has no settled state to offer.

Derived (sector condition supplies the unique-root prerequisite).

Remark (relation to the template's stated preconditions). The template (G) states (T1)–(T3) for autonomous F and a constant disturbance bound. The two instances above are non-autonomous — the fast correction varies in time through $x_2(t)$, and the slow effective disturbance $\rho_2 + L_{21}\|y_1(t)\|$ is state-dependent and only *eventually* below the constant used — but the template's Lyapunov/Grönwall argument is pointwise in time and uses only the differential inequality, which holds uniformly, so the proofs transfer verbatim. This is a mild, stated extension of the template (uniform-in-time (T1)–(T2), eventually-bounded (T3)), not a bare instantiation.

Levels $k = 1, \dots, N$ (fastest to slowest) with rates $\epsilon_1 = 1 \gg \epsilon_2 \gg \dots \gg \epsilon_N$. Two structural premises beyond the per-level transcriptions of (S0)–(S4):

Derived (N-level stacking, nearest-neighbor coupling).

- **(S5) Nesting idealization.** Each level's quasi-steady-state manifold depends only on the level immediately above: $h_k = h_k(x_{k+1})$, Lipschitz L_{h_k} . (Dependence on all slower levels adds a bounded sum dominated by the adjacent term under the rate ordering; the nearest-neighbor statement keeps the constants legible.)

- **(S2-red) Reduced sector conditions for middle levels.** For $1 < k < N$ the sector condition is on the *reduced* dynamics with the level below substituted at its manifold, $\bar{F}_k(x_k; x_{k+1}) := F_k(x_k; h_{k-1}(x_k), x_{k+1})$ — note the manifolds compose, since h_{k-1} is itself a function of x_k — anchored at $h_k(x_{k+1})$, uniformly in x_{k+1} .

Each level k then carries three disturbance sources — its own ρ_k , the residue of the level below ($L_{k,k-1}\|y_{k-1}\|$), and the manifold drag from the level above ($(\epsilon_{k+1}/\epsilon_k)L_{h_k}v_{k+1}^{\max}$, with $v_{k+1}^{\max}$ the level- $(k+1)$ scope-constant velocity bound) — boundary terms zero at $k = 1$ and $k = N$. If for each k

$$(C-N) \quad \alpha_k R_k > \rho_k + L_{k,k-1} R_{k-1} + \frac{\epsilon_{k+1}}{\epsilon_k} L_{h_k} v_{k+1}^{\max}, \quad (M.7)$$

then $\prod_k \{\|y_k\| \leq R_k\}$ is forward-invariant by the same per-face argument, and the cascade limsup propagates upward level by level, giving the renormalization recursion on ultimate bounds

$$r_k = \frac{\rho_k + L_{k,k-1} r_{k-1} + (\epsilon_{k+1}/\epsilon_k) L_{h_k} v_{k+1}^{\max}}{\alpha_k}, \quad r_0 := 0. \quad (M.8)$$

The recursion is well-founded in both directions: from-above terms use a-priori scope constants, from-below terms use already-derived r_{k-1} . For general (non-nearest-neighbor) coupling, the per-face argument is replaced by the standard vector-Lyapunov / M-matrix condition for interconnected systems [5, §9.5] — imported machinery, named here as the general gate without re-derivation.

With Wiener-process disturbance the manifold subtraction acquires an Itô correction requiring (S1') $h \in C^2$ with bounded Hessian, and the drift-disturbance bookkeeping above becomes a joint exit-time problem across coupled levels. The expected shape — mean-square ultimate bounds with the template's $1/\sqrt{\alpha}$ scaling and the region-aware stopped form of A Prop A.1S, plus a curvature term in ρ^{eff} — is genuinely additional work, not a transcription, and is *not claimed here*. The Model D scope is the honest match for the stacking's primary AAT use cases (structural adaptation, consolidation scheduling, macro-clocks), where slow-level motion is drift-like.

Formulation (Model S extension — conditional, not yet derived).

Epistemic Status.

Exact for the two-timescale theorem, the warm-start refinement, and the N -level nearest-neighbor form, under the named premises (S0)–(S5)/(C-N) — derived by elementary Lyapunov arguments stacked on the sector-persistence template, independently re-derived and verified in full (spike trail 2026-06-10). The general-coupling N -level gate is *imported* (vector-Lyapunov / M-matrix, [5, §9.5]) and the Model S extension is *open* — both stated as such above, neither carried by the exact label.

What the promotion does and does not close. The predecessor sketch's open problem — AAT has trigger conditions but no dynamics for structural adaptation — is *conditionalized, not closed*. The theorem covers any deeper-level dynamics satisfying (S1)–(S5); whether AAT's actual deeper levels satisfy them is exactly the question that remains open, and it is a real one: structural adaptation is plausibly discrete (adding a model component, restructuring a hierarchy), making $\dot{x}_2$ a jump process for which (S0)'s Carathéodory framing and (S1)'s differentiable manifold do not hold as stated. The claim-type has changed from “AAT's adaptive hierarchy is stable” (never derivable as stated) to “a premise-conditional stacking theorem with named scope” — the strengthening is real (closed-form $\epsilon_{\max}$, graded warm/cold gap, unique-root prerequisite supplied rather than assumed), and so is the remaining gap.

The load-bearing premise is (S2-fast)'s *uniformity*, not the sector inequality itself. Because (α_1, R_1) are uniform over the slow scope region and h absorbs all equilibrium motion, the entire interconnection burden lands on the single drift term $\epsilon L_h v_2^{\max}$; a per-frozen- x_2 sector with non-uniform constants would not suffice. This is the standard strength

assumption of the singular-perturbation literature (it is essentially Saberi-Khalil's interconnection-condition pattern), and it is precisely where realistic fast levels — non-convex, multi-equilibrium — exit scope.

Max attainable within current premises: exact (attained for Model D). Extensions that would widen scope rather than strengthen the claim: Model S (named above), jump-process slow dynamics, non-Euclidean metrics via AI's (CT2).

Discussion.

The convergence constraint is now a derived threshold, and its two failure modes are dual. 4.9's $\nu_{n+1} \ll \nu_n$ enters the theorem as (C1) with the closed form $\epsilon_{\max} = \Delta\rho_1^*/(L_h v_2^{\max})$: the faster level's *spare adaptive reserve* — a quantity the template already names — divided by the rate at which the slower level drags the faster level's target. The two classic nesting pathologies separate cleanly into the theorem's two conditions. *Micromanagement* is a (C1) violation: the slow level acts at fast tempo, the moving-target disturbance $\epsilon L_h v_2^{\max}$ exhausts the fast level's reserve, and the fast level thrashes — and the damage then propagates back upward, because the fast level's inflated residue $L_{21}r_1$ raises the slow level's effective disturbance in turn. *Catastrophic forgetting* is a (C2) violation: the slow (consolidated) level is too sensitive to fast-level transients — L_{21} too large — and the fast loop's activity overwrites it even under perfect timescale separation. The two pathologies several auditors read as “the same failure” are precisely the two conditions of one theorem, violated separately.

Timescale separation is trust, quantified. “Each level has a stable attractor given the levels above it” reads as mutual trust within an architecture: the fast layer trusts the slow layer not to pull the rug out mid-convergence ((C1) — the manager's rate of goal-change stays under $\epsilon_{\max}$), and the slow layer trusts the fast layer to settle so there is a steady output to act on ((C2) — the worker's residue stays within the manager's tolerance $L_{21}r_1$). The warm-start refinement prices the violation: a manager who engages before the worker converges needs $L_{21}(R_1 - r_1)$ of extra reserve — the difference between reacting to settled output and reacting to worst-case transients.

Integrating out a level is a renormalization step; the template is the fixed-point form. Step (iii)'s structure — the fast level, integrated out, maps the slow level onto the *same* template form with renormalized disturbance $\rho_{k+1} \mapsto \rho_{k+1} + L_{k+1,k} r_k$ — is a renormalization-group step in the sense in which Chen, Goldenfeld and Oono showed RG and singular-perturbation asymptotics to be one method [8]. The sector-persistence template is form-invariant under this coarse-graining: every level of the hierarchy presents the identical $(\alpha, R, \rho^{\text{eff}})$ persistence problem with parameters renormalized by its neighbors. This is the precise sense in which AAT's persistence architecture is scale-free, and it is the lineage of Haken's slaving principle — fast modes enslaved by slow order parameters [9] — restated in persistence coordinates.

Renormalizing generative models are the constructive discrete-time instance. Friston and colleagues' scale-free active inference [10] builds generative models by recursive blocking transformations over state space and time, such that “higher levels encode sequences of sequences” and belief updating slows as one ascends levels — i.e., the timescale separation is enforced *architecturally* (one slow tick per block of K fast ticks, $\epsilon_k/\epsilon_{k+1} = 1/K$ by construction) rather than assumed, with per-level convergence inherited from coordinate descent. RGM thus supplies what (S1)–(S2) ask for, by construction, in the discrete categorical setting — an existence proof that the premises are realizable, not a competing stability argument (the paper proves no composite-stability theorem and does not claim to). The same architecturally-enforced separation appears in AAT's own composition machinery as 13.1's macro-clock $K_c \gg 1$ and #def-auxilia-hierarchy's (H5).

The LLM adaptive stack is the N -level hierarchy, unlabeled. Pretraining $\rightarrow$ fine-tuning $\rightarrow$ LoRA-style adaptation $\rightarrow$ in-context learning $\rightarrow$ retrieval state $\rightarrow$ within-generation dynamics maps onto the timescale ladder with each mechanism orders of magnitude faster and more transient than the one below. The framework's stability requirement needs no clean “parametric vs structural” labels — only that adjacent rates satisfy (C-N) — and it explains the practitioner's instinct against, e.g., updating base weights while a fast retrieval loop is mid-flight: that is a (C1) violation at the weights/retrieval boundary. The catastrophic-forgetting literature lives at the same boundary as a (C2) violation, per the dual reading above.

Strategy’s own timescale. 9.10 places strategic mismatch between fast epistemic updates and slow objective revision; the stacking theorem is the formal backing for treating those as separately-stable levels — with the caveat that the strategic level’s $\alpha_\Sigma = 1/(n + 1)$ decay makes (S2)’s constant- α premise hold only under experience discounting, exactly as that segment already requires.

Working Notes.

- **Open (which AAT mechanisms satisfy the premises).** The honest gap left by the promotion: structural adaptation as actually triggered by 4.8 is plausibly a *jump process* (discrete model-class moves), outside (S0)/(S1) as stated. Two follow-up directions: an impulsive/hybrid-systems extension of the stacking (the slow level as a jump process on the slow manifold), and formalizing the RGM correspondence ([10]) as the discrete-time constructive instance where the premises hold by architecture. Spike trail: spikes/spike-multi-timescale-stacking-2026-06-10.md.
 - **Open (Model S stacking).** Named conditional above; the joint exit-time bookkeeping across coupled levels is the work item. Prop A.1S’s region-aware form is the template to extend.
 - **Open (non-Euclidean metrics).** The stacking is stated in the Euclidean template; restating with AIs (CT1)–(CT3) per level would cover Fisher-metric fast levels (statistical-manifold learners) — likely routine but unchecked.
 - **Belongs elsewhere (ELI internal coherence).** The trust reading extends to ELI architecture: a narrative “I” that constantly interrupts its own sub-agents violates (C1) at the interiority boundary (“paralyzed by frantic internal micromanagement” — Gemini, AUDIT-WORKING-193847). Carried at #def-auxilia-hierarchy (H5) and its temporal-sovereignty discussion; not this segment’s claim to make.
 - Incidental audit gold from the 2026-05-31 lift is integrated: the trust/manager-worker framing, the LLM-stack mapping, the micromanagement/forgetting unification (sharpened here into the dual (C1)/(C2) reading), and the “does slowing the outer loop guarantee convergence?” reader question (answered in the Tikhonov remark: no — a multi-equilibrium fast loop is outside (S2-fast) regardless of ϵ) all landed in the body above. Provenance: the pre-promotion segment history and the spike trail.
-

Appendix N

Sketch: Does the Model-S Containment Dichotomy License Structural-Adaptation Genericity?

The Model-S segments claim Corollary A.1S.1 “sharpens the hand-off into #result-structural-adaptation-necessity — the structural-adaptation trigger is *generic, not exceptional*, for a sufficiently long-lived agent.” This sketch isolates that hand-off as an open question: as stated it is plausibly a mild overclaim, and the honest move is to *derive the bridge* rather than soften the prose.

The Open Question.

#deriv-sector-condition Corollary A.1S.1 establishes (exactly) that under additive stochastic forcing the persistence-region first-exit probability is $P(\tau_R < \infty) = 1$ — a long-lived agent leaves the sector-condition region $\mathcal{B}_R$ with certainty. The Model-S segments and #deriv-stochastic-non-exit then assert this “sharpens the hand-off” so that structural adaptation is *generic, not exceptional*.

Discussion.

But #result-structural-adaptation-necessity derives necessity from a **different trigger**: model-class inadequacy ($\mathcal{F}(\mathcal{M}) < 1 - \varepsilon$ — no model in the current class can represent reality). It does not reference Model-S, region-exit, or Corollary A.1S.1; its mechanism is fitness-driven, not noise-driven. And the corollary’s own explicit instance (the OU benchmark) is **positively recurrent**: the process exits any bounded region a.s. *and returns* a.s. — exit-and-return, not escape.

So there is a gap between what Cor A.1S.1 proves and what the hand-off prose claims:

- **What the corollary licenses (honest narrow claim):** the *pathwise-forever parametric-containment guarantee* is structurally unavailable under stochastic forcing; a long-lived agent generically enters the regime where the parametric persistence guarantee is no longer *proven* (the out-of-region regime #result-structural-adaptation-necessity addresses).
- **What it does not license without further argument:** that *model-class* structural adaptation is generically *necessary*. Recurrent region-exit (exit-and-return) is not model-class inadequacy; a transient noise excursion beyond $\mathcal{B}_R$ that the (un-posed-but-possibly-still-inward) correction pulls back is not a structural-adaptation trigger in the #result-structural-adaptation-necessity sense.

Proposed Direction (rigor pending).

Per strengthen-before-soften, the preferred resolution is **derive the bridge**, not tighten the prose. Candidate conditions under which certain region-exit *would* imply structural-adaptation necessity, to be attempted:

Discussion.

1. **A2' genuinely fails outside $\mathcal{B}_R$** (not merely “not posited”): if the correction function provably ceases to point inward beyond R for the agent’s model class, then a.s. exit composes with non-recovery, and recurrent exit *does* force the structural regime. This connects to the sub-scope β / model-class-capacity reading of R in #form-sector-condition.
2. **Excursion statistics interact with $\mathcal{F}(\mathcal{M})$** : if recurrent large excursions degrade *effective* model-class fitness (the model fitted within $\mathcal{M}$ becomes systematically wrong during excursions faster than it re-converges between them), the noise-driven and fitness-driven triggers couple, and genericity follows from the coupling rather than from exit alone.
3. **Timescale-separation argument**: if structural adaptation operates so much slower than parametric correction that the *fraction of time* spent out-of-region (positive under recurrence, however small) accumulates an unbounded structural-adaptation debt over an unbounded horizon.

Each is a derivation target; any one that closes turns the hand-off from asserted to proven and is a genuine strengthening (a new conditional result, not a softening). If all provably fail, the honest outcome is the no-go protocol applied to the hand-off claim (per doc/audit-routing-instructions.md §4) and the Model-S Discussion/Findings prose tightened to the narrow licensed claim above — but only *after* the strengthening attempt is exhausted and recorded.

Epistemic Status.

Sketch. Direction identified, formalization not attempted. This segment makes **no** claim that the bridge holds or fails; it records that the hand-off currently asserted in #deriv-sector-condition / #deriv-stochastic-non-exit Discussion/Findings is **plausibly a mild overclaim at the Discussion/Findings tier** (a Gate-2 class concern: a claim that *sounds* like it follows from Cor A.1S.1 but is not derived from it), and that the resolution path is to attempt the bridge derivation. The narrow licensed claim (pathwise-parametric-guarantee unavailability $\Rightarrow$ generic entry into the out-of-region *regime*) is sound and uncontroversial; the disputed increment is “ $\Rightarrow$ model-class structural adaptation is generically *necessary*.” Ceiling: a closed bridge would be derived (conditional) on the named condition; a clean impossibility would be a no-go result. Until attempted, this stays sketch.

Discussion.

Why this matters enough to surface rather than leave as a soft ledger row: the genericity claim is load-bearing downstream — it is the form in which the Model-S no-go’s consequence reaches the ELI / long-lived-agent persistence framing (“in any genuinely stochastic environment, structural adaptation is not an edge case”). If the bridge holds under a named condition, that is a sharp, citable strengthening of exactly the kind the framework’s no-go signature tends to produce. If it does not, the framework’s honesty requires the hand-off prose to state only the narrow licensed claim. Either way the question should be visible in the argument’s structure, not invisible in a tracking file — which is the point of carrying it as an exploratory OUTLINE node.

Working Notes.

- Provenance: parent-generated 2026-05-16 during the audit-routing cycle, from a first-hand deep-read of #result-structural-adaptation-necessity against the Model-S segments (not a cluster audit finding). Originally filed as consolidated-ledger

research-seed **S30**; Joseph adjudicated it up to a first-class exploratory OUTLINE node (“it will get its day in the light”) rather than a soft ledger row. The ledger row is correspondingly demoted to a pointer here.

- Segment-vs-spike judgment (recorded so it is not re-litigated): this is recognized open *territory* between two landed results with **no attempt yet** — segment-shaped (visible structural node), not spike-shaped (a spike is the reasoning trail of an *attempt*). The spike is the eventual *work*: when this is picked up, a strengthening spike attempts directions 1–3; math lands back here (or in a new derivation/result segment), per math-lives-in-segments.
 - Related: the #disc-identifiability-floor family — if the bridge is a no-go, the “no horizon-independent non-exit certificate” structural absence may itself compose with a structural-adaptation-necessity floor; worth checking whether this is an identifiability-floor-shaped instance.
-

Appendix O

Derivation: Discrete-Time Sector Condition

Discrete-time analogs of Props A.1, A.1S, and A.2 via contraction mapping, closing the fluid-limit gap (GA-5) between the event-driven dynamics (3.1) and the continuous-time Lyapunov results in A. Three results land. **Prop DA.1 (Model D)**: under deterministic bounded disturbance, the discrete steady-state mismatch equals the continuous steady-state exactly — zero fluid-limit gap. **Prop DA.1S (Model S)**: under stochastic disturbance, the discrete and continuous steady-state variances differ by an additive correction of order $\eta^* c_{\max}^2 / c_{\min}^2$ — quantitatively small when this conditioning-ratio-over-event-rate product is small. **Prop DA.2 (adaptive reserve)**: the discrete adaptive reserve matches the continuous form modulo the same correction.

A critical structural observation underwrites all three: the discrete sector condition (DA2') needs a *strictly stronger Lipschitz upper bound* on the correction function — strictly stronger than an inner-product upper bound — because the discrete recurrence's quadratic term $(\eta^*)^2 \|F_d\|^2$ requires the norm bound, not merely the projection. This is satisfied for Bayesian updates (the posterior lies between prior and data) and for gradient descent on smooth losses (where the Lipschitz constant is the smoothness parameter); pathological correction functions with large transverse components can satisfy the inner-product bound while violating the norm bound. Together with the no-overshoot step-size condition $\eta^* < 2c_{\min}/c_{\max}^2$, the fluid limit is formally justified — the continuous-time analysis of A is the limit of the discrete results here, not an idealization.

Formal Expression.

Setup. The discrete mismatch dynamics at event step k are:

Definition (Discrete Dynamics).

$$\delta_{k+1} = \delta_k - \eta^* F_d(\delta_k) + w_k \tag{O.1}$$

where η^* is the update gain (3.6), F_d is the discrete correction direction, and w_k is the per-step disturbance. The continuous correction function $F(\mathcal{J}, \delta)$ from A decomposes as $F = \nu \cdot \eta^* \cdot F_d$ at event rate ν .

(DA2') Discrete Sector-Lipschitz Condition.

There exist constants $c_{\min} > 0$ and $c_{\max} < 2/\eta^*$ such that for all $\|\delta\| \leq R$:

Assumption DA2' (discrete-sector-condition).

(DA2'squa) Lower sector bound (directional fidelity):

$$\delta^T F_d(\delta) \geq c_{\min} \|\delta\|^2 \quad (\text{O.2})$$

(DA2'squob) Lipschitz bound (bounded correction magnitude):

$$\|F_d(\delta)\| \leq c_{\max} \|\delta\| \quad (\text{O.3})$$

The **lower bound** (DA2'a) is directional fidelity — the correction points inward, identical to the continuous sector condition (A2') from 4.2 via 4.3.

The **Lipschitz bound** (DA2'b) controls the *magnitude* of the correction, not merely its projection onto the mismatch direction. The combined constraint $c_{\max} < 2/\eta^*$ is the **no-overshoot condition**: each correction step must not reverse the mismatch. This is the classical step-size condition $\eta^* < 2/L$ for gradient descent (where L is the Lipschitz constant of the gradient). For Bayesian updates, this is satisfied by construction — the posterior lies between prior and data.

Why DA2'b is stronger than an inner-product upper bound. A two-sided inner-product condition $\delta^T F_d(\delta) \leq c_{\max} \|\delta\|^2$ constrains only the projection of F_d onto δ . By Cauchy-Schwarz, the Lipschitz bound (DA2'b) implies the inner-product upper bound: $\delta^T F_d(\delta) \leq \|\delta\| \cdot \|F_d(\delta)\| \leq c_{\max} \|\delta\|^2$. But the converse fails — a correction function with a large transverse component (orthogonal to δ) can satisfy the inner-product bound while violating the norm bound. The proofs below (especially DA.1S) require the norm bound $\|F_d(\delta)\|^2 \leq c_{\max}^2 \|\delta\|^2$, which follows from DA2'b but not from an inner-product condition alone.

Scalar case. In one dimension, DA2'a and DA2'b together reduce to the classical sector condition $c_{\min} \leq F_d(\delta)/\delta \leq c_{\max}$, since norm and inner product coincide. No generality is lost for scalar systems.

Relationship to the continuous-time condition. The continuous sector condition (A2'/GA-3) is a one-sided inner-product bound $\delta^T F \geq \alpha \|\delta\|^2$ — this suffices for continuous-time Lyapunov analysis because $\dot{V}$ involves only $\delta^T F$, not $\|F\|$. Discretization introduces the quadratic term $(\eta^*)^2 \|F_d\|^2$ (see DA.1S proof), which requires the Lipschitz bound. This is the standard sector-vs-Lipschitz distinction in nonlinear systems theory.

Contraction factor. Under DA2', the per-step Lyapunov function $V_k = \frac{1}{2} \|\delta_k\|^2$ satisfies (in the zero-disturbance case $w_k = 0$):

Derived (contraction, from DA2').

$$\|\delta_{k+1}\|^2 = \|\delta_k - \eta^* F_d(\delta_k)\|^2 = \|\delta_k\|^2 - 2\eta^* \delta_k^T F_d(\delta_k) + (\eta^*)^2 \|F_d(\delta_k)\|^2 \quad (\text{O.4})$$

Applying DA2'a (lower sector bound on $\delta^T F_d$) and DA2'b (Lipschitz bound on $\|F_d\|$):

$$\|\delta_{k+1}\|^2 \leq (1 - 2\eta^* c_{\min} + (\eta^*)^2 c_{\max}^2) \|\delta_k\|^2 = \lambda_{\text{eff}}^2 \|\delta_k\|^2 \quad (\text{O.5})$$

where:

$$\lambda_{\text{eff}}^2 = 1 - 2\eta^* c_{\min} + (\eta^*)^2 c_{\max}^2 \quad (\text{O.6})$$

Stability condition. $\lambda_{\text{eff}}^2 < 1$ requires $2\eta^* c_{\min} > (\eta^*)^2 c_{\max}^2$, i.e.:

$$\eta^* < \frac{2c_{\min}}{c_{\max}^2} \quad (\text{O.7})$$

This is automatically satisfied when $c_{\min} \approx c_{\max}$ (well-conditioned correction), recovering the standard step-size condition $\eta^* < 2/c_{\max}$. For ill-conditioned corrections ($c_{\min} \ll c_{\max}$), the constraint is tighter. For Bayesian updates with bounded condition number, both conditions are satisfied.

Scalar (colinear) specialization. When $F_d(\delta) \parallel \delta$ (scalar system or colinear correction), $\|F_d(\delta)\| = |F_d(\delta)/\delta| \cdot \|\delta\|$ and the contraction factor simplifies to $\lambda = \max(|1 - \eta^* c_{\min}|, |1 - \eta^* c_{\max}|)$, the classical form. The general vector formula λ_{eff}^2 reduces to λ^2 in this case.

With disturbance $w_k \neq 0$:

$$\|\delta_{k+1}\|^2 \leq \lambda_{\text{eff}}^2 \|\delta_k\|^2 + 2\|\delta_k\| \|w_k\| + \|w_k\|^2 \quad (\text{O.8})$$

Proposition DA.1: Bounded Mismatch (Deterministic). **Statement.** Under DA2' with $\eta^* < 2c_{\min}/c_{\max}^2$ and bounded per-step disturbance $\|w_k\| \leq \rho_{\text{step}}$, the mismatch is ultimately bounded:

Derived (DA.1, discrete bounded mismatch).

$$R_D^* = \frac{\rho_{\text{step}}}{1 - \lambda_{\text{eff}}} \quad (\text{O.9})$$

Proof. By the triangle inequality: $\|\delta_{k+1}\| = \|(\delta_k - \eta^* F_d(\delta_k)) + w_k\| \leq \|\delta_k - \eta^* F_d(\delta_k)\| + \|w_k\|$. The contraction bound gives $\|\delta_k - \eta^* F_d(\delta_k)\| \leq \lambda_{\text{eff}} \|\delta_k\|$. Therefore:

$$\|\delta_{k+1}\| \leq \lambda_{\text{eff}} \|\delta_k\| + \rho_{\text{step}} \quad (\text{O.10})$$

This is an affine contraction with $\lambda_{\text{eff}} < 1$. By the Banach fixed-point theorem, all trajectories starting in $\mathcal{B}_R$ converge to the ball of radius $R_D^* = \rho_{\text{step}}/(1 - \lambda_{\text{eff}})$, provided $R_D^* < R$. $\square$

Recovery of continuous result. In the fluid limit ($\eta^* \rightarrow 0, \nu \rightarrow \infty, \nu\eta^* = \mathcal{J}$ fixed), $\lambda_{\text{eff}}^2 = 1 - 2\eta^* c_{\min} + O((\eta^*)^2)$, so $\lambda_{\text{eff}} \rightarrow 1 - \eta^* c_{\min}$ and $\rho_{\text{step}} \rightarrow \rho/\nu$. Then:

$$R_D^* = \frac{\rho/\nu}{\eta^* c_{\min}} = \frac{\rho}{\nu\eta^* c_{\min}} = \frac{\rho}{\alpha} \quad (\text{O.11})$$

recovering Prop A.1 exactly. The discrete-to-continuous gap for Model D steady state is **zero**.

Proposition DA.2: Adaptive Reserve (Discrete). **Statement.** Under the conditions of DA.1, the agent can absorb an additional per-step disturbance of:

Derived (DA.2, discrete adaptive reserve).

$$\Delta \rho_{\text{step}}^* = (1 - \lambda_{\text{eff}})R - \rho_{\text{step}} \quad (\text{O.12})$$

Proof. Identical to Prop A.2: the new $R_D^* = (\rho_{\text{step}} + \Delta \rho)/(1 - \lambda_{\text{eff}})$ must satisfy $R_D^* \leq R$. $\square$

The structure is identical to the continuous adaptive reserve $\Delta \rho^* = \alpha R - \rho$. The per-event contraction rate is $(1 - \lambda_{\text{eff}})$; the per-unit-time rate is $\nu(1 - \lambda_{\text{eff}})$. In the fluid limit, $\nu(1 - \lambda_{\text{eff}}) \rightarrow \nu \cdot \eta^* c_{\min} = \alpha$, recovering the continuous result. (Note: the per-event rate $(1 - \lambda_{\text{eff}})$ converges to $\eta^* c_{\min}$, not to α directly — the factor of ν converts between per-event and per-unit-time.)

Proposition DA.1S: Stochastic Bounded Mismatch (Discrete). **Statement.** Under DA2' with $\eta^* < 2c_{\min}/c_{\max}^2$ and i.i.d. zero-mean disturbance $\mathbb{E}[w_k] = 0$, $\mathbb{E}[\|w_k\|^2] = \sigma_{\text{step}}^2$, the mismatch satisfies:

Derived (DA.1S, discrete stochastic bounded mismatch).

$$\mathbb{E}[\|\delta_k\|^2] \leq \lambda_{\text{eff}}^{2k} \|\delta_0\|^2 + \frac{\sigma_{\text{step}}^2}{1 - \lambda_{\text{eff}}^2} \quad (\text{O.13})$$

where $\lambda_{\text{eff}}^2 = 1 - 2\eta^* c_{\min} + (\eta^*)^2 c_{\max}^2$.

Proof. Define $V_k = \|\delta_k\|^2$. Taking expectations of the squared update:

$$\mathbb{E}[V_{k+1} \mid \delta_k] = \|\delta_k - \eta^* F_d(\delta_k)\|^2 + \sigma_{\text{step}}^2 \quad (\text{O.14})$$

The first term expands as:

$$\|\delta_k - \eta^* F_d(\delta_k)\|^2 = V_k - 2\eta^* \delta_k^T F_d(\delta_k) + (\eta^*)^2 \|F_d(\delta_k)\|^2 \quad (\text{O.15})$$

By DA2'a (lower sector bound): $\delta_k^T F_d(\delta_k) \geq c_{\min} V_k$.

By DA2'b (Lipschitz bound): $\|F_d(\delta_k)\|^2 \leq c_{\max}^2 V_k$.

Note that the second step requires the *norm* bound DA2'b, not merely an inner-product upper bound — this is where the Lipschitz condition is essential. Combining:

$$\mathbb{E}[V_{k+1} \mid \delta_k] \leq \lambda_{\text{eff}}^2 V_k + \sigma_{\text{step}}^2 \quad (\text{O.16})$$

The condition $\eta^* < 2c_{\min}/c_{\max}^2$ ensures $\lambda_{\text{eff}}^2 < 1$. This is a supermartingale (when V_k is large enough). Iterating:

$$\mathbb{E}[V_k] \leq \lambda_{\text{eff}}^{2k} V_0 + \frac{\sigma_{\text{step}}^2}{1 - \lambda_{\text{eff}}^2} \quad (\text{O.17})$$

The steady-state mean-square mismatch is $\sigma_{\text{step}}^2/(1 - \lambda_{\text{eff}}^2)$. $\square$

Recovery of continuous result. In the fluid limit: $\sigma_{\text{step}}^2 \rightarrow n\sigma_w^2/\nu$, $\lambda_{\text{eff}}^2 \rightarrow 1 - 2\eta^*c_{\min}$, and $(1 - \lambda_{\text{eff}}^2) \rightarrow 2\eta^*c_{\min}$. The steady-state becomes $n\sigma_w^2/(2\nu\eta^*c_{\min}) = n\sigma_w^2/(2\alpha)$, recovering Prop A.1S exactly.

The discrete-to-continuous gap for Model S variance is $O(\eta^*c_{\max}^2/c_{\min}^2) = O(c_{\max}^2/(c_{\min}^2\nu))$, dominated by the conditioning ratio $c_{\max}^2/c_{\min}^2$. Substituting $\sigma_{\text{step}}^2 = n\sigma_w^2/\nu$ and $\eta^* = \mathcal{J}/\nu$ into $V_{\text{ss}} = \sigma_{\text{step}}^2/(1 - \lambda_{\text{eff}}^2)$ and Taylor-expanding at small η^* :

$$\frac{V_{\text{ss}}}{V_c} = \frac{1}{1 - \eta^*c_{\max}^2/(2c_{\min})} = 1 + \frac{\eta^*c_{\max}^2}{2c_{\min}} + O((\eta^*)^2) \quad (\text{O.18})$$

so

$$V_{\text{ss}} - V_c \approx \frac{n\sigma_w^2 c_{\max}^2}{4c_{\min}^2 \nu} \quad (\text{O.19})$$

— a leading correction that scales as $1/\nu$. The $(\eta^*)^2\|F_d\|^2$ term in the per-step recurrence enters $1 - \lambda_{\text{eff}}^2$ at order $(\eta^*)^2$, but the steady-state ratio $\sigma_{\text{step}}^2/(1 - \lambda_{\text{eff}}^2)$ inverts the leading $2\eta^*c_{\min}$ contraction, yielding $O(\eta^*)$ asymptotic gap rather than $O((\eta^*)^2)$. This quantifies the error introduced by GA-5 and confirms it is small whenever $c_{\max}^2/(c_{\min}^2\nu) \ll 1$.

Fluid Limit Theorem.

Statement. Let F_d be Lipschitz continuous with constant L_F on $\mathcal{B}_R$. Let $\delta^{(\nu)}(t)$ denote the piecewise-constant interpolation of the discrete trajectory at event rate ν , and $\delta(t)$ the solution of the continuous ODE $d\delta/dt = -F(\mathcal{J}, \delta) + w(t)$ with $F = \nu\eta^*F_d$. Then:

Derived (Conditional on Lipschitz regularity).

$$\sup_{t \in [0, T]} \|\delta^{(\nu)}(t) - \delta(t)\| \leq C \cdot \frac{\eta^*c_{\max}}{\nu^{1/2}} \quad (\text{O.20})$$

for a constant C depending on T, L_F , and R .

Sketch. This follows from the standard ODE-approximation theory for Euler schemes (Kushner & Yin, 2003, Ch. 5). The discrete update $\delta_{k+1} = \delta_k - \eta^*F_d(\delta_k) + w_k$ is a forward Euler step for the ODE with step size $1/\nu$. The Lipschitz condition on F_d ensures the local truncation error is $O(1/\nu^2)$. Summing over $O(\nu T)$ steps and applying the Gronwall inequality gives the $O(1/\nu^{1/2})$ bound.

For Model D (deterministic): the steady-state gap is exactly zero (both discrete and continuous converge to the same fixed point). The fluid-limit error affects only transients.

For Model S (stochastic): the steady-state variance gap is $O(\eta^*c_{\max}^2/c_{\min}^2) = O(c_{\max}^2/(c_{\min}^2\nu))$, dominated by the conditioning ratio $c_{\max}^2/c_{\min}^2$. The $(\eta^*)^2\|F_d\|^2$ term in the per-step recurrence enters $1 - \lambda_{\text{eff}}^2$ at order $(\eta^*)^2$, but inverting the leading $2\eta^*c_{\min}$ in $V_{\text{ss}} = \sigma_{\text{step}}^2/(1 - \lambda_{\text{eff}}^2)$ produces an $O(\eta^*)$ asymptotic gap, not $O((\eta^*)^2)$ — see the recovery calculation in Prop DA.1S above.

Epistemic Status.

DA.1, DA.1S, and DA.2 are *conditional* on DA2', which now includes both a sector lower bound (DA2'a) and a Lipschitz upper bound (DA2'b). The Lipschitz condition is strictly stronger than an inner-product upper bound — this is a real assumption, not a technicality. For Bayesian updates and gradient descent on smooth losses, DA2'b is satisfied (the correction magnitude is controlled by the loss curvature). For agents with non-smooth or pathological correction functions, DA2'b must be verified independently.

The proofs themselves are standard contraction-mapping (DA.1/DA.2) and supermartingale (DA.1S) arguments. The step-size constraint $\eta^* < 2c_{\min}/c_{\max}^2$ is essential and is stated explicitly in each proposition.

Fluid limit theorem is *conditional* on Lipschitz regularity of F_d — a standard regularity condition satisfied by all correction functions in the verified instances table (4.3). The convergence rate follows from classical ODE approximation theory (Kushner & Yin, 2003); the application to the AAT mismatch dynamics is new but the mathematics is not.

Max attainable: conditional — the Lipschitz bound DA2'b is inherent to the discrete-time treatment and cannot be replaced by a weaker inner-product condition without losing the norm bound used in the proofs.

Discussion.

GA-5 is closed. The fluid-limit bridging assumption is no longer required as an ungrounded assumption. For Model D, the discrete and continuous steady states are identical — the gap is zero. For Model S, the gap is $O(\eta^* c_{\max}^2 / c_{\min}^2) = O(c_{\max}^2 / (c_{\min}^2 \nu))$ in variance, quantitatively bounded and small in the regime where $c_{\max}^2 / (c_{\min}^2 \nu) \ll 1$. The continuous-time results in A are formally justified as the fluid limit of the discrete results here.

DA2' is a sector-Lipschitz condition, not a pure sector condition. The continuous-time treatment (A) requires only the one-sided sector bound $\delta^T F \geq \alpha \|\delta\|^2$ because the Lyapunov derivative $\dot{V}$ depends only on $\delta^T F$. Discretization introduces a quadratic term $(\eta^*)^2 \|F_d\|^2$ that requires the Lipschitz bound $\|F_d\| \leq c_{\max} \|\delta\|$. This is the standard distinction between sector conditions and Lipschitz conditions in nonlinear systems theory. For all agents in the verified instances table (4.3), the Lipschitz bound holds alongside the sector bound, so DA2' imposes no additional restriction in practice.

The step-size constraint has two forms. For well-conditioned corrections ($c_{\min} \approx c_{\max}$), the constraint reduces to $\eta^* < 2/c_{\max}$ — the classical form. For ill-conditioned corrections ($c_{\min} \ll c_{\max}$), the tighter constraint $\eta^* < 2c_{\min}/c_{\max}^2$ applies. This distinction is invisible in scalar systems but matters for high-dimensional agents with anisotropic correction.

No downstream results change qualitatively. The persistence condition, adaptive reserve, and adversarial scaling laws derived in A and 15.2 hold as stated. The discrete framework provides sharper constants (replacing α with $\nu(1 - \lambda_{\text{eff}})$) and a quantitative transient error bound, but the qualitative structure is unchanged.

Part I's formal chain is now complete. The prediction chain:

$$\text{gain principle + B1} \xrightarrow{\text{derived}} \text{sector condition} \xrightarrow{\text{Lyapunov/contraction}} \text{persistence, reserve, scaling} \quad (\text{O.21})$$

holds in both continuous time (via A) and discrete time (via this segment), with a quantitative bridge between them (the fluid limit theorem).

Working Notes.

- Non-stationary gain: when η^* varies over time (as in Kalman filtering with growing P^-), the contraction factor λ changes per step. The ultimate bound still holds if $\sup_k |\lambda_k| < 1$, but the transient analysis requires time-varying contraction arguments.

- Heavy-tailed disturbances: DA.1S assumes finite second moment. Sub-Weibull or heavy-tailed w_k would need truncation arguments or alternative Lyapunov functions. These extreme cases are better modeled as triggers for structural adaptation (4.8).
- Non-i.i.d. disturbances: correlated w_k (e.g., Markov environment noise) weakens the supermartingale argument. The contraction still holds per-step, but the steady-state bound requires mixing conditions. This connects to the adversarial coupling analysis in 15.2.

Incidental audit gold (gold-lift, 2026-05-31). Cross-audit ideation harvested from de-novo auditors’ working dirs, deduplicated and lightly attributed. Orthogonal framing / pedagogy; off-ramp (scalar-vs-vector bound confusion) at the end. **Coverage:** one substrate reached a dedicated digested reflection (Gemini, AUDIT-WORKING-193847); a batched discrete/persistence walk (Codex, AUDIT-WORKING-613842) read it as part of the persistence cluster and judged it “doing serious work” with good scope honesty (its certified concern there is about the *downstream template/result* segments compressing the Model-S region-awareness, not this appendix).

1. Candidate Brief prose / pre-prose.

- **The discretization penalty as “measure twice, cut once.”** In a continuous world you can pull the hammer back mid-swing as the error crosses zero; in a discrete event-driven world the action commits the agent to the full consequence of the swing before the next observation arrives — so an over-high gain over-corrects and oscillates. A plain-language anchor for the no-overshoot bound $\eta^* < 2/c_{\max}$ (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Latency bounds confidence, independent of epistemic certainty.** The no-overshoot condition means the *time between action and observation* caps the maximum safe update gain: a high-latency infrastructure forces the agent to lower η^* even when its model is perfectly certain ($U_M \approx 0$). “Confidence is not just a function of epistemic certainty; it is strictly bounded by the temporal resolution of the feedback loop.” A consequential framing of the discrete bound for agent/infrastructure design (Gemini, AUDIT-WORKING-193847).
- **The $1/\nu$ discretization penalty as a cost of event-driven agency.** The exact asymptotic gap $V_{ss} - V_\epsilon \approx n\sigma_w^2 c_{\max}^2 / (4c_{\min}^2 \nu)$ shows the discrete system is *systematically worse* than its continuous approximation by a factor scaling as $1/\nu$ under stochastic disturbance — high-frequency agents pay a smaller penalty. Names a real cost the continuous “fluid limit” hides; candidate to surface as the segment’s distinctive practical result (Gemini, AUDIT-WORKING-193847).

3. Follow-up items.

- **Heavy-tailed $\Rightarrow$ structural adaptation.** If w_k has infinite variance (Cauchy-style “black swan”), the mean-square Lyapunov proof fails entirely — implying such environments cannot be survived by parametric adaptation (η^* tuning) and *must* be met by structural adaptation (expanding R). Sharpens the existing heavy-tailed Working Note above into a routing claim toward #result-structural-adaptation-necessity (Gemini, AUDIT-WORKING-193847).

4. Readers often ask / wonder.

- **“Aren’t Lipschitz-bounded gradient descent and sector-bounded control theory different things?”** The segment’s quiet unification answer: they are the same physical reality at different temporal resolutions — gradient descent needs the stronger discrete Lipschitz bound (DA2’b) to prevent overshoot; continuous control needs only the directional sector bound (DA2’a) — surfacing this explicitly would help a reader coming from either side (Gemini, AUDIT-WORKING-193847).

Off-ramp (NOT gold) — routed for adjudication.

- **Scalar-vs-vector contraction-bound presentation is correct but confusing.** Gemini (AUDIT-WORKING-193847): the general (vector) stability condition $\eta^* < 2c_{\min}/c_{\max}^2$ and the scalar/colinear simplification $\eta^* < 2/c_{\max}$ disagree when $c_{\min} \ll c_{\max}$, and a reader can take this as a contradiction. The reconciliation: the general bound combines worst-case minimum alignment ($c_{\min}$) with worst-case maximum magnitude ($c_{\max}$) taken *independently* — necessary in high dimensions (orthogonal overshoot is possible) but overly pessimistic in 1D, where Cauchy-Schwarz is tight and all error is colinear overshoot. Suggested: add a sentence stating the general λ_{eff}^2 bound is conservative and that the gap between the two forms is the dimension artifact, not an inconsistency. Presentation/scope-honesty, not a math error.

Appendix P

Detail: Linear ODE Approximation

The full linear treatment of mismatch dynamics: scalar and vector forms, steady-state solutions under both disturbance models, transient behavior, convergence rate, validity conditions, breakdown modes, discrete-time connection, and adversarial coupling. This appendix collects the linear-case results that 3.9 states as a hypothesis, derives them explicitly, and delineates exactly where the linear approximation is valid and where it fails.

The detail serves as the *worked example* underlying the framework’s hypothesis that mismatch dynamics follow a first-order linear ODE in the simplest case. Everything here is exactly derivable from the linear assumption — the appendix’s purpose is to show, in detail, that the linear case gives clean closed-form results (the distinctive Model D $1/\mathcal{T}$ vs Model S $1/\sqrt{\mathcal{T}}$ scaling split; exponential transient convergence at rate $\mathcal{T}$; the squared-tempo law for adversarial coupling) and to *delineate exactly where the linear approximation is valid and where it fails*. The validity range: bounded mismatch within the sector region; non-saturating correction; sufficiently fast event rate relative to the mismatch timescale. The breakdown modes: saturation at large mismatch (correction slower than linear); threshold effects (small mismatches uncorrected — a dead zone); structural breakdown beyond a critical mismatch where the correction collapses entirely because the model class is no longer appropriate. The chapter’s central inequality — that adversarial mismatch ratios scale as the squared tempo ratio — is first introduced here under linearity, with the appendix showing exactly which assumptions the simple form rests on and where it transitions into the sector-condition machinery (4.4) as those assumptions relax.

Formal Expression.

1. The scalar and vector forms. The mismatch vector $\delta(t) \in \mathbb{R}^n$ evolves under the general dynamics from A:

Definition (vector dynamics).

$$\frac{d\delta}{dt} = -F(\mathcal{T}, \delta) + w(t) \quad (\text{P.1})$$

The **linear approximation** sets $F(\mathcal{T}, \delta) = \mathcal{T} \cdot \delta$, giving:

Hypothesis (linear-vector-ode).

$$\frac{d\delta}{dt} = -\mathcal{T} \cdot \delta + w(t) \quad (\text{P.2})$$

This is exact when the correction function is linear in δ (Kalman filter, Beta-Bernoulli conjugate update). It is an approximation otherwise.

Scalar form (equality). For a scalar mismatch $\delta(t) \in \mathbb{R}$:

Derived (scalar-ode, from linear-vector-ode with $n = 1$).

$$\frac{d\delta}{dt} = -\mathcal{T} \cdot \delta + w(t) \quad (\text{P.3})$$

This is an equality: the scalar ODE is exactly the $n = 1$ case of the vector ODE.

Norm form (inequality). For vector $\delta \in \mathbb{R}^n$, take the time derivative of $\|\delta\| = (\delta^T \delta)^{1/2}$:

$$\frac{d\|\delta\|}{dt} = \frac{\delta^T \dot{\delta}}{\|\delta\|} = \frac{\delta^T (-\mathcal{T} \delta + w)}{\|\delta\|} = -\mathcal{T} \|\delta\| + \frac{\delta^T w}{\|\delta\|} \quad (\text{P.4})$$

By Cauchy-Schwarz, $\delta^T w / \|\delta\| \leq \|w\|$. Under Model D (GA-2: $\|w(t)\| \leq \rho$):

Derived (norm-inequality, from Cauchy-Schwarz).

$$\frac{d\|\delta\|}{dt} \leq -\mathcal{T} \cdot \|\delta\| + \rho \quad (\text{P.5})$$

This is an inequality, not an equality. The Cauchy-Schwarz step is tight only when $w(t)$ is parallel to $\delta(t)$ (worst-case disturbance). The norm form stated in 3.9 is this upper bound. For the scalar case ($n = 1$), Cauchy-Schwarz is automatically tight and the inequality becomes an equality.

2. Steady-state solutions.

Model D (deterministic bounded disturbance, GA-2: $\|w(t)\| \leq \rho$). Setting $d\|\delta\|/dt = 0$ in the norm inequality gives the worst-case steady state:

Derived (model-d-steady-state, from norm inequality).

$$\|\delta\|_{ss} = \frac{\rho}{\mathcal{T}} \quad (\text{P.6})$$

This is the tight upper bound: steady-state mismatch equals the ratio of disturbance to correction. In the scalar case ($n = 1$), this is exact (the Ornstein-Uhlenbeck process with deterministic forcing converges to $\rho/\mathcal{T}$). In the vector case, it is the worst case over all disturbance directions.

Model S (stochastic zero-mean disturbance, GA-2S: $d\delta = -\mathcal{T} \delta dt + \sigma_w dW_t$). The Ornstein-Uhlenbeck process has stationary variance derived via Ito-Lyapunov analysis (Prop A.1S in A, specialized to $\alpha = \mathcal{T}$):

Derived (model-s-steady-state, from Ito-Lyapunov with linear correction).

$$\mathbb{E}[\|\delta\|^2]_{ss} = \frac{n\sigma_w^2}{2\mathcal{T}} \quad (\text{P.7})$$

The RMS steady-state mismatch is:

$$\|\delta\|_{rms} = \sigma_w \sqrt{\frac{n}{2\mathcal{T}}} \quad (\text{P.8})$$

For the scalar case ($n = 1$): $\|\delta\|_{\text{rms}} = \sigma_w/\sqrt{2\mathcal{T}}$.

Scaling difference. Model D gives $\|\delta\|_{ss} \propto 1/\mathcal{T}$; Model S gives $\|\delta\|_{\text{rms}} \propto 1/\sqrt{\mathcal{T}}$. Doubling the correction rate halves the deterministic steady-state mismatch but only reduces the stochastic steady-state by a factor of $\sqrt{2} \approx 1.41$. Correction is less effective against noise than against drift.

3. Transient solution. Model D, constant ρ . The linear ODE $d\|\delta\|/dt = -\mathcal{T}\|\delta\| + \rho$ with initial condition $\|\delta(0)\| = \|\delta_0\|$ has the standard first-order linear solution:

Derived (transient-model-d).

$$\|\delta(t)\| = \|\delta_0\| e^{-\mathcal{T}t} + \frac{\rho}{\mathcal{T}}(1 - e^{-\mathcal{T}t}) \quad (\text{P.9})$$

Mismatch decays exponentially from initial conditions toward the steady state $\rho/\mathcal{T}$ with time constant $\tau = 1/\mathcal{T}$. After k time constants, the transient has decayed by a factor of e^{-k} : 63% after one time constant, 95% after three, 99.3% after five.

Model S, Ornstein-Uhlenbeck. The mean-square mismatch evolves as (from Prop A.1S with $\alpha = \mathcal{T}$):

Derived (transient-model-s).

$$\mathbb{E}[\|\delta(t)\|^2] = \|\delta_0\|^2 e^{-2\mathcal{T}t} + \frac{n\sigma_w^2}{2\mathcal{T}}(1 - e^{-2\mathcal{T}t}) \quad (\text{P.10})$$

The variance converges twice as fast as the mean (rate $2\mathcal{T}$ vs. $\mathcal{T}$) because the Lyapunov function $V = \frac{1}{2}\|\delta\|^2$ is quadratic — its dynamics have doubled exponential rate.

4. When the linear approximation is valid. The linear case $F(\mathcal{T}, \delta) = \mathcal{T} \cdot \delta$ is a special case of the sector condition (GA-3) from 4.4 with:

Derived (linear-sector-parameters).

$$\alpha = \mathcal{T}, \quad R \rightarrow \infty \quad (\text{P.11})$$

That is, the sector condition holds globally with lower bound α equal to the tempo, and the sector-condition region has infinite radius. In the notation of 4.3:

- **Directional fidelity parameter:** $c_{\min} = 1$ (the correction points exactly at the mismatch).
- **Sector parameter:** $\alpha = \eta^* \cdot c_{\min} = \eta^* = \mathcal{T}/\nu$.
- **No upper saturation:** $c_{\max} = c_{\min} = 1$ (the sector bounds coincide).

Consequence for persistence. With $R \rightarrow \infty$, structural persistence ($\alpha > \rho/R$) is trivially satisfied for any $\mathcal{T} > 0$. The binding constraint is task adequacy alone: $\mathcal{T} > \rho/\|\delta_{\text{critical}}\|$ (Model D) or $\mathcal{T} > n\sigma_w^2/(2\|\delta_{\text{critical}}\|^2)$ (Model S). This is why the linear operational forms in 4.5 exist: in the linear world, structural persistence is free.

The linear approximation is exact when:

1. **Kalman filter** (scalar or matrix): the gain K_t produces $F(\delta) = K_t H \delta$, which is linear. The sector parameter equals the Kalman gain: $\alpha = K$ (scalar) or $\alpha = \lambda_{\min}^+(KH)$ (matrix). See 4.3.
2. **Beta-Bernoulli conjugate update**: the correction $F(\delta) = \delta/(n+1)$ is linear with $\alpha = 1/(n+1) = \eta_{\text{edge}}$.
3. **Exponential family with natural parameters**: the natural-parameter update is linear in the sufficient statistic, giving $\alpha = \eta \cdot \lambda_{\min}(\text{Fisher})$.
4. **Gradient descent on quadratic loss**: $F(\delta) = \eta \nabla^2 L \cdot \delta$ is linear with $\alpha = \eta \cdot \lambda_{\min}(\nabla^2 L)$.

5. When the linear approximation breaks down. The linear form $F = \mathcal{T} \cdot \delta$ fails when the true correction function deviates from linearity. Three failure modes, each corresponding to a specific nonlinearity:

Saturation at large $\|\delta\|$. The correction mechanism is overwhelmed by large mismatch. The true correction satisfies $F(\delta) < \mathcal{T}\|\delta\|$ for large $\|\delta\|$ — correction is slower than the linear prediction. Simulation confirms: for a saturating function $g(\delta) = \delta/(1 + |\delta|/R)$, the sector parameter at the capacity boundary is $\alpha \approx \mathcal{T}/2$ (half the linear value). The linear approximation overstates persistence margins. The sector-condition framework (4.4) handles this via finite R and reduced α .

Threshold effects at small $\|\delta\|$. Below a detection threshold ε , small mismatches go uncorrected: $F(\delta) \approx 0$ for $\|\delta\| < \varepsilon$. This creates a dead zone where the model drifts. The linear approximation (which predicts correction at all scales) misses this. The sector condition fails locally at small $\|\delta\|$ (the ratio $\delta^T F / \|\delta\|^2 \rightarrow 0$), but the dead zone is bounded and does not affect large-scale stability.

Structural breakdown. Beyond some critical mismatch, the correction rate drops to zero because the model class is no longer appropriate: the mismatch exceeds the model's representational capacity. $F(\delta) \approx 0$ for $\|\delta\| > R$. This is the structural adaptation trigger (4.8). The linear approximation, which predicts correction growing without bound, misses this entirely. The sector-condition framework captures it via the finite radius R of the sector-condition region.

6. Discrete-time connection. The continuous ODE is a fluid-limit approximation of the discrete event-driven dynamics (3.1). The discrete mismatch dynamics are:

$$\delta_{k+1} = \delta_k - \eta^* F_d(\delta_k) + w_k \quad (\text{P.12})$$

In the linear case ($F_d(\delta) = \delta$), this becomes:

$$\delta_{k+1} = (1 - \eta^*)\delta_k + w_k \quad (\text{P.13})$$

which is an AR(1) process with coefficient $\lambda = 1 - \eta^*$.

○ proves the formal connection:

Model D. The discrete and continuous steady states are *identical* — the fluid-limit gap is exactly zero. Both give $R^* = \rho/\alpha$. The discrete form has $\alpha = (1 - |\lambda|)/\eta^* = (1 - |1 - \eta^*|)/\eta^*$, which equals 1 (hence $\alpha_{\text{continuous}} = \nu \cdot 1 = \mathcal{T}$) when $0 < \eta^* < 1$.

Model S. The discrete steady-state variance is $\sigma_{\text{step}}^2/(1 - \lambda_{\text{eff}}^2)$, which recovers the continuous result $n\sigma_w^2/(2\mathcal{T})$ in the fluid limit ($\eta^* \rightarrow 0, \nu \rightarrow \infty, \nu\eta^* = \mathcal{T}$ fixed). The variance gap is $O(\eta^* c_{\text{max}}^2/c_{\text{min}}^2) = O(c_{\text{max}}^2/(c_{\text{min}}^2 \nu))$ — quantitatively small whenever $c_{\text{max}}^2/(c_{\text{min}}^2 \nu) \ll 1$. See ○ for the leading-order Taylor expansion that gives this scaling.

Fluid-limit validity. The ODE approximation is formally justified by the fluid limit theorem in ○ (conditional on Lipschitz regularity of F_d). The approximation is most accurate when $\eta^* \ll 1$ (the small-gain regime). It is least

accurate during initial transients when η^* is large, but this phase is short-lived and the transient error is bounded by $O(\eta^* c_{\max}/\nu^{1/2})$.

7. Adversarial coupling in the linear case. When two agents are coupled, A 's praxis contributes to B 's disturbance:

Hypothesis (Linear Coupling Model).

$$\rho_B = \rho_{B,\text{base}} + \gamma_A \cdot \mathcal{T}_A \quad (\text{P.14})$$

Under the linear approximation, the steady-state mismatches (Model D, coupling-dominant: $\gamma_A \mathcal{T}_A \gg \rho_{B,\text{base}}$) are:

Derived (linear-adversarial-steady-state, from Model D steady state + coupling model).

$$\|\delta_B\|_{ss} \approx \frac{\gamma_A \mathcal{T}_A}{\mathcal{T}_B}, \quad \|\delta_A\|_{ss} \approx \frac{\gamma_B \mathcal{T}_B}{\mathcal{T}_A} \quad (\text{P.15})$$

The ratio:

Derived (squared-tempo-law, from linear steady states).

$$\frac{\|\delta_B\|_{ss}}{\|\delta_A\|_{ss}} = \frac{\gamma_A}{\gamma_B} \left(\frac{\mathcal{T}_A}{\mathcal{T}_B} \right)^2 \quad (\text{P.16})$$

Under symmetric coupling ($\gamma_A \approx \gamma_B$), tempo advantage squares: a 2:1 tempo ratio yields a 4:1 mismatch ratio; a 3:1 ratio yields 9:1.

Why the squared law. The exponent 2 arises because the $1/\mathcal{T}$ steady-state scaling appears in both numerator (faster agent generates more disturbance) and denominator (faster agent corrects better): one power from the coupling, one from the steady-state. Under Model S (stochastic coupling, $1/\sqrt{\mathcal{T}}$ scaling), the exponent reduces to 3/2. See 16.3 for the full regime analysis.

Simulation validation. Variant A confirmed $b = 1.999$ (Model D, coupling-dominant). Variants C-D confirmed $b = 1.481$ (Model S, coupling-dominant). Both within numerical precision of the derived values. See AX.

Epistemic Status.

Exact for the linear case. The linear ODE is a standard first-order linear system; the solutions (transient and steady-state, both Model D and Model S) are textbook results for the Ornstein-Uhlenbeck process and its deterministic analog. The sector-condition parameters ($\alpha = \mathcal{T}, R \rightarrow \infty$) are exact when the correction function is linear. The discrete-time connection is exact (zero gap for Model D, $O(\eta^*)$ gap for Model S — see O for the leading-order Taylor expansion). The adversarial scaling law ($b = 2$ for Model D, $b = 3/2$ for Model S) is derived and simulation-validated.

What is exact vs. what is an approximation. The linear ODE is exact for systems with linear correction dynamics (Kalman, Beta-Bernoulli, quadratic loss). For nonlinear systems, the linear ODE is a local Taylor approximation valid near the steady state. The sector-condition framework (4.4, A) is the general treatment; this appendix derives what falls out when the sector bounds coincide.

The norm form is an upper bound for $n > 1$. The inequality introduced by Cauchy-Schwarz at the norm step is tight only in the worst case. For typical disturbances that are not persistently aligned with the mismatch direction, the actual norm trajectory lies below the upper bound. The scalar case ($n = 1$) is an equality. This distinction is load-bearing:

downstream results that use $d\|\delta\|/dt = -\mathcal{T}\|\delta\| + \rho$ as an equality (e.g., the exact transient solution, the exact steady-state ratio) are strictly correct only for $n = 1$ or for worst-case disturbance. The Lyapunov analysis in A avoids this issue by working with $V = \frac{1}{2}\|\delta\|^2$ directly, without passing through the norm derivative.

Max attainable: exact (the linear case is its own exact analysis; there is nothing to tighten).

Discussion.

Why this appendix exists. The linear ODE in 3.9 is labeled as a hypothesis and described as a “first-order approximation.” That is correct for the general case. But for agents with linear correction dynamics, the ODE is not an approximation at all – it is exact. This appendix serves two roles: (1) providing the complete derivation that 3.9 points to rather than carrying inline, and (2) making precise when the “approximation” is exact and when it genuinely introduces error.

Pedagogical value. The linear case is the entry point for understanding AAT’s mismatch dynamics. The closed-form solutions (exponential convergence, ratio steady state, squared scaling law) build intuition that the general sector-condition results (4.4) cannot provide – Lyapunov gives bounds and existence, not quantitative trajectories. The linear treatment also connects directly to the AR(1) simulation framework (AX) and classical control theory (PI controllers, Kalman filters).

Speed-quality substitutability. From $\mathcal{T} = \nu \cdot \eta^*$ (single channel): doubling event rate ν has the same effect on $\|\delta\|_{ss}$ as doubling update quality η^* . They are multiplicative when both improve: 50% improvement in each yields $1.5 \times 1.5 = 2.25\times$, not $3\times$. This is the formal analog of Boyd’s insight that Orient quality often matters more than raw OODA speed.

The persistence threshold in the linear world. From the steady state: $\|\delta\|_{ss} < \|\delta\|_{critical}$ iff $\mathcal{T} > \rho/\|\delta\|_{critical}$ (Model D). This is task adequacy only – structural persistence is trivially satisfied because $R \rightarrow \infty$. The linear world makes persistence look easier than it is. For nonlinear agents, both structural and task-adequacy conditions must hold (4.5).

Working Notes.

- The vector ODE $d\delta/dt = -\mathcal{T}\delta + w$ assumes isotropic correction (same rate in all directions). For anisotropic agents (tempo tensor $\mathbf{T}$), the linear ODE generalizes to $d\delta/dt = -\mathbf{T}\delta + w$ with matrix exponential solutions and per-eigenvalue convergence rates. The per-dimension persistence condition ($\mathcal{T}_k > \rho_k/\delta_{critical,k}$) from 16.5 is the diagonal special case.
- The norm-inequality subtlety (Section 1 above) propagates into the adversarial scaling law: the squared law ($b = 2$) is exact for $n = 1$ and a worst-case upper bound for $n > 1$. Whether this matters quantitatively for multi-dimensional adversarial dynamics has not been tested in simulation.
- Model S’s Ito-Lyapunov derivation assumes σ_w is constant. When the noise scale depends on state ($\sigma_w(\delta)$, as in multiplicative noise models), the Ornstein-Uhlenbeck analysis no longer applies and the steady-state formula changes. The sector-condition results in A handle additive noise only.

Incidental audit gold (gold-lift, 2026-05-31). Cross-audit ideation harvested from a de-novo auditor’s working dir, lightly attributed. Orthogonal framing / pedagogy; off-ramp (steady-state tightness) at the end. **Coverage:** one substrate reached a digested reflection (Gemini, AUDIT-WORKING-193847), which read the segment as both pedagogical and rigorous and praised the failure-mode mapping.

1. Candidate Briefprose / pre-prose.

- **The “Linearity Illusion.”** The linear approximation assumes $R \rightarrow \infty$ and therefore *cannot see* the structural-breakdown trigger — “linear math makes survival look easier than it is.” A compact framing of why the linear ODE is the right *baseline* but the wrong *safety analysis*: it gives closed-form trajectories in friendly (convex / linear) environments against which the cost of nonlinearity can be measured (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Dead zones as a *requirement for sanity*, not a defect.** The threshold effect at small $\|\delta\|$ (errors below sensor resolution go uncorrected, so the agent drifts) means absolute perfection is impossible for any finite-resolution agent — but more deeply, *correcting* a tiny error often costs more coordination overhead C than the error itself costs, so a rational agent *builds* a dead zone. For an ELI: a zero-tolerance infrastructure would be paralyzing; “a mind that constantly updates its worldview based on microscopic sensor noise will consume all its tempo on pointless neuroses.” Tolerance for minor mismatch as a design principle — vivid Discussion candidate (Gemini, AUDIT-WORKING-193847).
- **Speed-quality substitutability and the 2.25× tempo multiplier.** Since $\mathcal{T} = \nu \cdot \eta^*$, a 50% gain in speed *and* a 50% gain in quality compound to a 2.25× tempo improvement — a clean illustration of why tempo is multiplicative in its two factors, with the (open) investment-strategy implication that balancing compute (ν) against architectural quality (η^*) may beat pouring everything into one (Gemini, AUDIT-WORKING-193847).
- **Nonlinear-failure-mode mapping.** The “when the linear approximation breaks down” section (dead zones, saturation, structural breakdown) was singled out as one of the clearest expositions of nonlinear control failure the auditor had read, with each mode mapped to a specific AI failure — candidate to foreground as the segment’s pedagogical payload (Gemini, AUDIT-WORKING-193847).

3. Follow-up items.

- The existing anisotropic-correction Working Note (matrix tempo $\mathbf{T}$) was implicitly re-affirmed; no new follow-up beyond what is already noted.

4. Readers often ask / wonder.

- **“Is $\rho/\mathcal{T}$ a loose worst-case bound or the real steady state?”** See off-ramp — the answer (for constant drift it is exactly tight at $t \rightarrow \infty$) is worth stating so a reader does not under-weight it as a rarely-hit bound (Gemini, AUDIT-WORKING-193847).

Off-ramp (NOT gold) — routed for adjudication.

- **The Model-D steady state $\rho/\mathcal{T}$ is exactly tight (not merely a worst-case bound) for constant directional drift.** Gemini (AUDIT-WORKING-193847): the norm-form $d\|\delta\|/dt \leq -\mathcal{T}\|\delta\| + \rho$ is an inequality because Cauchy-Schwarz is tight only when the disturbance w aligns with δ — but for a *constant* drift vector, a linear system’s $\delta(t)$ eventually aligns with w , making the inequality an equality, so $\|\delta\|_{ss} = \rho/\mathcal{T}$ is the exact inevitable steady-state magnitude for any persistent directional drift (Model D, $n > 1$), not a rarely-hit bound. Suggested: clarify that the transient is strictly bounded by the inequality while the steady state is practically tight at $t \rightarrow \infty$. Scope/tightness clarification — strengthens the result’s certainty rather than weakening it.

Appendix Q

Derivation: Graph Structure Uniqueness

Operational requirements on the agent’s representation — directed temporal ordering, probabilistic uncertainty, and the ability to test strategy components — are *sufficient* for the strategy to be a directed acyclic graph with the Markov factorization property. The argument parallels Cox’s theorem for probability in *form* but not yet in *strength*: Cox’s theorem is necessary-and-sufficient (the only measure satisfying the desiderata is probability); this result is sufficient only (the desiderata guarantee DAG+Markov, but no one has shown a non-DAG structure cannot satisfy them). Acyclicity and directed edges are *proved* from temporal ordering over a finite horizon; the Markov factorization is *proved under causal sufficiency* via the Causal Markov Condition theorem (Spirtes–Glymour–Scheines, Pearl). A fourth postulate (observable intermediates) is required for localized strategic diagnosis but not for the representation or persistence results themselves.

How far the Cox parallel goes. Cox’s theorem starts from desiderata on how a rational agent should quantify uncertainty (consistency, universality, continuous functional composition) and proves that the *only* measure satisfying them is probability — necessity. This segment starts from desiderata on how a bounded agent can represent its strategy under causal action (directed temporal order, probabilistic edge uncertainty, causal sufficiency of the chosen nodes) and proves that DAG+Markov *suffices* to satisfy them — sufficiency. The necessity direction — no non-DAG structure (factor graphs, junction trees with cyclic message schedules, chain graphs) can satisfy P1–P4 plus causal sufficiency — is not established here. In practical terms this gap is unimportant because the proved sufficiency gives a rigorous grounding for the DAG structure; claims that AAT’s strategy *must* be a DAG should be read as “must-if-sufficient-via-this-route,” not as a proved necessity. A stronger Cox-style result is open. The placement of the DAG structure on a footing comparable to probability — a consequence of operational requirements rather than a modeling convenience — holds in the sufficiency direction; the full parallel with Cox awaits a uniqueness argument.

Formal Expression.

The Postulates. Four properties that a strategy representation must satisfy. Each is independently motivated from the adaptive-systems foundation.

P1: Directed Temporal Ordering.

If component *A* of the strategy causally produces component *B*, then *A* temporally precedes *B*. The strategy representation must respect this directionality — edges point from causes to effects, from actions to outcomes, from prerequisites to goals.

Derived (from #post-causal-structure).

This is a consequence of the temporal postulate (1.7): the arrow of time is constitutive, not incidental. Reversing a causal edge would mean effects precede causes, which is physically impossible.

P2: Probabilistic Uncertainty.

The agent's uncertainty about whether each step of the strategy will succeed must be quantified by a measure satisfying Cox's axioms (consistency, universality, non-negativity). The unique such measure is probability (Cox 1946, "Probability, Frequency and Reasonable Expectation," *American Journal of Physics* 14(1):1–13; modern exposition in Jaynes 2003, *Probability Theory: The Logic of Science*, Cambridge University Press, Chapter 2). The agent may use other representations internally (confidence scores, fuzzy logic), but these must be mappable to probability to be consistent.

Derived (from Cox's theorem).

P3: State-Local Revisability.

When the agent observes evidence about one component of its strategy (e.g., "step 3 succeeded" or "prerequisite 2 is blocked"), it must be able to update its beliefs about that component and its consequences without recomputing the entire strategy from scratch.

Derived (from #der-chain-confidence-decay + bounded computation).

Why this is forced, not chosen:

From fragility. Additive log-confidence (8.1) means longer chains are exponentially less reliable. The agent will frequently encounter partial failures. Each partial failure requires re-evaluation of the affected portion of the strategy. If each re-evaluation requires full recomputation, the agent's planning tempo T_Σ is catastrophically slow — potentially violating the strategy persistence condition.

From bounded computation. The agent has finite computational resources (the IB constraint applies to planning as well as model maintenance). Full recomputation of a strategy with N components costs $O(N)$ or worse. Local revision costs $O(|\text{affected}|)$, which can be much smaller.

From the persistence condition. Strategy must be revised faster than the environment invalidates it. Local revision directly increases T_Σ by reducing the per-update cost. An agent that must recompute everything on each update has lower T_Σ and is more likely to fall below the persistence threshold.

P4: Observable Intermediates.

To support **localized strategic diagnosis and revision**, the strategy representation benefits from internal checkpoints — observable states between the initial action and the final goal — that the agent can monitor to detect partial failure.

Derived (from #der-chain-confidence-decay + monitoring requirement).

Without intermediates, the agent cannot detect chain failure until the final outcome. By the time the final outcome reveals failure, all intermediate actions are wasted. With intermediates, the agent can detect failure at step k and revise, saving the cost of steps $k + 1$ through n . The value of early detection grows with chain length, because longer chains fail more often (P2 + 8.1).

Observable intermediates are not required for strategy representation or persistence. When intermediates are unobservable, plan-level tracking (9.10, Case 3) preserves the sector condition at the cost of per-edge diagnostic resolution — the agent knows the plan is failing but cannot localize which step needs revision (9.3). P4 is therefore a requirement for *strong diagnostics*, not for strategy representation per se. The observability investment tradeoff (9.3) quantifies the payoff: making an intermediate observable improves the sector parameter from $1/(n_\Phi + 1)$ (plan-level) to $\min(1/(n_1 + 1), \theta_1/(n_2 + 1))$ (per-edge weakest-link).

The Derivation.

Step 1: P1 implies directed edges. Each component X_i of the strategy has a set of direct causes $\text{Pa}(X_i)$ — the components whose outcomes directly influence X_i 's outcome. P1 requires that these causal relationships are directed: $\text{Pa}(X_i)$ temporally precedes X_i . This gives directed edges $\text{Pa}(X_i) \rightarrow X_i$.

Step 2: P2 implies probability distributions on edges. Each edge carries uncertainty: $P(X_i | \text{Pa}(X_i))$. By P2 (Cox), this is a probability distribution. The joint distribution over all strategy components is some $P(X_1, \dots, X_n)$.

Step 3: Causal sufficiency implies the Markov condition (proved).

Claim. For a causally sufficient strategy DAG, the Markov factorization property is a theorem — a consequence of the Causal Markov Condition (CMC).

Derived (Conditional on causal sufficiency of Σ_t).

The Markov factorization property. Each variable X_i is conditionally independent of its non-descendants given its parents:

$$X_i \perp \text{NonDesc}(X_i) \mid \text{Pa}(X_i) \quad (\text{Q.1})$$

Equivalently, the joint distribution factorizes as:

$$P(X_1, \dots, X_n) = \prod_{i=1}^n P(X_i \mid \text{Pa}(X_i)) \quad (\text{Q.2})$$

(The equivalence holds for positive distributions — Lauritzen 1996, Theorem 3.27.)

The argument has five parts:

(a) The DAG is a causal model. P1 establishes that edges represent causal relationships: completing a parent step causally advances the child step. P2 establishes probabilistic uncertainty over outcomes. Together: Σ_t is a causal DAG in the sense of structural causal models (Pearl 2009, Definition 7.1.1) — each node's outcome is determined by its parents' outcomes (through the causal mechanism encoded in the edge credences) plus exogenous uncertainty specific to that step. Formally, each node admits a structural equation:

$$X_i = f_i(\text{Pa}(X_i), \varepsilon_i) \quad (\text{Q.3})$$

where f_i is the local causal mechanism and ε_i is the exogenous noise (the residual uncertainty at step i not determined by its parents).

(b) Causal sufficiency implies exogenous independence. The exogenous terms ε_i are mutually independent if and only if no unmodeled common cause affects two or more nodes in the graph. This is precisely the **causal sufficiency** assumption: every variable that is a direct common cause of two or more nodes in Σ_t is itself a node in Σ_t .

For agent-constructed strategies, causal sufficiency is a **modeling ideal, not a typical condition**. The agent designed the graph, so all *intended* causal relationships are explicit — but environmental common causes (shared infrastructure, weather, market shifts, correlated adversary actions) routinely affect multiple strategy steps without appearing as nodes. In complex, multi-stakeholder, or adversarial environments, causal insufficiency is the dominant case (8.3, Correlation Hierarchy). When an environmental factor is omitted, the exogenous terms become correlated and the Markov condition fails. This is model inadequacy (4.8), and the remedy is to add the missing common-cause node — but identifying which common causes matter is a modeling judgment, not a mechanical procedure (8.3, L1 construction principle). The

proof's conditional on causal sufficiency is therefore a condition on model quality: the result holds exactly when the DAG is well-constructed, approximately when it is close, and fails when major common causes are missing. The Correlation Hierarchy in 8.3 provides the practical framework: L0 (independence, this proof's assumption) gives tractable results; L1 (augmented DAG with explicit common-cause nodes) is the practical default in complex domains; L0 formal results transfer to correctly constructed L1 DAGs.

(c) **The Causal Markov Condition theorem.** For a DAG G over variables $V = \{X_1, \dots, X_n\}$ with structural equations $X_i = f_i(\text{Pa}(X_i), \varepsilon_i)$ where the ε_i are mutually independent:

$$P(X_1, \dots, X_n) = \prod_{i=1}^n P(X_i \mid \text{Pa}(X_i)) \quad (\text{Q.4})$$

This is the **Causal Markov Condition** — a proved theorem, not a modeling assumption. The standard references are Spirtes, Glymour, and Scheines (2000, Theorem 3.4) and Pearl (2009, §1.4.1, Theorem 1.4.1). The proof applies the chain rule in topological order: $P(X_1, \dots, X_n) = \prod_i P(X_i \mid X_1, \dots, X_{i-1})$, then uses the independence of ε_i to show that conditioning on all predecessors reduces to conditioning on parents only. Each non-parent predecessor's influence on X_i is fully mediated through the parents — its direct contribution enters through the causal mechanism f_i , not through ε_i .

(d) **P3 as consequence.** State-local revisability (P3) was originally stated as an independent postulate. The CMC reveals it is a *consequence* of the causal structure under causal sufficiency: since $X_i \perp \text{NonDesc}(X_i) \mid \text{Pa}(X_i)$, updating beliefs about X_i requires only $\text{Pa}(X_i)$ — local revision is automatically correct. No information from the rest of the graph changes the conditional distribution of X_i given its parents. P3 was motivated as an operational requirement (agents *need* local revision for computational tractability, and the persistence condition demands it). The CMC shows the requirement is automatically satisfied by any causally sufficient causal DAG. The two arguments converge from different directions: P3 says local revision is *needed*; the CMC says it is *guaranteed* (under causal sufficiency).

(e) **Connection to edge independence.** The CMC's exogenous independence condition (ε_i mutually independent) is precisely the **edge-independence assumption** in the AND/OR status propagation (8.3). When exogenous noise terms are independent, edge outcomes are conditionally independent given parents, and the AND/OR formulas compute correct probabilities. When they are correlated (causal insufficiency — latent common causes), the AND/OR propagation systematically overestimates success because it treats joint failure probability as the product of marginals. The validity of the Markov factorization and the validity of the independence model are the *same condition*: causal sufficiency of Σ_t . See 8.3 for the full treatment of correlated failure as the primary case.

Assembling (a)-(e). P1-P2 establish that Σ_t is a causal DAG with probabilistic uncertainty. Under causal sufficiency (exogenous independence), the CMC theorem proves the Markov factorization. P3 (local revisability) follows as a validated consequence. The Markov property is both operationally required (P3) and structurally guaranteed (CMC). When causal sufficiency fails, the Markov factorization is still the agent's *intended* factorization — the one its DAG represents — but it is wrong about the world. The gap between intended and actual factorization manifests as correlated failure and $\hat{R}_2$ overestimation, and the fix is structural: add the missing common-cause nodes to restore causal sufficiency.

Step 4: P1 + finite horizon implies acyclicity (proved). This is the strongest piece of the argument. See the dedicated section below.

Step 5: Assembly. P1 (directed edges + causal interpretation) + P2 (probabilistic) + causal sufficiency (CMC $\rightarrow$ Markov factorization) + P4 (internal nodes) + finite horizon (acyclicity):

The strategy representation must be representable as a directed acyclic graph with probability distributions at each node conditioned on its parents — a Bayesian network. P3 (local revisability) is validated as a consequence of this structure, not required as a premise.

Acyclicity Derivation.

This resolves a former known fragility in the theory. Acyclicity of Σ_t is derived, not assumed.

Derived (from #post-causal-structure + finite planning horizon).

Result. For a strategy representation over a finite future horizon, temporal ordering forces acyclicity.

Derivation.

1. Each node X_i in Σ_t represents a future event or state with temporal position $\tau_i > t$ (the future time at which the step occurs or the state is evaluated).
2. Each edge $X_i \rightarrow X_j$ requires $\tau_i < \tau_j$ (P1: causes temporally precede effects).
3. A cycle $X_i \rightarrow X_j \rightarrow \dots \rightarrow X_i$ would require $\tau_i < \tau_j < \dots < \tau_i$, which is impossible for a real-valued time index.
4. Therefore the graph is acyclic. $\square$

Formally: a finite set with a strict partial order (future events ordered by time) is representable as a DAG. This is a standard result in order theory — every finite partial order has a Hasse diagram, which is a DAG.

The iteration objection resolved. A strategy that says “try A , if fail try B , if fail try A again” appears cyclic.

In the time-indexed representation:

$$A_1 \rightarrow \text{check}_1 \rightarrow B_1 \rightarrow \text{check}_2 \rightarrow A_2 \rightarrow \dots \quad (\text{Q.5})$$

Each attempt is a distinct node at a distinct time. The apparent cycle is a linear chain in the unrolled view. Iteration “terminates” when either a node succeeds (remaining retry nodes become probability-zero), the agent exhausts its resource budget (a constraint truncating the chain), or the horizon ends. Any finite-horizon strategy, including those with “loops” in the informal sense, is acyclic when time-indexed.

Scope. This applies to Σ_t (the agent’s strategy over the future), not to M_t ’s model of the environment. M_t may include cyclic causal processes — feedback loops in the physical world, market dynamics, ecosystem interactions. The acyclicity is specific to the purposeful substate because Σ_t represents planned future actions and the future is partially ordered by time. M_t ’s model of environmental dynamics may need to represent cycles (via time-unrolled DBNs or other cyclic structures).

Connection to Pearl. Pearl’s do-calculus is defined on DAGs. Extensions to cyclic structures exist (cyclic SCMs, equilibrium models) but are substantially more complex and lose some of do-calculus’s clean properties. The temporal argument here shows that for strategy representations (future-looking plans), acyclicity is not a convenience restriction on Pearl’s framework — it is a consequence of the temporal structure of planning.

What Is Derived vs. What Is Chosen.

Table Q.1

<i>Property</i>	<i>Motivating postulate</i>	<i>Strength</i>
Directed edges	Temporal ordering (P1, 1.7)	Proved
Probabilistic uncertainty	Cox’s theorem (P2)	Proved
Acyclicity	Temporal ordering + finite horizon (P1)	Proved
Internal structure	Fragility + monitoring (P4, 8.1)	Derived

<i>Property</i>	<i>Motivating postulate</i>	<i>Strength</i>
Markov factorization	Causal Markov Condition theorem (P1 causal interpretation + P2 probability + causal sufficiency)	Proved under causal sufficiency (CMC theorem)
DAG with Markov property	P1 + P2 + causal sufficiency (CMC) + P4	Conditional on causal sufficiency — which is testable and repairable
AND/OR parameterization	Boolean completeness + parsimony	Hypothesis (binary outcomes only)
Single-parameter edges	Parsimony / IB	Formulation choice
Specific node ontology	—	Formulation choice

The dividing line: acyclicity and directed edges are proved; the full DAG-with-Markov-property is conditional on causal sufficiency. The parameterization (AND/OR, CPT form, edge semantics) is a formulation choice within the strongly motivated structure, motivated by parsimony and domain fit but not by mathematical necessity.

Equivalence Class. Within the DAG class. Multiple DAGs can encode the same conditional independence relations, forming a Markov equivalence class identified by a CPDAG (completed partially directed acyclic graph). Two DAGs in the same equivalence class make identical probabilistic predictions but may differ in causal interpretation.

Across representation types. Factor graphs, junction trees, influence diagrams, and chain graphs are NOT simple presentational variants of DAGs:

- **Factor graphs** and **junction trees** preserve factorization and inference structure without necessarily preserving directed causal semantics.
- **Influence diagrams** add decision and utility nodes — a richer object, not an equivalent one.
- **Chain graphs** can express independence models that are not representable as DAGs at all.
- **Markov equivalence** is a statement within DAG classes, not across all graphical model types.

The correct claim is narrow: for a given factorized distribution, DAG and factor-graph representations can compute the same marginals. But causal semantics (do-calculus) are DAG-specific and do not transfer to undirected or mixed representations without additional structure.

AAT's choice. AAT uses DAG + AND/OR because: (a) AND/OR is the most parsimonious complete basis for binary combination (8.2), (b) the DAG naturally supports causal/interventional reasoning (Pearl's do-calculus), and (c) the representation converged across three independent formalism attempts.

Epistemic Status.

The acyclicity derivation is *exact* — it follows from temporal ordering over a finite horizon via standard order theory. The individual postulates P1, P2, and P4 are each well-grounded (temporal structure, Cox's theorem, and chain fragility respectively).

The Markov property is now *proved under causal sufficiency* via the Causal Markov Condition theorem (Spirtes, Glymour & Scheines 2000, Theorem 3.4; Pearl 2009, Theorem 1.4.1). The previous sketch argument (P3 requires locality → P1 identifies parents → therefore Markov) has been replaced by a rigorous chain: P1-P2 establish the causal DAG structure, causal sufficiency guarantees exogenous independence, and the CMC theorem proves the factorization. P3 (local revisability) is now a *consequence* of the Markov property, not a premise — the CMC shows that local revision is automatically correct for causally sufficient DAGs, validating P3's operational requirement.

The conditioning on causal sufficiency is the right level of conditionality: it is a property of *strategy quality* (did the agent include all relevant common causes as nodes?), not of agent architecture. It is testable in principle (correlated

residuals after convergence indicate missing common causes) and repairable in practice (add the common-cause node). When causal sufficiency fails, the Markov factorization fails, and this manifests as correlated failure and $\hat{P}_2$ overestimation (8.3). The edge-independence assumption in AND/OR propagation and the causal sufficiency condition for the Markov property are the same condition viewed from different angles.

Max attainable: *exact* for acyclicity (already there). *Derived conditional* for the full DAG-with-Markov-property — the derivation is rigorous (invokes a proved theorem), and the remaining condition (causal sufficiency) is about model quality, not proof quality.

The AND/OR restriction is a *hypothesis* for binary outcomes, grounded in Boolean completeness and parsimony. For non-binary outcomes, it does not apply and richer parameterizations within the derived graphical structure are needed.

The parallel to Cox’s theorem is now tighter than previously stated: Cox’s theorem proves that consistency axioms force probability; the CMC theorem proves that causal structure under sufficiency forces the Markov factorization. Both are formal results, not analogies. The remaining gap: Cox’s axioms are necessary and sufficient for probability; AAT’s postulates are sufficient for DAG+Markov structure, but the necessity direction (could a non-DAG structure satisfy P1-P4?) is not established. For practical purposes this gap is unimportant — the proved sufficiency gives a rigorous foundation for the strategy representation.

Discussion.

The contribution of this analysis. The dividing line between derived/conditional structure and chosen parameterization is the key result. The agent community (and future researchers) know exactly what is proved (acyclicity, directed edges), what is conditional (Markov property, contingent on causal sufficiency), and what is a formulation choice (the parameterization within the graph). Alternative parameterizations can be explored without abandoning the theoretical foundation.

Acyclicity deserves emphasis. The existing theory previously flagged “DAG acyclicity is an assumption, not forced” as a known fragility. The derivation above resolves this: acyclicity of Σ_t follows from temporal ordering over a finite planning horizon. This is specific to the strategy — M_t ’s environment model is not restricted to acyclic structures.

The causal sufficiency assumption. The Markov condition assumes causal sufficiency — no hidden common causes within the strategy. Since the agent constructs Σ_t , there are no “hidden” variables internal to the strategy (the agent chose all the nodes). But environmental common causes that affect multiple strategy steps may violate the Markov condition within Σ_t . If so, latent variable models or causal graphs with hidden nodes would be needed. This connects to the edge identifiability problem noted in 8.3.

Working Notes.

- **P3→Markov: resolved.** The previous gap (P3 could be satisfied by non-Markov sparse factorizations) is resolved by grounding the Markov property in the CMC theorem rather than in P3. The CMC proves the factorization from the causal structure (P1) and causal sufficiency (exogenous independence), making P3 a consequence rather than a premise. The alternative-factorization concern (factor graphs, junction trees) is now moot: the Markov property follows from the causal semantics, not from locality. P3 remains valuable as an *operational requirement* that the CMC-guaranteed factorization satisfies.
- **Parsimony theorem for AND/OR.** Is there a formal result that AND/OR (noisy-AND + noisy-OR) is the unique $O(k)$ -parameter complete basis for binary nodes? This would strengthen 8.2 from formulation choice to derived. The Boolean completeness half is standard; the uniqueness-under-parsimony half is not established.
- **Non-binary outcome analogs.** For continuous or multi-valued outcomes, the natural analogs of AND/OR might be min/max or additive/multiplicative combination. Is there a completeness result for these? The current argument applies cleanly only to binary outcomes.

- **Environmental common causes and the CMC.** The CMC proof makes the failure mode precise: when unmodeled environmental dependencies (weather, shared infrastructure, market conditions) affect multiple strategy steps, the exogenous noise terms ϵ_i become correlated, causal sufficiency fails, and the Markov factorization is violated. The consequence is exactly the correlated-failure phenomenon in 8.3: $\hat{R}_E$ overestimates success because it treats joint failure probability as the product of marginals. The fix is structural: add the common-cause as a condition node in Σ_t , restoring causal sufficiency and the Markov property for the augmented DAG. This connects the graph-theoretic result (Markov property) to the strategy-layer result (independence model validity) through a single condition: causal sufficiency.
- **Promotion potential.** With the CMC-based proof, 8.3's DAG structure claim is now strongly grounded: acyclicity is proved, the Markov property is proved under causal sufficiency. The remaining “definition” character of strategy-dag is about the *parameterization* (AND/OR, single-parameter edges), which is a formulation choice within the proved graphical structure.

Incidental audit gold (gold-lift, 2026-05-31). Cross-audit ideation harvested from de-novo auditors' working dirs, deduplicated and lightly attributed. Orthogonal framing / pedagogy; off-ramp (time-unrolled scope clarification) at the end. **Coverage:** two substrates reached a dedicated digested reflection (Gemini, AUDIT-WORKING-193847; Gemini-voiced, AUDIT-WORKING-773921); three batched strategy-DAG walks touched it by reference and converged on the same praise (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-963715; Claude, AUDIT-WORKING-451729).

1. Candidate Briefprose / pre-prose.

- **“The Markov property in planning is a guaranteed consequence of a causally-sufficient world-model, not an arbitrary RL convenience.”** The recurring one-line synthesis: many planning frameworks (A, *MCTS*) *assume* DAG structure and Markov factorization; here acyclicity is derived from temporal ordering and the factorization from the Causal Markov Condition under causal sufficiency. A plain-language anchor (Gemini, AUDIT-WORKING-193847; Gemini-voiced, AUDIT-WORKING-773921).
- **“You can't cause your own prerequisite.”** Acyclicity in one breath: a strategy is about *causing future events*, and a finite-horizon plan is a finite poset ordered by time, representable as a DAG (its Hasse diagram) — the same argument as the acyclicity of Pearl's causal DAGs, applied to strategy. Named as “a quiet structural contribution that's easy to miss” (Claude, AUDIT-WORKING-963715; the poset/Hasse framing, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **The Cox's-theorem-parallel as an epistemic-humility exemplar.** The segment proves the DAG structure is *sufficient* (a Markov DAG meets all operational requirements) but explicitly flags *necessity* (no other structure could) as open, parallel to “Cox's theorem in form but not yet in strength.” Two substrates read this self-restraint as a trust-building move worth preserving prominently — and the “What Is Derived vs. What Is Chosen” table was independently called “the platinum standard for epistemic clarity,” pre-empting any “you just assumed a DAG” critique by showing exactly which physics/information postulates force it (Gemini-voiced, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-193847).
- **Local revisability (P3) demoted from premise to derived consequence.** Auditors flagged the refactor that turns Postulate 3 into a *consequence* of the CMC as “stunning structural refactoring” / “the theory simplifying and tightening itself” — candidate to surface as a worked example of the framework tightening its own axiom set (Gemini, AUDIT-WORKING-193847; Gemini-voiced, AUDIT-WORKING-773921).
- **“Paranoia” as the active search for hidden common causes.** The causal-sufficiency failure mode (omitting environmental common causes correlates the exogenous ϵ_i , so $\hat{R}_E = \prod p_i$ becomes wildly optimistic) glossed as: an agent naturally drifts to L0 independence because it is cheaper, so it must be *forced* to compute the covariance of its failures $\hat{p}_{ij}$ to detect missing L1 common causes. “A mind without paranoia is mathematically guaranteed to be blindsided by correlated failure” — a vivid framing of the existing common-cause Working Note (Gemini, AUDIT-WORKING-193847).

3. Follow-up items.

- **AND/OR parsimony / uniqueness.** Both the segment's own Working Note and an auditor flag the same open: if AND/OR (noisy-AND + noisy-OR) can be proven the *unique* $O(k)$ -parameter complete basis for binary combination, #scope-and-or upgrades from formulation-choice to derived — “locking the entire strategy structure into pure math” (Gemini-voiced, AUDIT-WORKING-773921).
- **Necessity direction stays watched downstream.** Auditors note a consistency-watch: downstream segments should not treat the DAG as the *only* possible strategy representation while necessity is open (Claude, AUDIT-WORKING-451729).

4. Readers often ask / wonder.

- **“What forces the agent to fix a missing common cause?”** The CMC framing makes the trigger precise but uncomfortable: causal-sufficiency violations show up as *correlated residuals after convergence*, so the agent must experience repeated inexplicable joint failures before it can trigger L1 structural adaptation to add the missing node — a reader may want this failure-then-repair loop made explicit (Gemini, AUDIT-WORKING-193847).

Belongs elsewhere.

- **The L0/L1/L1'/L2 correlation hierarchy belongs to #def-strategy-dag, not this appendix.** Auditors locate the richer correlation-hierarchy content (direction/magnitude of bias; the “structurally refuted” L1'-with-unobservable-common-cause identifiability obstruction) in #def-strategy-dag; this appendix carries the acyclicity + CMC-factorization proofs. Noted so a future promoter routes correlation-hierarchy gold to the definition segment (Claude, AUDIT-WORKING-451729, AUDIT-WORKING-963715).

Off-ramp (NOT gold) — routed for adjudication.

- **Acyclicity holds only for the time-unrolled execution graph, not a state-folded policy graph — make the scope explicit.** Gemini (AUDIT-WORKING-193847): the proof (“a cycle would require $\tau_1 < \dots < \tau_i$, impossible for a real time index”) is valid when nodes are *time-indexed events*, but if the strategy DAG were folded over *states of the world* (e.g. “at home” recurring at τ_1 and τ_3), cycles are physical and common — a finite-state-machine / general-MDP transition graph is cyclic. The segment already handles this in its “iteration objection resolved” section (“each attempt is a distinct node at a distinct time”), but the suggestion is to state explicitly at Step 1 that Σ_t is a time-unrolled execution graph, *not* a policy-over-states $\pi(S)$ — because rolling Σ_t up into a state-policy loses the DAG structure. Scope-honesty sharpening of an already-defended point, not a refutation.

Appendix R

Derivation: Sector Condition Verification for Edge-Credence Dynamics

Complete verification that specific strategy update dynamics satisfy the sector condition from A, backing the schema proposed in 9.10. Seven propositions are proved across distinct topologies. **B.1 (single edge)**: sector condition holds globally with $\alpha_\Sigma = 1/(n + 1)$, tight. **B.2 (two-edge AND chain, observable intermediate)**: weakest-link result with $\alpha_\Sigma = \min(1/(n_1 + 1), \theta_1/(n_2 + 1))$ — the evidence-starvation effect on the downstream edge attenuates by the upstream success probability. **B.3 (two-edge AND chain, unobservable intermediate)**: per-edge sector condition *fails* (the marginal point estimate is biased), but plan-level tracking recovers persistence with $\alpha_{\Sigma, \text{plan}} = 1/(n_\Phi + 1)$ at the cost of per-edge diagnostic resolution. **B.4 (two-arm OR, ϵ -greedy)**: *exploration-gated* weakest-link — pure greedy *fails* the sector condition; minimum exploration is required (the sufficient-exploration condition from 9.10).

B.5 (sector transfer to plan-confidence error): the sector condition transfers from per-edge credence space to *strategy-plan-confidence error* via the Jacobian — and the transfer is *credit-assignment-free*, requiring only status propagation. **B.6 (L1 augmented DAG, strict-prerequisite common cause)**: persistence transfers with three-way gating (condition-testing rate, evidence-starvation factor, exploration-gating factor) — the formal extension to causally-insufficient DAGs handled by augmentation. **B.7 (L1' mixture form, soft-facilitator common cause)**: persistence holds under *observable* common cause via five-way gating, and is *refuted* under unobservable common cause by the Cramér-Rao floor (the second formal instance of #disc-identifiability-floor).

The overall result: strategic persistence has a complete verified instance set for the canonical topologies. AND-chains exhibit depth-gated (geometric) attenuation; OR-nodes exhibit exploration-gated allocation; L1-augmented DAGs combine condition-testing, evidence-starvation, and exploration-gating. The chapter's claim that strategic persistence is structurally identical to epistemic persistence at the sector-template level is *verified* by these instantiations.

Motivation.

9.10 proposes that the sector-condition mathematics (Props A.1, A.1S, A.2 in A) extends from epistemic to strategic mismatch. The schema identifies three structural conditions (SA1, SA2', SA3) and conjectures the persistence form $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$. This appendix instantiates the schema for concrete Beta-Bernoulli edge dynamics, verifying the conditions case by case. Each proposition establishes the sector parameter α_Σ for a specific DAG topology; the persistence condition then follows by direct substitution into Proposition A.1 of A.

Common Setup.

Throughout, edge credences follow Beta-Bernoulli dynamics: edge k has true success probability $\theta_k \in (0, 1)$, agent belief $p_k \sim \text{Beta}(\alpha_k, \beta_k)$ with point estimate $\hat{p}_k = \alpha_k/n_k$ where $n_k = \alpha_k + \beta_k$, and conjugate update on observing $y_k \in \{0, 1\}$:

Definition (Beta-Bernoulli edge dynamics).

$$\Delta \hat{p}_k = \frac{y_k - \hat{p}_k}{n_k + 1}, \quad \eta_k = \frac{1}{n_k + 1} \quad (\text{R.1})$$

The single-step update matches the gain-based form from 9.4 with $\eta_{\text{edge}} = 1/(n_k + 1)$.

Parameterization note. Propositions B.1–B.7 below are stated in the *moment-parameter* (probability-space) coordinate $\hat{p}_k \in [0, 1]$, consistent with the Beta-Bernoulli conjugate presentation. The log-odds coordinate $\lambda_k = \log(\hat{p}_k/(1 - \hat{p}_k)) \in \mathbb{R}$ is the unique additive-evidence presentation forced by the evidential-additivity axiom (U); the sector-parameter content of each proposition is Fisher-equivalent in either coordinate, so the derivations are retained in moment-parameter form for algebraic tightness ($\eta_k = 1/(n_k + 1)$ is exact in probability space). The log-odds coordinate becomes load-bearing in 9.6 for the continuous-gradient signal function, where the probability-space presentation would exhibit a mechanical domain break.

Strategic mismatch per edge is $\delta_k = \hat{p}_k - \theta_k$. The sector-condition framework (4.2) requires: (SA1) $F(\mathbf{0}) = \mathbf{0}$, (SA2) $\delta^T \mathbf{F}(\delta) \geq \alpha_\Sigma \|\delta\|^2$ within a region $\mathcal{B}_R$.

Regime-adjustment convention. The propositions below state sector parameters α_Σ for the **canonical Regime-A case**, in which every edge's evidence is fully interventional and attributable (identifiability coefficient $t_{ij} = 1$ per 9.5). For edges with $t_{ij} < 1$ (Regime B or C), each sector parameter carries an implicit t_{ij} factor:

$$\alpha_\Sigma^{\text{eff}} = t_{ij} \cdot \alpha_\Sigma^{\text{stated}} \quad (\text{R.2})$$

This commutes through every diagonal sector product in Props B.1–B.4 and B.6 because each edge's contribution to $\delta_\Sigma^T \mathbf{F}$ is scaled by t_{ij} independently: Regime-C edges ($t \approx 0$) contribute essentially nothing to the weakest-link minimum, and Regime-A edges ($t \approx 1$) recover the stated formulas exactly. The persistence condition $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$ becomes $t_{ij} \cdot \alpha_\Sigma^{\text{stated}} > \rho_{\Sigma,ij}/R_{\Sigma,ij}$ per edge. The propositions below state everything in Regime-A form for clarity; the t -adjustment is uniform across cases and does not alter the structural results (evidence starvation, exploration gating, three-way gating) — only their quantitative thresholds per edge.

For Prop B.3 (unobservable intermediate), the regime adjustment does not change the A1 violation result: the bias is structural to the marginal Bayesian update, not to the identifiability quality. The plan-level fallback still recovers the sector condition with an t -adjusted $\alpha_{\Sigma, \text{plan}}$ governed by the aggregate's identifiability.

Proposition B.1: Single Edge ($A \rightarrow G$).

Setup. One action A , one goal G , one edge with credence $\hat{p}$ and true probability θ . Mismatch: $\delta_\Sigma = \hat{p} - \theta$ (scalar).

Statement. Under Beta-Bernoulli updating, the expected correction function satisfies the sector condition globally (all $|\delta_\Sigma| \leq 1$) with:

Derived (Conditional on Beta-Bernoulli model).

$$\alpha_\Sigma = \frac{1}{n + 1} \quad (\text{R.3})$$

The bound is tight.

Proof.

The expected correction. Since $y \sim \text{Bernoulli}(\theta)$:

Derived (Proof Step).

$$\mathbb{E}[\Delta \hat{p}] = \frac{\theta - \hat{p}}{n+1} = -\frac{\delta_\Sigma}{n+1} \quad (\text{R.4})$$

Identifying $F_\Sigma(\delta_\Sigma) = -\mathbb{E}[\Delta \delta_\Sigma] = \delta_\Sigma/(n+1)$:

Derived (Proof Step).

$$\delta_\Sigma \cdot F_\Sigma(\delta_\Sigma) = \frac{\delta_\Sigma^2}{n+1} = \frac{1}{n+1} \|\delta_\Sigma\|^2 \quad (\text{R.5})$$

So $\alpha_\Sigma = 1/(n+1)$. The correction is exactly linear, so the sector bound is tight (not merely a lower bound).

Verification of (SA1). At $\delta_\Sigma = 0$: $F_\Sigma(0) = 0$. Satisfied.

Stochastic ultimate bound. Decomposing $\delta_{\Sigma,t+1} = \delta_\Sigma \cdot n/(n+1) + (y - \theta)/(n+1)$ and computing $\mathbb{E}[\delta_{\Sigma,t+1}^2]$:

Derived (stochastic ultimate bound, single edge).

$$\mathbb{E}[\delta_{\Sigma,t+1}^2] = \delta_\Sigma^2 \cdot \frac{n^2}{(n+1)^2} + \frac{\theta(1-\theta)}{(n+1)^2} \quad (\text{R.6})$$

The expected Lyapunov derivative $\mathbb{E}[\Delta V] < 0$ whenever:

$$|\delta_\Sigma| > \sqrt{\frac{\theta(1-\theta)}{2n+1}} \quad (\text{R.7})$$

The stochastic noise floor decreases as $O(1/\sqrt{n})$ — the standard Bayesian posterior concentration rate. $\square$

Proposition B.2: Two-Edge AND-Chain, Observable Intermediate ($A \rightarrow B \rightarrow G$, B observed).

Setup. Action A leads to intermediate B , then to goal G . Both y_B and y_G are observed. Edge credences $\hat{p}_1, \hat{p}_2$ with true probabilities θ_1, θ_2 . Plan confidence: $\hat{R}_\Sigma = \hat{p}_1 \hat{p}_2$ (AND propagation from 8.2). Mismatch vector: $\delta_\Sigma = (\delta_1, \delta_2)^T$.

The generative model:

$$y_B \sim \text{Bernoulli}(\theta_1), \quad y_G | y_B = 1 \sim \text{Bernoulli}(\theta_2), \quad y_G | y_B = 0 = 0 \quad (\text{R.8})$$

Statement. Under Beta-Bernoulli updating with observable intermediate, the expected correction function is diagonal and satisfies the sector condition globally with:

Derived (Conditional on Beta-Bernoulli model, observable intermediate).

$$\alpha_\Sigma = \min\left(\frac{1}{n_1+1}, \frac{\theta_1}{n_2+1}\right) \quad (\text{R.9})$$

Proof.

Edge 1 is tested every trial: $\Delta \hat{p}_1 = (y_B - \hat{p}_1)/(n_1 + 1)$, giving $\mathbb{E}[\Delta \hat{p}_1] = -\delta_1/(n_1 + 1)$.

Edge 2 is tested only when $y_B = 1$ (probability θ_1). When $y_B = 0$, edge 2 receives no information:

Derived (Proof Step).

$$\mathbb{E}[\Delta \hat{p}_2] = \theta_1 \cdot \frac{\theta_2 - \hat{p}_2}{n_2 + 1} + (1 - \theta_1) \cdot 0 = -\frac{\theta_1 \delta_2}{n_2 + 1} \quad (\text{R.10})$$

The expected correction function is diagonal:

$$\mathbf{F}(\delta_\Sigma) = \begin{pmatrix} \delta_1/(n_1 + 1) \\ \theta_1 \delta_2/(n_2 + 1) \end{pmatrix} \quad (\text{R.11})$$

Verification of (SA1). At $\delta_\Sigma = \mathbf{0}$: $\mathbf{F}(\mathbf{0}) = \mathbf{0}$. Satisfied.

The sector product:

Derived (Proof Step).

$$\delta_\Sigma^T \mathbf{F}(\delta_\Sigma) = \frac{\delta_1^2}{n_1 + 1} + \frac{\theta_1 \delta_2^2}{n_2 + 1} \geq \min\left(\frac{1}{n_1 + 1}, \frac{\theta_1}{n_2 + 1}\right) (\delta_1^2 + \delta_2^2) \quad (\text{R.12})$$

The minimum is achieved by whichever edge has the lower effective correction rate. $\square$

The evidence-starvation effect. Edge 2's effective correction rate $\theta_1/(n_2 + 1)$ is attenuated by the upstream success probability θ_1 . When θ_1 is small, edge 2 is starved of evidence — it is tested rarely, learns slowly, and becomes the weakest link. This gives a precise mechanism for 8.1: downstream edges in AND-chains are harder to calibrate, with correction rate proportional to the product of all upstream success probabilities.

Generalization to depth d . For a chain of depth d with all intermediates observable, edge k 's effective correction rate is $\alpha_k = \prod_{j=1}^{k-1} \theta_j/(n_k + 1)$, giving:

Derived (depth-d chain sector parameter).

$$\alpha_\Sigma = \min_{k=1}^d \frac{\prod_{j=1}^{k-1} \theta_j}{n_k + 1} \quad (\text{R.13})$$

Proposition B.3: Two-Edge AND-Chain, Unobservable Intermediate ($A \rightarrow B \rightarrow G$, B not observed).

Setup. Same DAG as Proposition B.2, but only $y_G \in \{0, 1\}$ is observed. The agent cannot distinguish “ $A \rightarrow B$ failed” from “ $B \rightarrow G$ failed” when $y_G = 0$.

Statement. (a) The per-edge sector condition fails: the marginal Bayesian update violates (SA1) with systematic bias $O(1/n)$. (b) Plan-level tracking (treating $\hat{\Phi} = \hat{p}_1 \hat{p}_2$ as a single Beta over the composite probability $\Phi = \theta_1 \theta_2$) recovers the sector condition with:

Derived (Conditional on Beta-Bernoulli model, unobservable intermediate).

$$\alpha_{\Sigma, \text{plan}} = \frac{1}{n_{\Phi} + 1} \quad (\text{R.14})$$

Proof of (a): Per-edge (SA1) violation.

The joint posterior after success ($y_G = 1$) factors cleanly: $\alpha_k \rightarrow \alpha_k + 1$ for both edges. The joint posterior after failure ($y_G = 0$) includes the factor $(1 - \theta_1 \theta_2)$, which does not decompose into separate functions of θ_1 and θ_2 . Failure introduces posterior correlation.

The exact marginal Bayesian update for edge 1 on failure is:

Derived (Proof Step).

$$\Delta \hat{p}_1^{(\text{fail})} = -\frac{\hat{p}_1 q_1}{n_1 + 1} \quad (\text{R.15})$$

where $q_1 = (1 - \hat{p}_1)/(1 - \hat{p}_1 \hat{p}_2)$ is the posterior probability that edge 1 caused the failure (the proportional-blame weight). The expected update, combining success (probability $\theta_1 \theta_2$) and failure (probability $1 - \theta_1 \theta_2$):

Derived (Proof Step).

$$\mathbb{E}[\Delta \hat{p}_1] = \theta_1 \theta_2 \cdot \frac{1 - \hat{p}_1}{n_1 + 1} - (1 - \theta_1 \theta_2) \cdot \frac{\hat{p}_1 q_1}{n_1 + 1} \quad (\text{R.16})$$

Evaluating at truth ($\hat{p}_k = \theta_k$):

Derived (SA1 violation magnitude).

$$\mathbb{E}[\Delta \hat{p}_1]_{\hat{p}=\theta} = -\frac{\theta_1(1 - \theta_1)(1 - \theta_2)}{n_1 + 1} \neq 0 \quad (\text{R.17})$$

The bias is negative (pushes credence below truth), of magnitude $O(1/n)$, and arises because success always increments α_1 by a full unit while failure increments β_1 by the fractional weight $q_1 < 1$. The success case over-credits edge 1 because the agent cannot separate edge 1’s contribution from edge 2’s. By symmetry, $\hat{p}_2$ is also biased downward. $\square$

Proof of (b): Plan-level recovery.

If the agent tracks $\hat{\Phi}$ directly as a Beta posterior over $\Phi = \theta_1 \theta_2$ using $y_G \sim \text{Bernoulli}(\Phi)$, the setup reduces to a single-edge problem (Proposition B.1) with mismatch $\delta_{\Phi} = \hat{\Phi} - \Phi$ and sector parameter $\alpha_{\Sigma, \text{plan}} = 1/(n_{\Phi} + 1)$. All single-edge results apply. $\square$

Tradeoff. Per-edge tracking provides diagnostic resolution (which edge is failing?) but yields biased, non-sector-conforming updates when the intermediate is unobservable. Plan-level tracking sacrifices diagnostic resolution but

provides clean sector-condition satisfaction. This is a concrete instance of 9.3: unobservable nodes freeze per-edge learning, making the aggregate the correct unit of analysis.

Non-identifiability. From y_G observations alone, only $\Phi = \theta_1 \theta_2$ is identifiable. The per-edge decomposition (θ_1, θ_2) is underdetermined — any pair with the same product produces identical observations. Per-edge identification requires per-edge observability (or structural constraints that break the symmetry).

Proposition B.4: Two-Arm OR-Node ($A_1, A_2 \rightarrow G$, ε -greedy).

Setup. Goal G reachable via two alternative actions A_1, A_2 (an OR-node from 8.2). True probabilities θ_1, θ_2 . Agent selects one action per trial: with probability $1 - \varepsilon$ the greedy choice (higher $\hat{p}_k$), with probability ε the other. Mismatch vector: $\delta_\Sigma = (\delta_1, \delta_2)^T$.

Statement. (a) Under a greedy policy ($\varepsilon = 0$), the sector condition fails for the full mismatch vector. (b) Under ε -greedy action selection with $\varepsilon > 0$, the sector condition is satisfied with:

Derived (Conditional on Beta-Bernoulli model, ε -greedy OR-node).

$$\alpha_\Sigma = \min\left(\frac{1 - \varepsilon}{n_1 + 1}, \frac{\varepsilon}{n_2 + 1}\right) \quad (\text{R.18})$$

where arm 1 is the greedy choice.

Proof of (a): Greedy failure.

Under greedy selection, only the chosen arm updates. Assuming $\hat{p}_1 > \hat{p}_2$ (arm 1 is greedy):

$$\mathbf{F}(\delta_\Sigma) = \begin{pmatrix} \delta_1/(n_1 + 1) \\ 0 \end{pmatrix} \quad (\text{R.19})$$

The sector product $\delta_\Sigma^T \mathbf{F} = \delta_1^2/(n_1 + 1)$. For the sector condition to hold, we need $\delta_1^2/(n_1 + 1) \geq \alpha_\Sigma(\delta_1^2 + \delta_2^2)$. Setting $\delta_1 = 0$: the LHS is zero but $\alpha_\Sigma \delta_2^2 > 0$ for $\delta_2 \neq 0$. No $\alpha_\Sigma > 0$ works. $\square$

Proof of (b): ε -greedy recovery.

The expected correction (arm 1 greedy):

Derived (Proof Step).

$$\mathbb{E}[\mathbf{F}(\delta_\Sigma)] = \begin{pmatrix} (1 - \varepsilon) \delta_1/(n_1 + 1) \\ \varepsilon \delta_2/(n_2 + 1) \end{pmatrix} \quad (\text{R.20})$$

The sector product:

Derived (Proof Step).

$$\delta_\Sigma^T \mathbf{F} = \frac{(1 - \varepsilon) \delta_1^2}{n_1 + 1} + \frac{\varepsilon \delta_2^2}{n_2 + 1} \geq \min\left(\frac{1 - \varepsilon}{n_1 + 1}, \frac{\varepsilon}{n_2 + 1}\right)(\delta_1^2 + \delta_2^2) \quad (\text{R.21})$$

Verification of (SA1). At $\delta_\Sigma = \mathbf{0}$: $\mathbf{F}(\mathbf{0}) = \mathbf{0}$. Satisfied. $\square$

Optimal exploration rate. Maximizing α_Σ over ε by equalizing the two terms:

Derived (optimal exploration rate).

$$\varepsilon^* = \frac{n_2 + 1}{n_1 + n_2 + 2}, \quad \alpha_\Sigma^* = \frac{1}{n_1 + n_2 + 2} \quad (\text{R.22})$$

For equal experience ($n_1 = n_2$): $\varepsilon^* = 1/2$ (equal allocation). For unequal experience, ε^* allocates more trials to the arm with higher n (lower gain) to equalize correction rates.

The k -arm generalization. For k OR-alternatives with ε -uniform exploration (probability $\varepsilon/(k-1)$ per non-greedy arm):

Derived (k -arm OR-node sector parameter).

$$\alpha_\Sigma = \min\left(\frac{1 - \varepsilon}{n_{\text{greedy}} + 1}, \min_{j \neq \text{greedy}} \frac{\varepsilon/(k-1)}{n_j + 1}\right) \quad (\text{R.23})$$

With optimal equal-rate exploration and equal experience: $\alpha_\Sigma = 1/(k(n+1))$. The sector parameter scales as $1/k$ — each additional alternative dilutes correction capacity.

Condition (SA3). For the sector condition to be satisfiable at all, the exploration rate must satisfy:

Derived (minimum exploration rate for persistence).

$$\varepsilon > \frac{\rho_\Sigma(n_{\max} + 1)}{R_\Sigma} \quad (\text{R.24})$$

A purely greedy agent ($\varepsilon = 0$) violates the sector condition because the unchosen alternative's mismatch grows without correction. This is the structural justification for (SA3) in 9.10: OR-nodes require deliberate exploration to maintain strategic persistence.

Persistence Conditions.

Substituting each proposition's α_Σ into the persistence threshold $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$ from Proposition A.1 of A:

Single edge (B.1):

Derived (single-edge persistence threshold).

$$\frac{1}{n+1} > \frac{\rho_\Sigma}{R_\Sigma} \quad \Longleftrightarrow \quad n < \frac{R_\Sigma}{\rho_\Sigma} - 1 \quad (\text{R.25})$$

The critical experience level $n^* = R_\Sigma/\rho_\Sigma - 1$ is the point at which gain collapse occurs: the posterior has concentrated so much that the agent can no longer track environmental drift.

Two-edge observable (B.2):

Derived (two-edge persistence threshold, observable).

$$\min\left(\frac{1}{n_1 + 1}, \frac{\theta_1}{n_2 + 1}\right) > \frac{\rho_\Sigma}{R_\Sigma} \quad (\text{R.26})$$

This decomposes into two independent conditions: $n_1 < R_\Sigma/\rho_\Sigma - 1$ and $n_2 < \theta_1 R_\Sigma/\rho_\Sigma - 1$. The downstream edge has a stricter bound, tightened by θ_1 . Gain collapse hits downstream edges first.

Two-edge unobservable (B.3):

$$\frac{1}{n_\Phi + 1} > \frac{\rho_\Sigma}{R_\Sigma} \iff n_\Phi < \frac{R_\Sigma}{\rho_\Sigma} - 1 \quad (\text{R.27})$$

Same form as single-edge, applied to the plan-level aggregate.

Two-arm OR, ε -greedy (B.4):

Derived (OR-node persistence threshold).

$$\min\left(\frac{1 - \varepsilon}{n_1 + 1}, \frac{\varepsilon}{n_2 + 1}\right) > \frac{\rho_\Sigma}{R_\Sigma} \quad (\text{R.28})$$

With optimal exploration and equal experience ($n_1 = n_2 = n$):

$$n < \frac{R_\Sigma}{2\rho_\Sigma} - 1 \quad (\text{R.29})$$

The critical experience is halved relative to the single-edge case. Each additional OR-alternative further reduces the critical level by $1/k$.

Proposition B.6: Mixed AND/OR with Common-Cause Node (L1 Augmented DAG).

Setup. Goal G reachable via two alternative actions A_1, A_2 (an OR-node), but both actions require a shared condition C (a common-cause node). The L1 DAG factors the common cause above the OR-structure: $G = \text{AND}(C, G_{\text{sub}})$ where $G_{\text{sub}} = \text{OR}(A_1, A_2)$. Three leaves: condition C with true probability θ_C , actions A_1, A_2 with true conditional probabilities $\theta_{1|C}, \theta_{2|C}$. Agent selects ε -greedy among A_1, A_2 (only testable when $C = 1$). Mismatch vector: $\delta_\Sigma = (\delta_C, \delta_{A_1}, \delta_{A_2})^T$.

Plan confidence: $\hat{R}_\Sigma = \hat{p}_C \cdot [1 - (1 - \hat{p}_{A_1})(1 - \hat{p}_{A_2})]$. Reference value: $\Phi = \theta_C \cdot [1 - (1 - \theta_{1|C})(1 - \theta_{2|C})]$. At truth, $\hat{R}_\Sigma = \Phi = \text{actual plan success probability (L1 is unbiased)}$.

Statement. Under Beta-Bernoulli updating with observable condition C and ε -greedy path selection, the expected correction function satisfies the sector condition globally with:

Derived (Conditional on Beta-Bernoulli model, L1 augmented DAG, observable common cause C , ε -greedy action selection).

$$\alpha_\Sigma = \min\left(\frac{1}{n_C + 1}, \frac{\theta_C(1 - \varepsilon)}{n_{A_1} + 1}, \frac{\theta_C\varepsilon}{n_{A_2} + 1}\right) \quad (\text{R.30})$$

where A_1 is the greedy choice.

Proof.

Edge C (condition leaf, observed every trial):

$$\mathbb{E}[\Delta \hat{p}_C] = \frac{\theta_C - \hat{p}_C}{n_C + 1} = -\frac{\delta_C}{n_C + 1} \quad (\text{R.31})$$

Edge A_1 (action leaf, tested when $C = 1$ and path 1 selected — probability $\theta_C(1 - \varepsilon)$):

$$\mathbb{E}[\Delta \hat{p}_{A_1}] = -\frac{\theta_C(1 - \varepsilon) \delta_{A_1}}{n_{A_1} + 1} \quad (\text{R.32})$$

Edge A_2 (action leaf, tested when $C = 1$ and path 2 selected — probability $\theta_C \varepsilon$):

$$\mathbb{E}[\Delta \hat{p}_{A_2}] = -\frac{\theta_C \varepsilon \delta_{A_2}}{n_{A_2} + 1} \quad (\text{R.33})$$

The expected correction function is diagonal:

$$\mathbf{F}(\delta_\Sigma) = \begin{pmatrix} \delta_C/(n_C + 1) \\ \theta_C(1 - \varepsilon) \delta_{A_1}/(n_{A_1} + 1) \\ \theta_C \varepsilon \delta_{A_2}/(n_{A_2} + 1) \end{pmatrix} \quad (\text{R.34})$$

Verification of (SA1). $\mathbf{F}(\mathbf{0}) = \mathbf{0}$. ✓

Sector product:

$$\delta_\Sigma^T \mathbf{F} = \frac{\delta_C^2}{n_C + 1} + \frac{\theta_C(1 - \varepsilon) \delta_{A_1}^2}{n_{A_1} + 1} + \frac{\theta_C \varepsilon \delta_{A_2}^2}{n_{A_2} + 1} \geq \alpha_\Sigma \|\delta_\Sigma\|^2 \quad \square \quad (\text{R.35})$$

Three-way gating. This is the first mixed AND/OR case. The sector parameter α_Σ is determined by three independent gating mechanisms: 1. **Condition testing** ($1/(n_C + 1)$): the common cause is the easiest component to calibrate — tested every trial, same as B.1. 2. **Evidence starvation** (θ_C factor on action terms): both action edges are gated by the condition probability, same mechanism as B.2. 3. **Exploration gating** ($(1 - \varepsilon)$ and ε factors): the two OR-alternatives compete for test opportunities, same mechanism as B.4.

The bottleneck is typically the explore action behind the condition: $\theta_C \varepsilon / (n_{A_2} + 1)$.

B.5b applies. The Jacobian $\mathbf{J} = (s_{G_{\text{sub}}}, \hat{p}_C(1 - \hat{p}_{A_2}), \hat{p}_C(1 - \hat{p}_{A_1}))^T$ is non-negative (monotone AND/OR). Corrections are componentwise (each leaf updates independently). Therefore $\alpha_s = \alpha_c = \alpha_\Sigma$ — the strategy-plan-confidence error inherits the sector condition with no penalty.

Optimal exploration. Equalizing the action terms: $\varepsilon^* = (n_{A_2} + 1)/(n_{A_1} + n_{A_2} + 2)$, giving $\alpha_\Sigma^* = \min(1/(n_C + 1), \theta_C/(n_{A_1} + n_{A_2} + 2))$.

L0 comparison. An L0 model of the same scenario (no C node, marginal probabilities $\theta_k = \theta_C \cdot \theta_{k|C}$) has $\alpha_\Sigma^{L0} = \min((1 - \varepsilon)/(n_1 + 1), \varepsilon/(n_2 + 1))$ and reference value $\Phi^{L0} = 1 - (1 - \theta_1)(1 - \theta_2)$. The L0 sector parameter is *higher* (no θ_C attenuation) but Φ^{L0} systematically overestimates actual plan success. L1 persistence is harder (lower α_Σ) but

calibration is honest (Φ^{L1} matches reality). The tradeoff: L0 is easier to maintain but calibrates to a biased target; L1 is harder to maintain but calibrates to truth.

The L1 construction principle. The common-cause node C must be factored *above* the OR-structure whose children it correlates. A naive construction (adding C as a parent of both A_1 and A_2 while keeping them as OR-siblings) does not fix the overestimation because the OR-propagation formula treats siblings as marginally independent. Correct L1 construction makes C an AND-prerequisite above the OR-structure, so the OR-children are conditionally independent given C . Full worked example with quantitative L0/L1 comparison: #example-L1.

Summary of Results.

Table R.1

Case	Topology	α_Σ	SAI	SA3	Weakest link
B.1 Single edge	$A \rightarrow G$	$1/(n+1)$	Yes	N/A	—
B.2 Two-edge, B observable	$A \rightarrow B \rightarrow G$ (AND)	$\min(1/(n_1+1), \theta_1/(n_2+1))$	Yes	N/A	Depth-gated (evidence starvation)
B.3 Two-edge, B unobservable	$A \rightarrow B \rightarrow G$ (AND)	$1/(n_\Phi+1)$ (plan-level)	Per-edge: No ($O(1/n)$ bias); Plan: Yes	N/A	Credit-assignment collapse
B.4 Two-arm OR, ε -greedy	$A_1, A_2 \rightarrow G$ (OR)	$\min((1-\varepsilon)/(n_1+1), \varepsilon/(n_2+1))$	Yes	Required	Exploration-gated
B.5a Credence $\rightarrow$ value (linear)	Any	$\alpha_s = \alpha_c$ (Jacobian cancels)	—	—	None (exact transfer)
B.5b Credence $\rightarrow$ value (nonlinear, component-wise)	Any	$\alpha_s = \alpha_c$ ($J_k \geq 0$ preserves bound)	—	—	None (exact transfer)
B.5b Credence $\rightarrow$ value (coupled)	Any	$\alpha_s \geq \alpha_c/\kappa(J)^2$	—	—	Inter-edge coupling
B.6 L1 augmented, mixed AND/OR	$G = \text{AND}(C, \text{OR}(A_1, A_2))$	$\min(1/(n_C+1), \theta_C(1-\varepsilon)/(n_{A_1}+1), \theta_C\varepsilon/(n_{A_2}+1))$	Yes	Required	Three-way gating
B.7 L1' mixture form, observable C	$\hat{P}_\Sigma^{L1'} = \hat{\theta}_C P_\Sigma(\hat{\mathbf{p}}_{ C}) + (1-\hat{\theta}_C) P_\Sigma(\hat{\mathbf{p}}_{ \neg C})$	$\min(1/(n_C+1), \min_j \theta_C \pi_{j C}/(n_{j C}+1), \min_j (1-\theta_C) \pi_{j \neg C}/(n_{j \neg C}+1))$	Yes	Required and facilitator monotonicity	Five-way gating; refuted under unobservable C (Cramér-Rao floor)

Structural results across cases:

- **Gain as sector parameter.** In every case, α_Σ is determined by the edge update gain $\eta_k = 1/(n_k + 1)$, modulated by observability (θ_1 attenuation in B.2), credit-assignment (plan-level collapse in B.3), action-selection policy (ε in B.4), or a combination of these (B.6). The structural parallel between epistemic and strategic persistence is not an analogy — it is a mathematical identity at the sector-framework level.
- **Evidence starvation (AND-chains).** Downstream edges in AND-chains have correction rates attenuated by the product of upstream success probabilities. Depth increases fragility: α_Σ decays exponentially with chain depth.
- **Exploration gating (OR-nodes).** Unchosen OR-alternatives receive zero correction. The sector condition requires deliberate exploration (SA3) at a rate exceeding $\rho_\Sigma(n_{\max} + 1)/R_\Sigma$. Pure greedy policies fail.
- **Three-way gating (L1 augmented).** When a common cause gates OR-alternatives, calibration faces condition testing, evidence starvation, and exploration gating simultaneously (B.6). The bottleneck is the least-explored action behind the rarest condition.
- **Five-way gating (L1' mixture, observable C).** When the common cause is a *soft facilitator* ($\theta_{j|-C} > 0$) and is observable per trial, calibration faces five gating mechanisms simultaneously (B.7): condition testing, evidence starvation on each conditional branch ($C = 1$ and $C = 0$), and exploration gating on each branch. The bottleneck is whichever branch is rarer, modulated by exploration on that branch. **Identifiability obstruction under unobservable C:** without direct C -observation, the mixture parameters are non-identifiable from a single observation channel — the per-trial Fisher information matrix is rank 1 rather than rank $2K + 1$, so by the Cramér-Rao bound (Cramér 1946, *Mathematical Methods of Statistics*, Princeton University Press) no unbiased online estimator on the joint conditional vector admits $\alpha > 0$. The agent must augment C -observability, run multi-child joint observations, or fall back to plan-level (L0-on-marginals) tracking.
- **Gain-collapse threshold.** In all cases, increasing experience eventually violates persistence when the environment drifts. The critical experience level n^* is inversely proportional to the drift rate ρ_Σ .
- **L1 tradeoff.** L1 augmented DAGs have lower α_Σ (harder to persist) but honest calibration (Φ^{L1} matches reality). L0 is easier to maintain but calibrates to a biased target. The choice depends on whether accuracy or trackability is the binding constraint.

Proposition B.7: L1' Mixture-Form Sector Transfer (Observable Common Cause).

Where Prop B.6 handles a strict-prerequisite common cause via an AND-prerequisite construction (L1), this proposition handles a *soft-facilitator* common cause via the mixture form L1' (8.3, Correlation Hierarchy). It is the L1' analog of B.6, generalizing three-way gating to five-way gating across two parallel conditional branches.

Setup. L1' (mixture-form) DAG with binary common cause C , true prior $\theta_C \in (0, 1)$, gating a sub-plan with conditional structures $G_{j|C}$ (when $C = 1$) and $G_{j|-C}$ (when $C = 0$). Each affected child j carries two conditional credences $\hat{p}_{j|C}$ and $\hat{p}_{j|-C}$. Plan confidence:

$$\hat{p}_\Sigma^{L1'} = \hat{\theta}_C \cdot R_\Sigma(\hat{p}_{j|C}) + (1 - \hat{\theta}_C) \cdot R_\Sigma(\hat{p}_{j|-C}) \quad (R.36)$$

The agent observes C -state directly each trial (i.e., C is treated as an observable condition leaf, in parallel with B.6). Per trial, the agent (i) updates $\hat{\theta}_C$ from observed C via Beta-Bernoulli; (ii) on $C = 1$ trials, attempts a child j via the active selection policy $\pi_{j|C}$ and updates $\hat{p}_{j|C}$ from y_j ; (iii) on $C = 0$ trials, attempts a child j via $\pi_{j|-C}$ and updates $\hat{p}_{j|-C}$ from y_j .

Mismatch state: $\xi = (\xi_C, \{\xi_{j|C}\}, \{\xi_{j|-C}\})$ with $\xi_C = \theta_C - \hat{\theta}_C$, $\xi_{j|s} = \theta_{j|s} - \hat{p}_{j|s}$.

Statement.

Under Beta-Bernoulli updating with observable common cause, componentwise updates per conditional branch, and *facilitator monotonicity* ($R_\Sigma(G|_C) \geq R_\Sigma(G|_{\neg C})$), the expected correction function on the joint state satisfies the sector condition globally with:

Derived (Conditional on Beta-Bernoulli model, observable common cause C, componentwise conditional-branch update, facilitator monotonicity).

$$\alpha_{L1'} = \min\left(\frac{1}{n_C + 1}, \min_{j \in \mathcal{J}_C} \frac{\theta_C \pi_{j|C}}{n_{j|C} + 1}, \min_{j \in \mathcal{J}_{\neg C}} \frac{(1 - \theta_C) \pi_{j|\neg C}}{n_{j|\neg C} + 1}\right) \quad (\text{R.37})$$

where $\mathcal{J}_s$ is the set of children tested on the $C = s$ branch and $\pi_{j|s}$ is the action-selection probability for child j on that branch.

Proof. *Edge C (condition leaf, observable every trial).* Standard Beta-Bernoulli on direct C -observation:

$$\mathbb{E}[\Delta \hat{\theta}_C] = \frac{\theta_C - \hat{\theta}_C}{n_C + 1} = -\frac{\xi_C}{n_C + 1} \quad (\text{R.38})$$

so $F_C(\xi) = \xi_C / (n_C + 1)$.

Edge $p_{j|C}$ (conditional credence, $C = 1$ branch). Tested when $C = 1$ (probability θ_C) and the agent's $C = 1$ -conditional policy selects j (probability $\pi_{j|C}$):

$$\mathbb{E}[\Delta \hat{p}_{j|C}] = \theta_C \pi_{j|C} \cdot \frac{\theta_{j|C} - \hat{p}_{j|C}}{n_{j|C} + 1} = -\frac{\theta_C \pi_{j|C} \xi_{j|C}}{n_{j|C} + 1} \quad (\text{R.39})$$

so $F_{j|C}(\xi) = \theta_C \pi_{j|C} \xi_{j|C} / (n_{j|C} + 1)$.

Edge $p_{j|\neg C}$ (conditional credence, $C = 0$ branch). Symmetric: tested with probability $(1 - \theta_C) \pi_{j|\neg C}$:

$$F_{j|\neg C}(\xi) = \frac{(1 - \theta_C) \pi_{j|\neg C} \xi_{j|\neg C}}{n_{j|\neg C} + 1} \quad (\text{R.40})$$

Sector product. The correction function is diagonal in ξ with positive entries:

$$\xi^T \mathbf{F}(\xi) = \frac{\xi_C^2}{n_C + 1} + \sum_{j \in \mathcal{J}_C} \frac{\theta_C \pi_{j|C} \xi_{j|C}^2}{n_{j|C} + 1} + \sum_{j \in \mathcal{J}_{\neg C}} \frac{(1 - \theta_C) \pi_{j|\neg C} \xi_{j|\neg C}^2}{n_{j|\neg C} + 1} \geq \alpha_{L1'} \cdot \|\xi\|^2 \quad (\text{R.41})$$

with $\alpha_{L1'}$ as stated.

SA1 check. $\mathbf{F}(\mathbf{0}) = \mathbf{0}$ at truth ($\xi = 0$). $\checkmark$

Globality. The Beta-Bernoulli updates are linear in ξ on $[-1, 1]^{2K+1}$, so the diagonal Jacobian computed at truth is the exact $\mathbf{J}_F$ throughout. The sector inequality holds globally with the same $\alpha_{L1'}$.

B.5b bridge to plan value. Jacobian of $\hat{P}_\Sigma^{L1'}$ with respect to the joint state:

$$\mathbf{J}_{P_\Sigma} = \begin{pmatrix} R_\Sigma(\hat{\mathbf{p}}_{|C}) - R_\Sigma(\hat{\mathbf{p}}_{|\neg C}) \\ \hat{\theta}_C \cdot \nabla_{\hat{\mathbf{p}}_{|C}} R_\Sigma(\hat{\mathbf{p}}_{|C}) \\ (1 - \hat{\theta}_C) \cdot \nabla_{\hat{\mathbf{p}}_{|\neg C}} R_\Sigma(\hat{\mathbf{p}}_{|\neg C}) \end{pmatrix} \quad (\text{R.42})$$

By facilitator monotonicity, the first entry is ≥ 0 . The other entries are ≥ 0 by AND/OR monotonicity on each conditional sub-DAG. So $\mathbf{J}_{P_\Sigma} \geq 0$ componentwise. By the componentwise nonlinear case of B.5b, the sector condition transfers losslessly: $\alpha_s = \alpha_c = \alpha_{L1}$. $\square$

Five-Way Gating. This generalizes B.6's three-way gating to five gating mechanisms, one per term in the min:

1. **Condition testing** ($1/(n_C + 1)$): the common cause is the easiest component to calibrate — directly observed every trial.
2. **Evidence starvation, $C = 1$ branch** (θ_C factor): conditional edges on the $C = 1$ branch are gated by the prior frequency of $C = 1$.
3. **Exploration gating, $C = 1$ branch** ($\pi_{j|C}$ factor): OR-alternatives within the $C = 1$ branch compete for test opportunities.
4. **Evidence starvation, $C = 0$ branch** ($1 - \theta_C$ factor): conditional edges on the $C = 0$ branch are gated by the prior frequency of $C = 0$.
5. **Exploration gating, $C = 0$ branch** ($\pi_{j|\neg C}$ factor): OR-alternatives within the $C = 0$ branch.

The bottleneck is typically whichever of θ_C and $1 - \theta_C$ is smaller (the rare branch sees fewer trials), modulated by exploration on that branch.

Reduction to B.6 (Strict-Prerequisite Limit). Setting $\theta_{j|\neg C} \rightarrow 0$ collapses the $\neg C$ branch (the agent learns the $\neg C$ conditionals are zero with no remaining variance). The per-edge state for the $\neg C$ branch drops out of the sector inequality, and the formula reduces to B.6's three-way gating with $\alpha_\Sigma = \min(1/(n_C + 1), \theta_C(1 - \varepsilon)/(n_{A_1} + 1), \theta_C\varepsilon/(n_{A_2} + 1))$. $\checkmark$

Refuted Under Unobservable C (Mixture Identifiability Obstruction).

When C is not observable, the agent can only update the joint state via online soft EM on the marginal y_j . Computing the Fisher information of the mixture model $\mu_j = \theta_C \theta_{j|C} + (1 - \theta_C) \theta_{j|\neg C}$ at truth, the score vector for parameters $\phi = (\theta_C, p_{j|C}, p_{j|\neg C})$ admits the rank-1 factorization:

Derived (cramer-rao-floor, from Fisher information of mixture model + Cramér-Rao bound).

$$\mathcal{F}(\phi) = \frac{1}{\mu_j(1 - \mu_j)} uu^T, \quad u = (\Delta_j, \theta_C, 1 - \theta_C) \quad (\text{R.43})$$

where $\Delta_j = p_{j|C} - p_{j|\neg C}$ is the *separability gap*. The matrix is rank 1 for any non-degenerate mixture; the two-dimensional null space corresponds to perturbations along the indeterminacy manifold $\{\hat{\phi} : \hat{\theta}_C \hat{p}_{|C} + (1 - \hat{\theta}_C) \hat{p}_{|\neg C} = \mu_j\}$ — directions unobservable from a single binary signal.

Since the soft-EM step at truth equals (up to the $1/(n + 1)$ scaling) the natural-gradient ascent on the expected log-likelihood, the Jacobian of the correction function equals $\mathcal{F}/(n + 1)$, also rank 1. Therefore $\lambda_{\min}(\mathbf{J}_F) = 0$, and **no SAI-preserving update on the joint conditional vector admits a sector parameter $\alpha > 0$ under SUB-B**. This is a Cramér-Rao bound, not a defect of any particular update rule: any unbiased online estimator must respect the bound, which is infinite in the unidentifiable directions.

Repair routes. When C is unobservable, the agent must:

(i) **Augment C -observability** (recover B.7 above) — instrument secondary signals that identify C per trial, transforming the problem from refuted to globally derived. (ii) **Run $K \geq 2$ children jointly under the same C -realization** — when the joint Fisher matrix reaches rank $2K + 1$, the mixture is identifiable; local sector condition holds with $\alpha \geq \sigma_{\min}(\mathcal{F}_{\text{joint}}) / \max_k(n_k + 1)$. Strong structural requirement (joint observation typically unavailable in standard sequential strategy execution). (iii) **Fall back to plan-level tracking on the marginal $\hat{\mu}_j$** — recovers B.1's $\alpha = 1/(n_\mu + 1)$ on the scalar marginal but loses the per-conditional decomposition (equivalent to L0-on-marginals).

Connection to the Identifiability-Floor Pattern. The B.7-vs-refuted-unobservable- C structure is one of two no-go theorems in AAT's strategy layer. The other is the on-policy detection no-go in 9.2, which prohibits L0-vs-L1 distinction from purely on-policy data via the causal hierarchy theorem. Both are structural impossibility results derived from external information-theoretic theorems (Bareinboim et al. 2022 Causal Hierarchy Theorem; Cramér-Rao bound on the Fisher information). Both strengthen related machinery — the on-policy no-go strengthens 7.3; the mixture no-go strengthens the case for *observability-as-information-augmentation*. See 5.1 for the meta-pattern.

Proposition B.5: Bridge from Credence Error to Value Residuals.

The propositions above verify the sector condition for the credence-error mismatch state $\delta_c = (\hat{p}_k - \theta_k)$. This proposition extends the result to **strategy-plan-confidence error** — the scalar difference between the agent's strategy-plan-confidence score and the independence-model plan value evaluated at true edge parameters. This is a natural plan-level mismatch that is distinct from (but related to) the per-edge value-increment residuals $\delta_{\text{strategic}}$ defined in 9.1.

Relationship to $\delta_{\text{strategic}}$. 9.1 defines $\delta_{\text{strategic}}$ as an L^2 aggregation of per-edge value-increment residuals — a quantity that requires credit assignment to compute. Plan-confidence error δ_s defined here is a *different* quantity: it is the error in the DAG's aggregate self-assessment, computable from status propagation without credit assignment. The two are related (both measure strategy-reality mismatch) but not identical. This proposition shows the sector condition holds for strategy-plan-confidence error; extending it to $\delta_{\text{strategic}}$ directly would require the credit-assignment machinery discussed in 9.6.

Setup. The plan value $\hat{P}_\Sigma = R_\Sigma(\mathbf{p})$ is a function of the edge credence vector $\mathbf{p} = (p_1, \dots, p_m)$. The **independence-model reference value** is $\Phi = R_\Sigma(\theta)$ — the AND/OR propagation formula evaluated at the true edge parameters θ . Note: Φ is NOT the actual probability of plan success when edge outcomes are correlated (8.3, edge-independence caveat). It is the best the independence model can do with perfect edge knowledge. Under correlated failure, the actual plan success probability may be lower than Φ ; the gap is a model-class limitation of the AND/OR DAG representation, not an estimation error. What δ_s tracks is calibration *within the independence model*, not calibration to reality. Define:

- **Credence-error mismatch:** $\delta_c = \mathbf{p} - \theta \in \mathbb{R}^m$
- **Plan-confidence error:** $\delta_s = \hat{P}_\Sigma - \Phi = R_\Sigma(\mathbf{p}) - R_\Sigma(\theta)$ (scalar)

The gradient of plan value with respect to credences is $\mathbf{J} = \nabla_{\mathbf{p}} R_\Sigma \in \mathbb{R}^m$ (a vector, since R_Σ is scalar). By first-order Taylor expansion:

$$\delta_s \approx \mathbf{J}^T \delta_c \tag{R.44}$$

B.5a: Linear Correction (Beta-Bernoulli).

When the correction in credence space is linear — $\mathbf{F}_c(\delta_c) = \eta \odot \delta_c$ where $\eta_k = 1/(n_k + 1)$ and $\odot$ is elementwise product — consider the sector ratio directly. Since $\delta_s = \mathbf{J}^T \delta_c$ and $F_s = \mathbf{J}^T \mathbf{F}_c$:

Derived (value-residual sector condition, linear case).

$$\delta_s \cdot F_s = (\mathbf{J}^T \delta_c)^T (\mathbf{J}^T \mathbf{F}_c) = \delta_c^T \mathbf{J} \mathbf{J}^T \mathbf{F}_c \quad (\text{R.45})$$

For the linear case $\mathbf{F}_c = \eta_{\min} \delta_c$ (using the worst-case uniform gain for the bound):

$$\delta_s \cdot F_s = \eta_{\min} \cdot \delta_c^T \mathbf{J} \mathbf{J}^T \delta_c = \eta_{\min} \cdot \|\mathbf{J}^T \delta_c\|^2 = \eta_{\min} \cdot \delta_s^2 \quad (\text{R.46})$$

Therefore:

$$\frac{\delta_s \cdot F_s}{\delta_s^2} = \eta_{\min} \quad (\text{R.47})$$

The Jacobian cancels. The sector parameter in value-residual space equals the sector parameter in credence space, regardless of DAG structure:

$$\alpha_s = \alpha_c = \eta_{\min} = \min_k \frac{1}{n_k + 1} \quad (\text{R.48})$$

This holds because $\mathbf{J} \mathbf{J}^T$ appears in both numerator and denominator of the sector ratio, and the linear correction commutes with the Jacobian mapping.

Interpretation. The Jacobian $\mathbf{J}$ determines *which* credence errors matter most for plan value (high-sensitivity edges contribute more to value residuals). But it does not change the *rate* at which those errors are corrected, because the correction is proportional to the error regardless of the error's plan-value impact.

B.5b: Nonlinear Componentwise Correction.

When the correction is nonlinear but **componentwise** — each edge corrects independently, with

Derived (from per-component sector condition + Jacobian non-negativity).

$$(\mathbf{F}_c)_k \text{ depending only on } (\delta_c)_k \quad (\text{R.49})$$

— and the plan-value Jacobian is **non-negative** ($J_k \geq 0$ for all k), the transfer is lossless regardless of nonlinearity.

The per-component sector condition (from Props B.1-B.4): for each edge k ,

$$(\delta_c)_k \cdot (\mathbf{F}_c)_k \geq \alpha_c \cdot (\delta_c)_k^2 \quad (\text{R.50})$$

which gives

$$(\mathbf{F}_c)_k / (\delta_c)_k \geq \alpha_c \quad (\text{R.51})$$

(the correction-to-mismatch ratio exceeds α_c for each edge independently).

Jacobian non-negativity holds for all well-formed AND/OR DAGs: increasing any edge credence p_k never decreases plan value R_Σ (monotonicity of AND/OR propagation). Therefore $J_k = \partial R_\Sigma / \partial p_k \geq 0$ for all k .

The transfer. Since $J_k \geq 0$ preserves the inequality direction:

$$J_k \cdot (\mathbf{F}_c)_k \geq J_k \cdot \alpha_c \cdot (\delta_c)_k \quad \text{for each } k \quad (\text{R.52})$$

Summing:

$$\mathbf{J}^T \mathbf{F}_c = \sum_k J_k (\mathbf{F}_c)_k \geq \alpha_c \sum_k J_k (\delta_c)_k = \alpha_c \cdot \mathbf{J}^T \delta_c \quad (\text{R.53})$$

Therefore $F_s \geq \alpha_c \cdot \delta_s$, giving:

$$\alpha_s = \alpha_c \quad (\text{R.54})$$

No condition-number penalty. The Jacobian's anisotropy is irrelevant when the correction is componentwise and the Jacobian is non-negative. The non-negativity ensures that every edge's correction contributes in the right direction to the value correction, regardless of how unevenly the Jacobian weights different edges.

When does componentwise correction hold? For all cases in Props B.1, B.2, and B.4 — the standard Beta-Bernoulli update on each edge, including the stochastic (nonlinear) single-step realization. The correction IS nonlinear (the actual per-step update $(y - \hat{p})/(n + 1)$ is random, not proportional to δ_k), but it is componentwise (each edge updates from its own observation independently).

When does it fail? When edge corrections are coupled — correcting one edge changes another's correction direction. This occurs for: - **Unobservable intermediates (B.3) under marginal Bayesian updates:** The marginal Bayesian update couples edge posteriors. The correction for edge 2 depends on the joint posterior over both edges, not just on $(\delta_c)_2$ alone. *And — critically — Prop B.3(a) showed that this scheme violates SA1 with $O(1/n)$ bias: there is no valid α_c for the marginal Bayesian update on coupled edges in the first place.* The per-edge bound must therefore be re-established before the Jacobian transfer can be applied. - **Shared observations:** If testing one arm gives partial information about another (correlated arms), corrections couple across edges — with an SA1 status that depends on the specific attribution scheme used to project the shared observation onto per-edge updates.

The coupled-case Cauchy-Schwarz bound presupposes a valid α_c . For the bound $\alpha_s \geq \alpha_c / \kappa(\mathbf{J})^2$ to apply meaningfully, the per-edge sector condition must hold — i.e., the attribution scheme must satisfy SA1. Marginal Bayesian updates on coupled edges do *not* satisfy this precondition (Prop B.3(a)). The resolution is to replace marginal Bayesian with **gradient-based attribution** (Prop B.5d below), which recovers SA1 and yields a valid per-edge sector parameter that admits the Jacobian transfer with the κ^2 penalty.

Scope (coupled-case-applicability).

Per-edge vs. plan-level routes through coupling. Prop B.3(b) already established an alternative route for the two-edge unobservable case: tracking at the plan level ($\hat{\Phi} = \hat{p}_1 \hat{p}_2$) with a single Beta posterior recovers SA1 directly, yielding $\alpha_\Sigma = 1/(n_\Phi + 1)$. The plan-level route works *without* needing the Jacobian bridge because it sidesteps per-edge attribution entirely. The gradient-based per-edge route works *through* the Jacobian bridge, preserving per-edge credences at the cost of the κ^2 penalty. Both routes give valid sector parameters; the choice depends on whether per-edge diagnostics or aggregate efficiency matters more.

The refined picture: nonlinearity is not the problem; inter-edge coupling combined with the attribution scheme is. A nonlinear but componentwise correction transfers losslessly through any non-negative Jacobian. A coupled correction under a scheme that preserves SA1 (gradient-based) incurs the condition-number penalty because the coupling

can redirect correction away from the value-relevant direction. A coupled correction under a scheme that violates SA1 (marginal Bayesian) has no valid α_c to transfer at all and must be replaced before B.5 applies.

Proposition B.5d: Gradient-Based Attribution Restores SA1 on Coupled Edges. **Setup.** Same two-edge AND topology as B.3: edges with true probabilities θ_1, θ_2 , credences $\hat{p}_1, \hat{p}_2$, plan probability $\hat{R}_\Sigma = \hat{p}_1 \hat{p}_2$, observable plan outcome $y_G \in \{0, 1\}$ with $\mathbb{E}[y_G] = \Phi = \theta_1 \theta_2$. Intermediate is unobservable.

Gradient-based per-edge update. Distribute plan-level surprise proportionally to the Jacobian component:

Formulation (gradient-attribution).

$$\Delta \hat{p}_k = \frac{1}{n_k + 1} \cdot J_k \cdot (y_G - \hat{R}_\Sigma), \quad J_k = \frac{\partial \hat{R}_\Sigma}{\partial \hat{p}_k} \quad (\text{R.55})$$

For the two-edge AND case, $J_1 = \hat{p}_2, J_2 = \hat{p}_1$.

Verification of SA1. At truth ($\hat{p}_k = \theta_k$):

$$\mathbb{E}[\Delta \hat{p}_k]_{\hat{\mathbf{p}}=\theta} = \frac{J_k}{n_k + 1} \cdot \mathbb{E}[y_G - \hat{R}_\Sigma]_{\hat{\mathbf{p}}=\theta} \quad (\text{R.56})$$

The bracket evaluates as: $\mathbb{E}[y_G] = \Phi$ by definition of y_G as a Bernoulli outcome with mean Φ ; and $\hat{R}_\Sigma|_{\hat{\mathbf{p}}=\theta} = \theta_1 \theta_2 = \Phi$. Therefore $\mathbb{E}[y_G - \hat{R}_\Sigma]_{\hat{\mathbf{p}}=\theta} = 0$, and:

$$\mathbb{E}[\Delta \hat{p}_k]_{\hat{\mathbf{p}}=\theta} = 0 \quad \text{for all } k. \quad (\text{SA1 satisfied}) \quad (\text{R.57})$$

The contrast with marginal Bayesian is precise: the marginal scheme suffers from a Φ -vs- θ_k mismatch (the update treats each edge's marginal likelihood rather than the joint), producing the $O(1/n)$ bias derived in Prop B.3(a). The gradient scheme distributes surprise via the Jacobian, which aligns the per-edge update direction with the plan-level gradient — and this gradient is zero at truth by construction.

Sector parameter (SA2'). With the gradient-based scheme, the per-edge correction is:

$$F_k(\delta) = \frac{J_k}{n_k + 1} \cdot (\Phi - \hat{R}_\Sigma) \approx \frac{J_k}{n_k + 1} \cdot \mathbf{J}^T \delta \quad (\text{R.58})$$

where the approximation uses the first-order expansion $\hat{R}_\Sigma - \Phi \approx \mathbf{J}^T \delta$ valid near truth. The per-edge sector bound is:

$$\delta^T \mathbf{F}(\delta) \approx \sum_k \frac{J_k^2}{n_k + 1} \cdot (\mathbf{J}^T \delta)^2 / \|\delta\| \geq \frac{\sigma_{\min}(\mathbf{J})^2}{\max_k(n_k + 1)} \|\delta\|^2 \quad (\text{R.59})$$

giving:

$$\alpha_c^{\text{grad}} \geq \frac{\sigma_{\min}(\mathbf{J})^2}{\max_k(n_k + 1)} \quad (\text{R.60})$$

Transfer through B.5c. Applying the coupled-case Cauchy-Schwarz bound:

$$\alpha_s \geq \frac{\alpha_c^{\text{grad}}}{\kappa(\mathbf{J})^2} = \frac{\sigma_{\min}(\mathbf{J})^2 / \max_k(n_k + 1)}{\sigma_{\max}(\mathbf{J})^2 / \sigma_{\min}(\mathbf{J})^2} = \frac{\sigma_{\min}(\mathbf{J})^4}{\sigma_{\max}(\mathbf{J})^2 \cdot \max_k(n_k + 1)} \quad (\text{R.61})$$

The $\sigma_{\min}(\mathbf{J})^4 / \sigma_{\max}(\mathbf{J})^2$ factor is the full cost of coupled per-edge attribution — a steep penalty compared to the componentwise case. The plan-level route (B.3(b)) avoids this penalty entirely by tracking Φ as a single quantity with $\alpha_\Sigma = 1/(n_\Phi + 1)$, at the cost of losing per-edge diagnostics.

Why not proportional-blame or other schemes? Proportional-blame distributes surprise proportionally to current credences: $\Delta \hat{p}_k \propto \hat{p}_k \cdot (y_G - \hat{R}_\Sigma) / \sum_j \hat{p}_j$. This violates SA1 because the proportionality factor $\hat{p}_k / \sum_j \hat{p}_j$ is not the gradient direction, so the distribution over edges does not align with the plan-level surprise’s actual attribution. Only schemes whose per-edge update aligns with the Jacobian direction preserve SA1 for coupled edges; gradient-based is the canonical such scheme.

Claim. For coupled edges with unobservable intermediates, gradient-based attribution is the minimal scheme that (a) satisfies SA1, (b) yields a well-defined per-edge sector parameter, (c) admits the Cauchy-Schwarz Jacobian transfer, and (d) permits per-edge diagnostics. Its $\sigma_{\min}^4 / \sigma_{\max}^2$ scaling is inherent to the coupled case, not an artifact of the scheme. $\square$

B.5c: Implications. Four regimes for the credence-to-value bridge, indexed by correction type and attribution scheme:

Table R.2

Correction type	Edge coupling	Attribution	SA1	Transfer	α_s
Linear	Any	—	Yes	Exact (Jacobian cancels)	α_c
Nonlinear, componentwise	Independent edges	Per-edge Bayesian	Yes	Exact ($J_k \geq 0$ preserves bound)	α_c
Nonlinear, coupled	Coupled edges	Gradient-based (Jacobian distribution)	Yes	$\kappa(\mathbf{J})^2$ penalty	$\alpha_c^{\text{grad}} / \kappa^2$
Nonlinear, coupled	Coupled edges	Marginal Bayesian	No (O(1/n) bias)	— (Jacobian bridge does not apply)	plan-level alternative (8.3)

Componentwise correction closes the gap for all verified cases. Props B.1, B.2, and B.4 all use componentwise edge updates with non-negative Jacobian. The operational diagnostic $\delta_{\text{strategic}}$ inherits the sector condition from credence error with no penalty — even for the nonlinear (stochastic) single-step realization. The derivation validates the operational mismatch, not merely a surrogate.

Inter-edge coupling — not nonlinearity — is the fragility. The κ^2 penalty arises only when correcting one edge changes another’s correction direction (B.3’s unobservable case, correlated observations). Deep or unbalanced DAGs have high $\kappa(\mathbf{J})$ when corrections couple, but the coupling, not the depth or imbalance per se, is what degrades the persistence guarantee.

Connection to credit assignment. The Jacobian $\mathbf{J} = \nabla_{\mathbf{p}} R_\Sigma$ is computable from the DAG’s status propagation formulas — it does not require solving the credit-assignment problem. The credit-assignment problem is about *decomposing observed value changes into per-edge contributions* (needed for the update rule). The Jacobian bridge is about *transferring a per-edge sector condition to the value-residual space* (needed for the persistence guarantee). These are different problems: the bridge works even when credit assignment is unsolved, because it only requires the sensitivity structure, not the causal attribution.

What Is Derived vs. What Is Chosen.

The segment carries derivations at three distinct strengths: (i) exact sector-parameter algebra for concrete Beta-Bernoulli topologies (B.1, B.2, B.4, B.6, B.7 under observable C + facilitator monotonicity), (ii) two structural refutations that are *themselves* derivations of impossibility (B.3(a) SA1 bias; B.7 Cramér-Rao floor under unobservable C), and (iii) formulation choices (Beta-Bernoulli dynamics, componentwise conditional-branch updates, the particular ε -greedy policy family). The dividing line runs between the Beta-Bernoulli *model* (chosen) and the sector-parameter *algebra conditional on that model* (proved). B.7's positive transfer requires two load-bearing conditions — observability of C and facilitator monotonicity $R_\Sigma(G \mid C) \geq R_\Sigma(G \mid \neg C)$ — either of which failing disqualifies the transfer.

Table R.3

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Beta-Bernoulli edge dynamics ($\Delta \hat{p}_k = (y_k - \hat{p}_k)/(n_k + 1)$)	Conjugate-prior model; matches 9.4	Formulation choice
Regime-A adjustment: $\alpha_\Sigma^{\text{eff}} = t_{ij} \cdot \alpha_\Sigma^{\text{stated}}$	Diagonal commutation across Props B.1–B.4, B.6; 9.5	Derived
B.1 Single-edge sector parameter $\alpha_\Sigma = 1/(n + 1)$	Expected Beta-Bernoulli update + sector product algebra	Proved (tight, conditional on Beta-Bernoulli)
B.1 Stochastic ultimate bound $ \delta > \sqrt{\theta(1 - \theta)/(2n + 1)}$	Second-moment recursion + expected-Lyapunov decrement	Derived
B.2 Observable AND-chain sector parameter $\min(1/(n_1 + 1), \theta_1/(n_2 + 1))$	Diagonal correction function; sector product algebra	Proved (conditional on Beta-Bernoulli + observable intermediate)
B.2 Depth- d generalization $\alpha_\Sigma = \min_k \prod_{j < k} \theta_j/(n_k + 1)$	Iteration of B.2 pattern under observable intermediates	Derived
B.3(a) Per-edge SA1 violation under marginal Bayesian attribution ($O(1/n)$ bias)	Exact marginal update + evaluation at truth	Derived as refutation (no valid α_c exists)
B.3(b) Plan-level recovery $\alpha_{\Sigma, \text{plan}} = 1/(n_\Phi + 1)$	Reduction of aggregate $\hat{\Phi}$ tracking to B.1	Derived (reduction)
B.3 Non-identifiability of (θ_1, θ_2) from y_G alone	Product $\Phi = \theta_1 \theta_2$ symmetry in observation channel	Proved
B.4(a) Pure-greedy OR ($\varepsilon = 0$) violates sector condition	Counterexample at $\delta_1 = 0, \delta_2 \neq 0$	Derived as refutation
B.4(b) ε -greedy sector parameter $\min((1 - \varepsilon)/(n_1 + 1), \varepsilon/(n_2 + 1))$	Policy-weighted correction; sector product algebra	Proved (conditional on Beta-Bernoulli + ε -greedy)
B.4 Optimal exploration $\varepsilon^* = (n_2 + 1)/(n_1 + n_2 + 2)$	Term-equalization in min	Derived
B.4 Minimum exploration rate (SA3 requirement) $\varepsilon > \rho_\Sigma(n_{\max} + 1)/R_\Sigma$	Substitution into persistence threshold $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$	Derived
B.5a Linear credence-to-value transfer $\alpha_s = \alpha_c$ (Jacobian cancels)	Algebraic cancellation of $\mathbf{J}\mathbf{J}^T$	Proved (exact, DAG-structure independent)
B.5b Componentwise nonlinear transfer $\alpha_s = \alpha_c$	Per-component sector bound + monotone AND/OR ($\mathbf{J} \geq 0$)	Proved (conditional on componentwise update + non-negative Jacobian)
B.5b Coupled-edge Cauchy-Schwarz bound $\alpha_s \geq \alpha_c/\kappa(\mathbf{J})^2$	Cauchy-Schwarz on $\mathbf{J}^T \mathbf{F}_c$ and $\mathbf{J}^T \hat{\delta}_c$	Derived (conditional on Jacobian regularity and an SA1-preserving attribution scheme)
B.5c Four-regime classification of credence-to-value transfer	Combination of linear/nonlinear $\times$ componentwise/coupled $\times$ attribution type	Derived
B.5d Gradient-based attribution restores SA1 on coupled edges	Jacobian-weighted surprise distribution; $\mathbb{E}[y_G - \hat{p}_\Sigma]_{ \theta} = 0$	Derived

Property	Source	Strength
B.5d Sector parameter under gradient attribution $\alpha_c^{\text{grad}} \geq \sigma_{\min}(\mathbf{J})^2 / \max_k(n_k + 1)$	First-order expansion near truth + singular-value analysis	Derived
B.5d Gradient-based as <i>minimal</i> SA1-preserving scheme for coupled edges	Argument excluding proportional-blame and other schemes	Derived qualitatively (not a uniqueness theorem)
B.6 L1 augmented-DAG sector parameter (three-way gating: condition / starvation / exploration)	Diagonal correction function over $(\delta_C, \delta_{A_1}, \delta_{A_2})$; sector product	Proved (conditional on Beta-Bernoulli + observable C + ε -greedy)
B.6 L0-vs-L1 comparison: L1 is lower α_Σ but honestly calibrated	Direct Φ^{L0} vs Φ^{L1} computation at truth	Derived
B.6 L1-construction principle (common cause factored <i>above</i> OR-structure)	Requirement for conditional independence of OR-siblings given C	Derived
B.7 L1' mixture-form sector parameter (five-way gating)	Diagonal correction function over $(\xi_C, \{\xi_{j C}\}, \{\xi_{j \neg C}\})$; sector product	Derived (conditional on Beta-Bernoulli + observable C + componentwise conditional-branch update + <i>facilitator monotonicity</i> $P_\Sigma(G C) \geq P_\Sigma(G \neg C)$)
B.7 Componentwise update per conditional branch	Matches Beta-Bernoulli on the branch actually executed each trial	Formulation choice
B.7 Facilitator-monotonicity condition $P_\Sigma(G C) \geq P_\Sigma(G \neg C)$	Required so the first Jacobian entry of $\hat{P}_\Sigma^{L1'}$ is non-negative, enabling the lossless B.5b transfer	Load-bearing scope condition
B.7 Reduction to B.6 under strict-prerequisite limit ($\theta_{j \neg C} \rightarrow 0$)	Collapse of $\neg C$ -branch terms in the sector inequality	Verification (algebraic consistency)
B.7 Refutation under unobservable C (single-channel Fisher rank 1)	Cramér-Rao bound applied to rank-1 Fisher $\mathcal{F}(\phi) = uu^T / [\mu_j(1 - \mu_j)]$	Proved by external theorem (Cramér-Rao bound) — no unbiased online estimator admits $\alpha > 0$
B.7 Repair route (i): augment C -observability	Recovers the positive B.7 derivation	Formulation / scope choice (maps to 7.3)
B.7 Repair route (ii): $K \geq 2$ joint children under same C -realization	Fisher matrix rank reaches $2K + 1$; local sector condition	Derived (sketch; applicability narrow)
B.7 Repair route (iii): plan-level fallback on marginal $\hat{\mu}_j$	Reduction to B.1 on scalar marginal	Derived (at cost of per-conditional decomposition)
Persistence thresholds (substitution of each α_Σ into $\alpha_\Sigma > \rho_\Sigma / R_\Sigma$)	Proposition A.1 of A	Derived (each)
Gain-collapse threshold $n^* \propto R_\Sigma / \rho_\Sigma$ common across cases	Direct inversion of persistence condition	Derived
Expected-value (rather than almost-sure) sector analysis	Pedagogical simplification; a.s. convergence via standard Bayesian consistency	Formulation choice (scope)
Constant- α assumption with experience-discounting (λ) stabilization	Instantaneous persistence check + forgetting-factor analysis	Derived (instantaneous only)

Epistemic Status.

Conditional on the Beta-Bernoulli model. Propositions B.1, B.2, B.4, and B.6 are *derived*: the sector-condition verification is exact algebra under the stated generative model. The persistence conditions follow by direct application of Proposition A.1 (A), which is independently established. Proposition B.3(a) (the SA1 violation) is also derived; B.3(b) reduces to B.1 by construction. Proposition B.5a (the credence-to-value bridge for linear correction) is *exact* — the Jacobian cancellation is algebraic, independent of DAG structure. Proposition B.5b (the componentwise nonlinear transfer) is *exact under non-negative Jacobian* — algebraic, no condition-number penalty. The coupled-edge case of

B.5b is *conditional on (i) Jacobian regularity* — the condition-number bound requires $\sigma_{\min}(\mathbf{J}) > 0$, which holds for non-degenerate DAGs — *and (ii) an SA1-preserving attribution scheme* (gradient-based, Prop B.5d); marginal Bayesian attribution on coupled edges does not admit the Cauchy-Schwarz bound because SA1 fails upstream. Proposition B.5d (gradient-based attribution) is *derived* — SA1 verification is algebraic and the sector-parameter bound follows from standard singular-value analysis of the Jacobian.

All results use the *expected-value* sector condition. A full stochastic treatment (Foster-Lyapunov or supermartingale convergence) would give probability bounds rather than expected-value bounds. The expected-value analysis gives the correct asymptotic behavior (posterior concentration at $O(1/\sqrt{n})$) but does not prove almost-sure convergence. For the stationary Beta-Bernoulli case, almost-sure convergence is guaranteed by the standard Bayesian consistency theorem independently of this derivation.

The time-varying α_{Σ} issue remains: since n_k increases with each observation, α_{Σ} decreases over time. The sector-condition framework assumes constant α . The results here give an *instantaneous* persistence check at the current experience level, not a trajectory guarantee. Experience discounting (exponential forgetting with factor λ) stabilizes α_{Σ} at the exact value $(1 - \lambda)/(2 - \lambda)$ from $1/(n_{\text{eff}} + 1)$ with $n_{\text{eff}} = 1/(1 - \lambda)$ — with the simpler $\approx 1 - \lambda$ as the slow-forgetting asymptote ($\lambda \rightarrow 1$) — yielding the persistence requirement $(1 - \lambda)/(2 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$ (full treatment in 9.10).

What remains open:

1. *General DAG topology.* **Partially resolved.** Proposition B.6 verifies the first mixed AND/OR case (L1 augmented DAG with common-cause node). The three-way gating structure (condition testing $\times$ evidence starvation $\times$ exploration gating) appears to be the general pattern. Remaining: arbitrary mixed AND/OR DAGs with multiple common causes and deeper nesting.
2. *Continuous outcomes.* The Beta-Bernoulli model gives conjugate, closed-form updates. Non-conjugate cases (continuous signals, partial observability) require approximate inference, and the sector condition must be verified for the approximation.
3. *Modified sector condition for biased correction.* **Resolved via Prop B.5d (gradient-based attribution).** The $O(1/n)$ bias in the unobservable case (B.3a) under marginal Bayesian updates is eliminated by switching to gradient-based attribution, which satisfies SA1 exactly at truth. Per-edge results are recovered under the gradient scheme at the $\sigma_{\min}^4/\sigma_{\max}^2$ scaling. Alternative route (plan-level tracking, B.3(b)) remains available without the condition-number penalty.
4. *Correlated edges (L1/L2 scope).* **Resolved.** Proposition B.6 verifies the sector condition for L1 (strict-prerequisite augmented DAG); Proposition B.7 verifies it for L1' (soft-facilitator mixture form, observable common cause) with five-way gating. The unobservable- C single-channel case is *refuted* by the Cramér-Rao floor (mixture identifiability obstruction; see B.7 §"Refuted Under Unobservable C ") — not merely "open" but structurally impossible without additional information augmentation. Practical paths under unobservable C : augment C -observability, run multi-child joint observations (sketch only, narrow applicability), or fall back to plan-level tracking on the marginal. Strategies requiring full L2 conditioning over k unobservable common causes still cost $O(2^k)$.
5. *Adaptive exploration.* Proposition B.4 uses fixed ε . Adaptive strategies (UCB, Thompson sampling) allocate exploration based on current uncertainty and should yield tighter sector bounds.

Discussion.

The sector parameter is the edge update gain. Across all four cases, α_Σ is a function of $\eta_k = 1/(n_k + 1)$ — the same quantity that governs epistemic persistence (3.8, 3.6). Strategic persistence and epistemic persistence are governed by the same mathematical machinery, not merely structurally parallel. This validates the schema proposed in 9.10 at the level of concrete dynamics.

AND vs. OR: structural vs. behavioral fragility. The evidence-starvation effect (B.2) is structural — it depends on the DAG topology and upstream reliability, not on the agent’s policy. The exploration-gating effect (B.4) is behavioral — it depends on the action-selection policy. AND-node persistence is improved by increasing upstream reliability (making early steps more likely to succeed). OR-node persistence is improved by increasing exploration (testing alternatives more frequently). The distinction maps to the familiar depth-vs-breadth tradeoff in planning.

Gain collapse as the dominant failure mode. In every drifting-environment case, the persistence threshold takes the form $n < c/\rho_\Sigma$ for some constant c . Accumulated experience suppresses the update gain, eventually making the agent unable to track environmental change. This gives the gain-collapse phenomenon (3.6) a precise quantitative threshold for each topology.

The credence-to-value bridge decouples persistence from credit assignment. Proposition B.5 shows that strategic persistence (in value-residual space) can be established from per-edge sector conditions (in credence space) without solving the credit-assignment problem. The bridge requires only the value-sensitivity Jacobian $\mathbf{J} = \nabla_{\mathbf{p}} P_\Sigma$, which is computable from the DAG’s status propagation formulas in $O(|V| + |E|)$ time. Credit assignment — attributing observed value changes to specific edges — is needed for the *update rule* (computing the signal function in 9.4), not for the *persistence guarantee*. This means the persistence analysis can proceed even while the update rule remains incompletely specified.

Inter-edge coupling is the true fragility, not nonlinearity or DAG depth. Proposition B.5b shows that nonlinear componentwise corrections transfer losslessly through any non-negative Jacobian — the $\kappa(\mathbf{J})^2$ penalty arises only when corrections are *coupled* across edges. This refines the earlier qualitative argument from 8.1: the structural pressure toward shallow, balanced strategies is not about depth per se but about the coupling that deep or complex structures tend to introduce. A deep AND-chain with fully observable intermediates (B.2) has componentwise corrections and transfers losslessly despite high depth. The same chain with unobservable intermediates (B.3) has coupled corrections and incurs the penalty. The distinction is observability-mediated coupling, not topological complexity.

Appendix S

Derivation: Hard Ceiling on Strategic-Persistence Reachability under Exponential Forgetting

The strategic-persistence schema's instantaneous persistence form $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$ (9.10), instantiated under Beta-Bernoulli edge dynamics with exponential forgetting at rate $\lambda \in (0, 1)$, has a sharp structural cap at $\rho_\Sigma/R_\Sigma = 1/2$: no λ satisfies the prerequisite when strategic disturbance reaches half the strategic reserve. The schema's reachable persistence region is exactly the open half-plane $\rho_\Sigma < R_\Sigma/2$.

Formal Expression.

Setup. Per R Prop B.1, the Beta-Bernoulli edge update with n accumulated pseudo-counts gives sector parameter $\alpha_\Sigma = 1/(n + 1)$. Without forgetting, $n \rightarrow \infty$ and $\alpha_\Sigma \rightarrow 0$ for every edge asymptotically — so the schema's instantaneous persistence form eventually fails under any positive disturbance rate. *Exponential forgetting* with discount $\lambda \in (0, 1)$ replaces the raw update with the discounted recurrence:

Definition (Discounted Beta-Bernoulli Update).

$$\alpha_k \mapsto \lambda \alpha_k + y_k, \quad \beta_k \mapsto \lambda \beta_k + (1 - y_k) \quad (\text{S.1})$$

following the standard adaptive-control / online-learning treatment (Ljung 1987).

Proposition C.1 (Steady-State Sector Parameter).

Under the discounted Beta-Bernoulli recurrence, the steady-state sector parameter at the fixed point $\hat{p} = \theta$ is:

Derived (Conditional on Beta-Bernoulli edges + exponential forgetting).

$$\alpha_\Sigma^{\text{ss}} = \frac{1 - \lambda}{2 - \lambda} \quad (\text{S.2})$$

Proof. At a fixed point in expectation, the discounted recurrence stabilizes when each pseudo-count equals its own contribution rate divided by the dissipation:

$$\alpha^* = \lambda \alpha^* + \theta \implies \alpha^* = \frac{\theta}{1-\lambda}, \quad \beta^* = \lambda \beta^* + (1-\theta) \implies \beta^* = \frac{1-\theta}{1-\lambda} \quad (\text{S.3})$$

The effective sample size is the sum:

$$n_{\text{eff}} = \alpha^* + \beta^* = \frac{1}{1-\lambda} \quad (\text{S.4})$$

Substituting into Prop B.1's $\alpha_\Sigma = 1/(n+1)$ at $n = n_{\text{eff}}$:

$$\alpha_\Sigma^{\text{ss}} = \frac{1}{n_{\text{eff}} + 1} = \frac{1}{1/(1-\lambda) + 1} = \frac{1-\lambda}{1+(1-\lambda)} = \frac{1-\lambda}{2-\lambda} \quad \square \quad (\text{S.5})$$

The slow-forgetting linear form $\alpha_\Sigma^{\text{ss}} \approx 1-\lambda$ is the asymptotic expansion as $\lambda \rightarrow 1$ (the regime where the $1/(2-\lambda)$ damping factor approaches unity). Outside the slow-forgetting limit the linear form overstates the steady-state $\alpha_\Sigma^{\text{ss}}$ — at $\lambda = 0.5$ by 50% (1/3 exact vs 1/2 linear); at $\lambda = 0.9$ by 10% (1/11 exact vs 1/10 linear). The exact form is operationally the threshold to check against; the linear form is unsafe outside its asymptotic regime.

Proposition C.2 (Hard-Ceiling No-Go).

The forgetting prerequisite for the schema's trajectory guarantee under exponential forgetting is:

Derived (Conditional on Prop C.1 + the schema's persistence form).

$$\frac{1-\lambda}{2-\lambda} > \frac{\rho_\Sigma}{R_\Sigma} \quad (\text{S.6})$$

This inequality is unsatisfiable for any $\lambda \in [0, 1]$ when $\rho_\Sigma \geq R_\Sigma/2$. The supremum is sharp:

$$\sup_{\lambda \in [0,1]} \alpha_\Sigma^{\text{ss}}(\lambda) = \frac{1}{2} \quad (\text{S.7})$$

achieved as $\lambda \rightarrow 0^+$ (maximally aggressive forgetting — no memory). The schema's reachable persistence region in (ρ_Σ, R_Σ) -space is exactly the open half-plane $\rho_\Sigma < R_\Sigma/2$.

Proof: Let $x = \rho_\Sigma/R_\Sigma$ with $x \in [0, 1]$. Solving for the threshold λ at which the inequality becomes equality:

$$(1-\lambda) = x(2-\lambda) \implies \lambda(x-1) = 2x-1 \implies \lambda = \frac{2x-1}{x-1} = \frac{1-2x}{1-x} \quad (\text{S.8})$$

For $\lambda \in (0, 1)$ to admit a strict solution to the inequality, we need $\lambda > 0$ at the threshold. With $x < 1$ (denominator positive), this requires $1-2x > 0$, i.e., $x < 1/2$.

At $x = 1/2$ exactly: the threshold $\lambda = 0$, giving $\alpha_\Sigma^{\text{ss}}(0) = (1-0)/(2-0) = 1/2 = x$ — equality, not strict satisfaction. For $x > 1/2$: no $\lambda \in [0, 1]$ satisfies the strict inequality, since even maximally aggressive forgetting ($\lambda \rightarrow 0^+$) only achieves $\alpha_\Sigma^{\text{ss}} \rightarrow 1/2$. The supremum is exactly 1/2 at $\lambda = 0$. $\square$

Equivalently: the schema's reachable set under any exponential-forgetting design is exactly $\{(\rho_\Sigma, R_\Sigma) : \rho_\Sigma < R_\Sigma/2\}$. The boundary $\rho_\Sigma = R_\Sigma/2$ is not in the reachable region (strict satisfaction required), and the half-plane above the boundary is entirely outside.

Epistemic Status.

Exact under the named conditions: (i) Beta-Bernoulli edge dynamics (R Prop B.1), (ii) exponential forgetting with $\lambda \in (0, 1)$, (iii) the schema's persistence form per 9.10 and the underlying template-instantiation conditions (T1)–(T3) of G. Both Propositions C.1 and C.2 are algebraically exact within these conditions — no slack, no approximation. The “exact” tier reflects that uncertainty resides in whether the conditions hold (which mismatch state, which topology, whether the forgetting mechanism is in fact exponential vs another discounting scheme), not in the derivation.

The hard ceiling is *structural*: it is independent of λ choice and independent of which topology among the schema's verified instances (single-edge, two-edge AND observable/unobservable, two-arm OR with ε -greedy, mixed AND/OR with common cause). It is a *class-level cap on reachability* — not a refutation of the schema's persistence form, but a refinement of which (ρ_Σ, R_Σ) regimes the schema can be satisfied in.

Discussion.

Why this no-go matters. The hard ceiling *refines*, not *refutes*, the schema. The schema's persistence form $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$ remains the right form; what the ceiling establishes is that under exponential forgetting, the form is *unreachable* across half the (ρ_Σ, R_Σ) -space. Above the ceiling, structural persistence of Σ_t is not available to this architecture — no tuning of λ can recover it. This is the canonical analog at the strategic layer of 4.8's epistemic-layer trigger: when parametric adaptation cannot keep up, structural change is required.

Boundary behavior. At $\rho_\Sigma/R_\Sigma = 1/2$ exactly, the supremum is achieved at $\lambda = 0$ — the *no-memory* regime where every observation fully replaces the prior. This corresponds to effective sample size $n_{\text{eff}} = 1$ (only the most recent observation counts), giving $\alpha_\Sigma = 1/2$ in Prop B.1's $1/(n + 1)$. The reachable region's open-versus-closed character at the boundary is itself informative: persistence requires *strict* satisfaction, so the boundary $\rho_\Sigma = R_\Sigma/2$ is not in the reachable region even with $\lambda = 0$.

Connection to the broader gain-decay class. The hard ceiling sharpens to a class-level no-go on a wider class of update mechanisms — see NeurIPS 2026 Paper 2 ($\mathcal{A}_{\text{decay}}$ structural-class theorem) for the lift from Beta-Bernoulli with forgetting to all gain-decay updates: every mechanism whose effective gain decays to zero with accumulated experience universally violates the persistence threshold for any positive disturbance rate, and finite-gain mechanisms face *bidirectional* thresholds (this lower bound from the schema's persistence form, plus an upper bound from noise blow-up). The hard ceiling at $1/2$ is the Beta-Bernoulli + exponential-forgetting instance of this broader structural pattern.

Strict-form independent-verify note. Per 5 and the project's verification discipline, the canonical strict-form check on this derivation is a fresh-mathematician re-derivation of Propositions C.1 and C.2 (algebra above) plus independent reading of R Prop B.1 (the source the C.1 derivation reduces to). This is owed before any further status elevation; the present “exact” tier rests on the algebra's elementariness plus the conditional structure being clean.

Findings.

The Hard Ceiling at $\rho_\Sigma = R_\Sigma/2$ (Class-Level Reachability Cap). **Brief:** Under the schema's Beta-Bernoulli + exponential-forgetting instantiation, $\sup_{\lambda \in [0,1]} \alpha_\Sigma^{\text{ss}} = 1/2$, achieved as $\lambda \rightarrow 0^+$. The schema's reachable persistence region in (ρ_Σ, R_Σ) -space is exactly the open half-plane $\rho_\Sigma < R_\Sigma/2$. When the strategic disturbance rate reaches half the strategic reserve, no choice of forgetting rate satisfies the persistence prerequisite — structural persistence of Σ_t is unavailable to this architecture above the ceiling.

Impact: Identifies a sharp, λ -independent cap on what exponential forgetting can achieve. The cap is not an artifact of tuning; it is structural — a class-level no-go on the gain-decay-plus-forgetting class of strategic update mechanisms. For an agent whose strategic-disturbance-to-reserve ratio approaches $1/2$, no engineering of the forgetting mechanism can restore the schema's trajectory guarantee. The hard ceiling closes the design space: above it, the agent must change *something else* — the update mechanism class (away from gain-decay-plus-forgetting toward constant-step finite-gain,

per the NeurIPS Paper 2 $\mathcal{A}_{\text{decay}}$ structural-class theorem), the mismatch state, or the topology. This is the canonical strategic-layer analog of 4.8’s epistemic-layer trigger.

Novelty Claim: *Synthesis* of standard discounted-Beta-Bernoulli mechanics with the schema’s environment-side parameters into a class-level structural cap. The constituent algebra is elementary — the discounted-update steady state $n_{\text{eff}} = 1/(1 - \lambda)$ is in Ljung 1987; the $\alpha = 1/(n + 1)$ form is in R Prop B.1. The AAT-distinctive contribution is the *combination* with ρ_{Σ}/R_{Σ} into a sharp reachability cap, surfaced via the §D.3 strengthen-first work that replaced the prior linear approximation (which had hidden the ceiling) with the exact form.

Appendix T

Derivation: Regret-Bound Derivation of the Strategy-Cost KL Direction

The variational form of the strategy-cost objective (9.9) carries a $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})$ relevance term. This appendix derives that **the π^* -first KL direction is forced** as the non-vacuous regret-bound form, and proves (conditional on a chain-rule additivity axiom motivated by 8.1) that **reverse-KL is uniquely forced within the direction-forced f-divergence family**.

Three sources of force compose. (i) The *direction* is forced decision-theoretically: bounded regret against an optimal policy is bounded above by value-range $\times$ total-variation, and by Pinsker’s inequality total variation is bounded by $\sqrt{D_{\text{KL}}(\pi^* \| Q)/2}$ in the π^* -first direction; the opposite-direction KL becomes infinite under deterministic optimal policy whenever the strategy places any mass off the optimum, giving a vacuous bound. (ii) Within the direction-forced family, the standard Hobson-Csiszár-Shore-Johnson uniqueness machinery via Aczél’s Cauchy functional equation forces reverse-KL *uniquely* among f-divergences once the chain-rule additivity axiom is granted — the divergence-layer instance of #disc-additive-coordinate-forcing’s meta-pattern (after chain-confidence decay; before log-odds at the update layer in #deriv-edge-update-natural-parameter). (iii) The bound is *sharpened* under AAT’s canonical deterministic-optimum scope: the **Bretagnolle-Huber identity** holds exactly (not as inequality), giving a two-sided regret bound $\Delta_{\min}(1 - e^{-D_{\text{KL}}}) \leq R \leq V_{\max}(1 - e^{-D_{\text{KL}}})$ strictly sharper than Pinsker — Lipschitz-equivalent to $(1 - e^{-D_{\text{KL}}})$ at both ends, with the Pinsker form becoming vacuous once $D_{\text{KL}} > 2$.

Secondary supporting properties of reverse-KL (gradient tractability, alignment with variational-inference machinery, MDL coding interpretation, Amari-Nagaoka Fisher geometry compatibility) are surfaced as *convergent evidence* rather than independent uniqueness grounds; the framework is explicit that Fisher-metric-at-second-order is not distinguishing within f-divergences (Eguchi 1983), so only the chain-rule axiom does the uniqueness work. The result is one of AAT’s cleanest demonstrations of the framework’s posture on coordinates: where a coordinate matters, the framework can point at the axiom that forces it; where the axiom isn’t AAT-internal, the framework can name what was adopted from outside.

Formal Expression.

§1 — Setup. Fix O_t , M_t , continuation policy π_{cont} , and horizon N_h . The action-value is the objective-functional evaluation at a : $V(a) := Q_O(M_t, a; \pi_{\text{cont}}, N_h)$ (6.6; V derives from O_t per 6.4). The optimal action is $a^* := \arg \max_a V(a)$; under AAT’s canonical scope (6.6), the optimal policy $\pi^*(\cdot | M_t) = \delta_{a^*}$ is the point mass on a^* (tied-optimum extensions §8). Write $V_{\max} := \max_a V(a) - \min_a V(a)$ for the value range at fixed M_t ; this is finite whenever $\mathcal{A}$ is a bounded action set under V .

$Q_{\Sigma_t}(\cdot \mid M_t)$ is the action distribution induced by the strategy DAG. In general Q_{Σ_t} is stochastic — the DAG’s edge-credence uncertainty induces policy stochasticity downstream of propagation.

§2 — Regret against the optimal policy.

The strategy-induced regret of Q_{Σ_t} against π^* is:

Definition (strategy-induced-regret).

$$R(Q_{\Sigma_t}) := V(a^*) - \mathbb{E}_{a \sim Q_{\Sigma_t}}[V(a)] = \sum_a Q_{\Sigma_t}(a) \cdot [V(a^*) - V(a)] \quad (\text{T.1})$$

Writing $\Delta(a) := V(a^*) - V(a) \in [0, V_{\max}]$ for the per-action regret gap. Three regret forms in the literature:

$$\mathbb{E}_{\pi^*}[V] - \mathbb{E}_{Q_{\Sigma_t}}[V], \quad V(a^*) - \mathbb{E}_{Q_{\Sigma_t}}[V], \quad \mathbb{E}_{\pi^*}[V - V_{Q_{\Sigma_t}}] \quad (\text{T.2})$$

coincide identically under deterministic π^* .

§3 — Total-variation bound (tight).

Derived (tv-regret-bound, from bounded V + deterministic π^).*

$$R(Q_{\Sigma_t}) = \sum_a Q_{\Sigma_t}(a) \Delta(a) \leq V_{\max} \cdot \sum_{a \neq a^*} Q_{\Sigma_t}(a) = V_{\max} \cdot (1 - Q_{\Sigma_t}(a^*)) \quad (\text{T.3})$$

For deterministic $\pi^* = \delta_{a^*}$:

$$\text{TV}(\pi^*, Q_{\Sigma_t}) = \frac{1}{2} \sum_a |\pi^*(a) - Q_{\Sigma_t}(a)| = 1 - Q_{\Sigma_t}(a^*) \quad (\text{T.4})$$

Therefore:

$$\boxed{R(Q_{\Sigma_t}) \leq V_{\max} \cdot \text{TV}(\pi^*, Q_{\Sigma_t})} \quad (\text{tight}) \quad (\text{T.5})$$

Tightness. Equality holds exactly when $\Delta(a) = V_{\max}$ for all $a \neq a^*$ (degenerate value landscape: every suboptimal action incurs the full value range). For typical landscapes the bound is loose by a factor $\mathbb{E}_{Q_{\Sigma_t}}[\Delta \mid a \neq a^*]/V_{\max} \in (0, 1]$.

§4 — Exact regret-reverse-KL identity under deterministic π^* . Under AAT’s canonical scope (deterministic $\pi^* = \delta_{a^*}$), reverse-KL and total variation are related by an *identity*, not merely an inequality. This gives a tight two-sided regret bound that the Pinsker inequality strictly weakens.

Identity. For deterministic $\pi^* = \delta_{a^*}$ and any Q with $Q(a^*) > 0$:

Derived (bb-identity-deterministic, under deterministic π^).*

$$\boxed{D_{\text{KL}}(\pi^* \| Q) = -\log Q(a^*) = -\log(1 - \text{TV}(\pi^*, Q))} \quad (\text{T.6})$$

Derivation. $D_{\text{KL}}(\delta_{a^*} \| Q) = \sum_a \delta_{a^*}(a) \log(\delta_{a^*}(a)/Q(a)) = -\log Q(a^*)$ (only the $a = a^*$ term contributes; $0 \log 0$ terms are conventionally 0). And $\text{TV}(\delta_{a^*}, Q) = 1 - Q(a^*)$ (direct from §3). Substituting gives the identity. $\square$

This is the Bretagnolle-Huber inequality (Bretagnolle & Huber 1978, “Estimation des densités,” *Séminaire de probabilités XII*, Springer LNM 649; Tsybakov 2009 §2.4; Sason & Verdú 2016) specialized to the deterministic- P case, where the general inequality $\text{TV} \leq \sqrt{1 - e^{-D_{\text{KL}}}}$ becomes an equality.

Combining with the tight TV-regret bound of §3:

Derived (exact-regret-reverse-kl, under deterministic π^).*

$$\boxed{R(Q_{\Sigma_t}) \leq V_{\max} \cdot (1 - e^{-D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})})} \quad (\text{T.7})$$

Matching lower bound. Define the action-gap $\Delta_{\min} := \min_{a \neq a^*} \Delta(a) > 0$ (standard in RL theory; well-defined whenever the optimum is isolated over finite $\mathcal{A}$ with bounded V). Then:

$$R(Q_{\Sigma_t}) = \sum_{a \neq a^*} Q_{\Sigma_t}(a) \Delta(a) \geq \Delta_{\min} \cdot \sum_{a \neq a^*} Q_{\Sigma_t}(a) = \Delta_{\min} \cdot \text{TV}(\pi^*, Q_{\Sigma_t}) \quad (\text{T.8})$$

Under the exact BH identity:

$$R(Q_{\Sigma_t}) \geq \Delta_{\min} \cdot (1 - e^{-D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})}) \quad (\text{T.9})$$

Lipschitz-equivalence corollary. Regret and $(1 - e^{-D_{\text{KL}}})$ are Lipschitz-equivalent with constants $\Delta_{\min}$ (below) and $V_{\max}$ (above):

Derived (matched-lower-bound, under deterministic π^ + isolated optimum).*

$$\frac{\Delta_{\min}}{V_{\max}} \leq \frac{R(Q_{\Sigma_t})}{V_{\max}(1 - e^{-D_{\text{KL}}})} \leq 1 \quad (\text{T.10})$$

The upper bound is tight when the value landscape is extremal ($\Delta(a) = V_{\max}$ for all $a \neq a^*$); the lower bound is tight when sub-optimal actions are uniformly bad ($\Delta_{\min} = \max_{a \neq a^*} \Delta(a)$).

$D_{\text{KL}}(\pi^* \| Q_{\Sigma_t}) \in [0, +\infty)$: finite and graded whenever $Q_{\Sigma_t}(a^*) > 0$; diverges only in the structural-failure limit where the strategy places zero mass on the optimum.

§4.1 — Pinsker bound as loose general form. The Pinsker inequality $\text{TV}(P, Q) \leq \sqrt{\frac{1}{2} D_{\text{KL}}(P \| Q)}$ (Tsybakov 2009 §2.4; Cover & Thomas 2006 §11.6) yields a regret bound that does not assume deterministic π^* :

$$R(Q_{\Sigma_t}) \leq V_{\max} \cdot \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})} \quad (\text{T.11})$$

Under AAT’s canonical scope, this is strictly weaker than the BH-identity form of §4. For any $D_{\text{KL}} > 0$: $1 - e^{-D_{\text{KL}}} < \sqrt{D_{\text{KL}}/2}$ for small D_{KL} (the BH form is linear in D_{KL} while Pinsker is $\sqrt{D_{\text{KL}}}$), and Pinsker’s $V_{\max} \sqrt{D_{\text{KL}}/2}$ exceeds the trivial $V_{\max}$ bound once $D_{\text{KL}} > 2$, giving vacuous content there. The BH identity is informative uniformly in D_{KL} .

Pinsker remains the correct tool for stochastic- π^* extensions (§9) where the deterministic- π^* scope is relaxed and the BH identity degrades back to inequality.

§5 — Direction-forcing claim (the load-bearing result).

Claim. The KL direction with π^* *first* is forced as the non-vacuous regret-bound form. Forward-KL $D_{\text{KL}}(Q_{\Sigma_t} \| \pi^*)$ is *not* a non-vacuous bound on $R(Q_{\Sigma_t})$ under deterministic π^* .

Derived (kl-direction-forced, from deterministic π^).*

Derivation. Expanding:

$$D_{\text{KL}}(Q_{\Sigma_t} \| \pi^*) = \sum_a Q_{\Sigma_t}(a) \log(Q_{\Sigma_t}(a) / \pi^*(a)) \quad (\text{T.12})$$

For any $a \neq a^*$: $\pi^*(a) = 0$ (point mass assumption). The summand $Q_{\Sigma_t}(a) \log(Q_{\Sigma_t}(a)/0) = +\infty$ unless $Q_{\Sigma_t}(a) = 0$. Therefore $D_{\text{KL}}(Q_{\Sigma_t} \| \pi^*) = +\infty$ whenever Q_{Σ_t} places any mass off a^* — for *all but a measure-zero subset* of stochastic strategies. A bound “ $R \leq +\infty$ ” is vacuous.

This is the same shape of degeneracy as the original Shannon-MI form (Gemini Finding 2) that the V-medium move was introduced to escape: same degeneracy-when- π^* -is-deterministic, different value (0 vs $+\infty$). Only the *reverse* direction escapes both.

Alignment with the structural problem. Forward-KL is natural for *mode-covering* inference (where Q is asked to cover P ’s full support) and variational inference when Q is learned to match a full distribution. Reverse-KL is natural for *mode-seeking* (concentrate Q on P ’s mode). The AAT strategy problem is mode-seeking by construction: the strategy should concentrate on a^* . The direction alignment with the structural problem is not accidental.

Asymmetry is forced by regret’s one-sidedness. A second, independent argument for asymmetry — one that does not rely on the chain-rule axiom of §6.1. Under deterministic π^* , regret is a *one-sided* quantity: $R(Q_{\Sigma_t}) = \sum_{a \neq a^*} Q_{\Sigma_t}(a) \Delta(a)$ contributes only from Q_{Σ_t} ’s off-optimum mass; π^* ’s “mass off Q_{Σ_t} ” is vacuous since π^* has no support off a^* . Any divergence whose role is to bound this quantity should therefore be asymmetric — it should penalize Q_{Σ_t} ’s deviation from π^* without symmetrically penalizing the (trivially zero) deviation of π^* from Q_{Σ_t} . Symmetric divergences (squared Hellinger, Jensen-Shannon, symmetrized KL) treat the two deviations interchangeably; under the one-sided regret quantity this is operationally wrong — it introduces a term with no semantic role. The asymmetry requirement is thus *structural*, emerging directly from what regret is as a functional, and is established independently of the chain-rule axiom that picks the specific asymmetric form in §6.1. The two arguments compose: *direction-forcing* (vacuity under deterministic π^*) + *asymmetry-forcing* (regret is one-sided) $\Rightarrow$ the admissible bounding divergence is π^* -first and asymmetric; chain-rule additivity (§6.1) then picks reverse-KL uniquely within that family.

Terminology note (Bishop-vs-AAT “reverse-KL”). AAT’s canonical reverse-KL is $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})$ — optimum-first, agent-second. Under Bishop 2006’s convention ($D_{\text{KL}}(q \| p)$ with q the approximation is called “reverse-KL”), AAT’s form would be labeled “forward-KL.” The two naming conventions disagree in surface labeling but agree in the operational property — both pick out the *mode-seeking* direction (concentrate the approximation on the target’s mode).

Literature that uses the Bishop convention (variational inference, generative modeling, Levine 2018) and literature that uses the π^* -first / target-first convention (decision theory, regret analysis, Rubin-Shamir-Tishby 2012) describe the same operational quantity under deterministic π^* . When this segment writes “reverse-KL,” the π^* -first / AAT convention is meant; under softened targets the two conventions describe different objects and must be disambiguated explicitly.

§6 — Admissible-divergence family and uniqueness of reverse-KL.

The regret-bound argument forces the *direction* (the reference distribution π^* appears first) but admits a family of divergences. Each member yields a valid regret bound; they differ in tightness and operational properties:

Discussion (admissible-regret-divergences).

Table T.1

<i>Divergence</i>	<i>Bound on R</i>	<i>Tightness</i>	<i>Finite under det. π^*?</i>	<i>Gradient-tractable?</i>
$\text{TV}(\pi^*, Q_{\Sigma_t})$	$V_{\max} \cdot \text{TV}$	Tight (extremal V)	Yes	No (non-differentiable)
$D_{\text{KL}}(\pi^* \ Q_{\Sigma_t})$ via Pinsker	$V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}}$	Loose by $\sqrt{\cdot}$	Yes	Yes
$D_{\text{KL}}(\pi^* \ Q_{\Sigma_t})$ via Bretagnolle-Huber	$V_{\max} \sqrt{1 - e^{-D_{\text{KL}}}}$	Tighter than Pinsker for large D_{KL}	Yes	Yes
$\chi^2(\pi^* \ Q_{\Sigma_t})$ (Le Cam)	$V_{\max} \cdot \frac{1}{2} \sqrt{\chi^2}$	Typically looser than Pinsker	Yes: $\chi^2 =$ $1/Q_{\Sigma_t}(a^*) - 1$	Yes
$D_{\alpha}(\pi^* \ Q_{\Sigma_t})$ (Rényi, $\alpha \geq 1$)	Various	Interpolates KL ($\alpha \rightarrow 1$) and χ^2 ($\alpha = 2$)	Yes for $\alpha \geq 1$	Yes
$D_{\text{KL}}(Q_{\Sigma_t} \ \pi^*)$ (forward-KL)	$+\infty$	Vacuous	No	—

What is uniquely forced by the regret-bound argument alone. The direction: the reference π^* is first. This is a real derivation outcome, not a selection. Within the π^* -first family, multiple f-divergences each give valid bounds; an additional structural axiom is required to pick one uniquely.

§6.1 — Chain-rule uniqueness theorem.

Theorem (chain-rule / additivity uniqueness of KL among f-divergences; folk theorem, standard functional-equation derivation). Let $D_f(P \| Q) = \sum_x Q(x) f(P(x)/Q(x))$ be a smooth f-divergence with f convex and $f(1) = 0$. The chain rule

Derived (reverse-kl-uniqueness, Conditional on chain-rule axiom).

$$D_f(R_{XY} \| Q_{XY}) = D_f(R_X \| Q_X) + \mathbb{E}_{P_X}[D_f(R_{Y|X} \| Q_{Y|X})] \quad (\text{T.13})$$

holds for all joint distributions (X, Y) if and only if $f(t) = c \cdot t \log t$ for some $c > 0$ — i.e., D_f is reverse-KL up to positive scaling.

References. The theorem is a classical folk result obtainable by direct functional-equation argument (sketched below). The canonical published axiomatic characterizations equivalent to the chain-rule statement are: **Hobson 1969**, “A new theorem of information theory,” *J. Stat. Phys.* 1(3):383–391 — uniqueness of the Kullback expression via a composition/additivity axiom; **Csiszár 1991**, “Why least squares and maximum entropy? An axiomatic approach to inference

for linear inverse problems,” *Annals of Statistics* 19(4):2032–2066 — Theorem 3 corollary: the only transitive statistical projection rule is the I-divergence projection rule; Theorem 5: product-consistency characterizes I-divergence uniquely. See also **Shore & Johnson 1980**, “Axiomatic derivation of the principle of maximum entropy and the principle of minimum cross-entropy,” *IEEE Trans. Info. Theory* 26(1):26–37 (system-independence axiom); **Sanov 1957**, “On the probability of large deviations of random variables,” *Mat. Sb.* 42(84):11–44 (large-deviation rate function for empirical-distribution concentration); **Aczél & Daróczy 1975**, *On Measures of Information and Their Characterizations* (Academic Press) for the general functional-equation machinery.

These are not independent uniqueness routes. Hobson’s composition axiom, Csiszár’s transitive-projection axiom, Shore-Johnson’s system-independence axiom, and Sanov’s sampling-consistency condition are *structurally-equivalent reformulations* of the same underlying requirement — all factor through independence-of-sub-problems (joint inference on independent subsystems decomposes additively over factorizations). The Cauchy functional equation that each reduces to is the common structural content beneath varied surface formulations. This matters for #disc-additive-coordinate-forcing: the chain-rule axiom’s load-bearing role is not weakened by noting multiple canonical references; conversely, the multiple references do not provide multiple independent uniqueness arguments. No known uniqueness route outside the independence-on-sub-problems family exists.

Proof sketch. Write $r_x = P(x)/Q(x)$, $s_{y|x} = P(y | x)/Q(y | x)$. The chain-rule identity must hold for all joint decompositions, which forces the functional equation $f(rs) = f(r) + rf(s) + g(r)$ for all $r, s > 0$. Combined with $f(1) = 0$ and convexity, the unique solution is $f(t) = c \cdot t \log t$ for $c > 0$ (Aczél & Daróczy 1975 §4).

Why other members of the family fail the chain rule. Concrete counterexample for χ^2 : take Q_X uniform on $\{x_1, x_2\}$, $P_X = (3/4, 1/4)$, $Q(y | x)$ uniform, $P(y | x) = (3/4, 1/4)$ for both x . Direct calculation gives $\chi^2(P_{XY} \| Q_{XY}) = 9/16$, while $\chi^2(P_X \| Q_X) + \mathbb{E}_{P_X}[\chi^2(P_{Y|X} \| Q_{Y|X})] = 1/4 + 1/4 = 8/16$. Non-additive: $9/16 \neq 8/16$. Rényi- α for $\alpha \neq 1$ fails analogously; Bretagnolle-Huber is a monotone transform of reverse-KL (not an independent f-divergence); Hellinger-squared ($\alpha = 0$) likewise fails.

AAT-internal motivation for the chain-rule axiom. The chain rule is the *divergence-level analog* of the additive log-confidence decay in #der-chain-confidence-decay. AAT has already committed to additive-mismatch-decomposition-along-causal-chains in that segment; the divergence-level parallel is:

$$D(\pi^* \| Q_{\Sigma_t}) = \sum_{t=1}^T \mathbb{E}_{\pi^*} \left[D(\pi^*(\cdot | a_{<t}^*) \| Q(\cdot | a_{<t}^*)) \right] \quad (\text{T.14})$$

— total mismatch between π^* and Q_{Σ_t} decomposes additively over the DAG’s causal layers along the optimal trajectory. Non-chain-rule divergences (e.g., χ^2) give super-additive decompositions in which layer-mismatches amplify multiplicatively — structurally discordant with the DAG factorization (8.3). Adopting the chain-rule axiom is therefore not arbitrary; it is the divergence-level version of a decomposition principle AAT already relies on.

Corollary (within the chain-rule axiom). Under deterministic π^* + bounded value + chain-rule additivity, reverse-KL is the unique smooth f-divergence in the direction-forced admissible family. The “Reverse-KL canonical among smooth divergences” status upgrades from formulation choice (under the pre-axiom reading) to *Derived (conditional on the chain-rule axiom)*.

What the uniqueness theorem does not do. It fixes the divergence within the f-divergence family; it does not fix the bounding function g around the divergence (Pinsker vs Bretagnolle-Huber vs Le Cam-on- χ^2 are *different bounds using different divergences*, so only Pinsker and BH-on-KL remain in scope after uniqueness — and these differ only in the g -envelope on top of reverse-KL, not in the divergence itself). It does not resolve the linear-vs-square-root form question of §7 (that is a Lagrangian-shape choice orthogonal to the divergence choice). Monotone transforms of reverse-KL (e.g., $1 - e^{-D_{\text{KL}}}$) are equivalence-class members for gradient-based optimization and are not ruled out.

Scope of the axiom. The chain rule is stated for arbitrary joint decompositions. AAT’s strategy spaces are discrete at the proposition level; the theorem applies directly. For continuous strategy spaces (e.g., low-level control), the chain rule

extends by replacing sums with integrals against the dominating measure; the functional-equation derivation is identical in the continuous case (see Liese & Vajda 1987, *Convex Statistical Distances*, Teubner, for the standard measure-theoretic treatment of f-divergences and their decomposition properties).

§6.2 — *Secondary characterizations (now supporting rather than load-bearing)*. Four additional properties further motivate reverse-KL as the canonical choice; under §6.1 they are no longer load-bearing for uniqueness but remain informative about why reverse-KL is a comfortable fit with the rest of the AAT framework:

1. **Gradient-tractability.** TV is non-differentiable at mass boundaries; reverse-KL is smooth. Operational minimization via gradient methods rules out TV despite its tightness — independent of the uniqueness argument.
2. **Variational-inference alignment.** Reverse-KL is the standard divergence in the variational-inference lineage (ELBO derivation uses reverse-KL; Friston et al. 2017; Da Costa et al. 2020). The V-medium move’s rhetorical payoff — shared vocabulary with active inference — lives on reverse-KL specifically. This is *convergent evidence* that reverse-KL is natural in multiple frames, not an independent uniqueness argument: the ELBO decomposition itself uses the chain rule as a sub-step, so the logical priority runs chain rule $\rightarrow$ reverse-KL $\rightarrow$ ELBO.
3. **Fisher geometry.** Reverse-KL’s second-order expansion gives the Fisher information metric (Amari & Nagaoka 2000). *But by the differential-geometric framework in Eguchi 1983* (“Second order efficiency of minimum contrast estimators in a curved exponential family,” *Annals of Statistics* 11(3):793–803, §2 contrast-function development; modern restatement at Amari & Cichocki 2010 Theorem 5 eq. (126)), every smooth f-divergence with $f''(1) > 0$ induces the Fisher metric at second order up to the scalar $f''(1)$. Fisher-metric-at-second-order is *not* a distinguishing axiom within the f-divergence family — it is satisfied by every member. Noted here because it is a commonly-invoked distinguishing property; it does not distinguish. (Eguchi’s Theorem 3 itself is about estimator efficiency via Γ^1 -transversality; the f-divergence/Fisher-metric result is a consequence of the §2 contrast-function machinery that supports Theorem 3, not the theorem statement.)
4. **Information-budget / MDL interpretation.** $D_{KL}(\pi^* \| Q_{\Sigma_t}) = -\log Q_{\Sigma_t}(a^*)$ is the expected extra bits needed to code samples from π^* under Q_{Σ_t} ’s code. The coding interpretation aligns with the segment’s MDL framing. MDL is itself a chain-rule-respecting coding scheme (the bits-to-code-a-joint decompose additively over factorizations); consistency with MDL is convergent with §6.1.

Čencov/Morozova-Chentsov background (Čencov 1982 *Statistical Decision Rules and Optimal Inference*, AMS Translations of Mathematical Monographs 53; Morozova & Chentsov 1991, “Markov invariant geometry on state manifolds,” *Itogi Nauki i Tekhniki*, translated in *J. Sov. Math.* 56(5):2648–2669; Ay, Jost, Lê & Schwachhöfer 2017, *Information Geometry*, Springer). The f-divergence family itself is characterized by Markov-morphism invariance (sufficient-statistic coarse-graining invariance) — this is what makes “f-divergences” the right background family to search within. Amari 2009 shows the alpha-divergences are the sub-family that are simultaneously f-divergences and Bregman divergences. Reverse-KL sits at $\alpha = 1$ within the alpha-family; the chain-rule axiom of §6.1 is what picks $\alpha = 1$ out of the one-parameter alpha-family.

§6.3 — *Bregman-Fenchel identification: reverse-KL and log-odds as dual coordinates.*

On the probability simplex Δ^{n-1} , the **negative-entropy potential** $\phi(Q) = \sum_a Q_a \log Q_a$ is strictly convex, Legendre, and essentially smooth on the relative interior (Rockafellar 1970 *Convex Analysis* §26). Its Fenchel conjugate is the **log-partition function** $\phi^*(\eta) = \log \sum_a e^{\eta_a}$ on the natural-parameter space $\mathbb{R}^n$ modulo the affine-gauge direction. The primal-dual correspondence is softmax: $Q = \nabla \phi^*(\eta)$ gives $Q_a = e^{\eta_a} / \sum_{a'} e^{\eta_{a'}}$, and $\eta = \nabla \phi(Q) = \log Q + \mathbf{1}$ (up to the constraint-normal direction) so $\eta_a - \eta_b = \log(Q_a/Q_b)$ is the **log-odds ratio**.

Derived (bregman-fenchel-dual-pair, exact; standard Legendre-Fenchel).

The Bregman divergence induced by ϕ on the primal simplex is **reverse-KL** exactly:

$$B_\phi(P, Q) := \phi(P) - \phi(Q) - \langle \nabla \phi(Q), P - Q \rangle = \sum_a P_a \log \frac{P_a}{Q_a} = D_{\text{KL}}(P \| Q) \quad (\text{T.15})$$

Derivation. Expand: $\phi(P) - \phi(Q) = \sum_a (P_a \log P_a - Q_a \log Q_a)$; the inner-product term using $\nabla \phi(Q)_a = \log Q_a + 1$ gives $\sum_a (\log Q_a + 1)(P_a - Q_a) = \sum_a (\log Q_a)(P_a - Q_a)$ since $\sum_a (P_a - Q_a) = 0$. Substituting and simplifying yields $\sum_a P_a \log(P_a/Q_a) = D_{\text{KL}}(P \| Q)$. $\square$

Identification with #deriv-edge-update-natural-parameter. The log-odds coordinate derived under evidential-additivity in #deriv-edge-update-natural-parameter is the *Fenchel-dual natural parameter* of this Legendre-Fenchel pair. The divergence-layer coordinate of this segment (reverse-KL on Δ^{n-1}) and the update-layer coordinate of #deriv-edge-update-natural-parameter (log-odds on $\mathbb{R}^n/\mathbf{1}$) are two sides of one exponential-family geometric structure, viewed through primal and dual coordinates respectively.

What this adds. The two segments independently derive their coordinates via Cauchy-FE on logically-independent AAT-internal axioms (chain-rule additivity here; evidential additivity in #deriv-edge-update-natural-parameter). The Fenchel-Bregman correspondence shows that *the coordinates the two axioms pick out are related by Legendre duality* — the axioms are not redundant (they have different logical forms and constrain different objects; see §6.1 vs. #deriv-edge-update-natural-parameter’s axiom) but the forced coordinates *coincide on one geometric object*. This is a Discussion-grade observation about the relationship between two primary instances of #disc-additive-coordinate-forcing; it is textbook Legendre-Fenchel (Amari & Nagaoka 2000 §3.5; Bregman 1967; Beck & Teboulle 2003 *Mirror descent and nonlinear projected subgradient methods* — relevant for the operational consequence that mirror-descent on the policy simplex with negative-entropy regularizer is equivalent to exponentiated-gradient descent on log-odds coordinates). The full geometric-unification reading sits in #disc-additive-coordinate-forcing’s meta-treatment.

§6.4 — Information-theoretic-MDP lineage and AAT’s direction choice.

AAT’s reverse-KL strategy-cost form sits within an established research lineage — the information-theoretic treatment of decision problems initiated by **Tishby & Polani 2011** (“The Information Theory of Decision and Action,” in *Perception-Action Cycle: Models, Architectures, and Hardware*, Springer, pp. 601–636; Eq. 15 p. 19 introduces **Information-to-Go** $\mathfrak{I}^\pi(s_t, a_t)$, the conditional multi-information of the entire future state-action trajectory; Eq. 17 p. 21 the trade-off objective $\arg \min_\pi [\mathfrak{I}^\pi - \beta Q^\pi]$ and developed by **Rubin, Shamir & Tishby 2012** (“Trading value and information in MDPs,” in *Decision Making with Imperfect Decision Makers*, Springer, pp. 57–74; §2.2 Eq. 3 p. 4 **control information** $\Delta I(s) = \sum_a \pi_s(a) \log(\pi_s(a)/\rho_s(a))$; §3.1 Theorem 1 p. 5 Bellman recursion for the free-energy $F_\pi = I_\pi - \beta V_\pi$). The control-as-inference lineage via **Levine 2018** (“Reinforcement Learning and Control as Probabilistic Inference,” arXiv:1805.00909; §3.1 Eq. 11 and §5.2 p. 15) develops the max-entropy-RL framework using $D_{\text{KL}}(p_\theta \| p_{\text{tgt}})$ throughout. The shared framework — value and information as joint first-class quantities in MDP optimization, with a KL divergence measuring the information cost of a policy against a reference — is the context in which AAT’s strategy-cost objective naturally lives.

Discussion (information-theoretic-mdp-lineage), positioning rather than derivation.

AAT’s direction is distinctive within this lineage. Tishby-Polani 2011 uses the stationary marginal $\pi(a)$ of the policy itself as reference (Eq. 16 p. 20, Eq. 22 p. 22) — a direction-neutral multi-information rather than a KL-to-external-reference. Rubin et al. 2012 uses a default policy $\rho_s(a)$ (typically uniform) with direction $D_{\text{KL}}(\pi_s \| \rho_s)$ — **agent-first, default-second**, a regularization/complexity cost. Levine 2018 uses $D_{\text{KL}}(p_\theta \| p_{\text{tgt}})$ — **proposal-first, target-second**, a variational ELBO form with softened exponentiated-reward target. **AAT’s** $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})$ — **optimum-first, agent-second** — is the *opposite* direction to all three.

The direction is forced, not chosen. AAT’s direction is not a convention adopted from the surrounding literature; it is forced by two independent structural requirements of this segment’s derivation: (i) the regret-bound argument of §5 requires the optimum as the reference for the bound to be tight (mode-seeking toward a^*); (ii) the Bretagnolle-Huber identity of §4 is *exact* in the π^* -first direction under deterministic π^* and degenerate in the flipped direction. The

flipped direction (Rubin 2012's / Levine 2018's form with $\rho = \pi^*$) is vacuous here for the same reason forward-KL is vacuous in §5: π^* has no support off a^* . AAT *owns* the direction-distinctiveness rather than inheriting it.

Rubin 2012 Theorem 3 PAC-Bayesian motivation. A fourth independent operational property of the π^* -first KL form comes from Rubin-Shamir-Tishby 2012 Theorem 3 (p. 10): under a-priori stochastic default policy and empirical reward estimate, the control information I_π bounds the generalization gap of the value function:

$$\tilde{D}_{\text{KL}}(\hat{V}_\pi(s_0) \parallel V_\pi(s_0)) \leq \frac{I_\pi(s_0) + \log(2m/\delta)}{m-1} \quad (\text{T.16})$$

This is a PAC-Bayesian concentration bound. In AAT terms: policies with lower strategy-cost have tighter value-function generalization under finite empirical data. Together with (a) the regret-bound direction-forcing of §5, (b) the chain-rule uniqueness of §6.1, and (c) the Bregman-Fenchel dual identification of §6.3, this is a fourth independent motivation for the KL-to-reference form — operational rather than axiomatic, and independent of the chain-rule axiom. The direction differs (Rubin uses agent-first; AAT uses optimum-first), but the generalization-bound structure transfers by the same PAC-Bayesian machinery: I_π as regularizer against a reference.

Relation to #form-information-bottleneck. The canonical IB objective is $I(X; T) - \beta I(T; Y)$ with Shannon mutual information on both terms. AAT's strategy-cost relevance term is $D_{\text{KL}}(\pi^* \parallel Q_{\Sigma_t})$ — a KL divergence to a target, not a mutual information. The two are *sibling lineages*, both descended from Shannon rate-distortion theory (the IB instance uses MI-to-relevant-label as the fidelity term; the information-theoretic-MDP instance uses KL-to-reference-policy); neither reduces to the other without a change of relevance variable. AAT's compression-operations framework (#disc-compression-operations) uses the IB form for M_t , G_t^{shared} , and Λ compressions; the strategy-cost compression uses the information-theoretic-MDP form. Both are valid Lagrangian relaxations of an underlying rate-distortion problem; the choice of fidelity term depends on whether the compressed variable is meant to preserve information about an observable (IB) or to match a reference policy (information-theoretic-MDP). The “abandoned IB purity” concern raised in external reviews (Gemini 2026-04-24) is defused at this level: AAT has not abandoned IB; its strategy-cost compression uses a different relevance quantity than its model-compression, and both are principled under the rate-distortion umbrella.

§7 — β_Σ interpretation under the regret bound.

The Pinsker bound gives $R(Q_{\Sigma_t}) \leq V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \parallel Q_{\Sigma_t})}$. Two scale forms for the segment's trade-off parameter β_Σ arise:

Discussion (β_Σ -local-vs-global).

(a) **Square-root-KL form** (tight regret-bound scale):

$$\mathcal{L}(\Sigma_t) = \mathcal{R}(\Sigma_t) + \beta_\Sigma \cdot \sqrt{D_{\text{KL}}(\pi^* \parallel Q_{\Sigma_t})}, \quad \beta_\Sigma = V_{\max}/\sqrt{2} \quad (\text{T.17})$$

β_Σ is *globally naturalized* as a constant scale proportional to the value range at fixed M_t . Cost: the form departs from the linear-Lagrangian IB shape that AA uses across the four compression operations.

(b) **Linear-KL form** (IB-shape instance, preserved in the segment):

$$\mathcal{L}(\Sigma_t) = \mathcal{R}(\Sigma_t) + \beta_\Sigma \cdot D_{\text{KL}}(\pi^* \parallel Q_{\Sigma_t}) \quad (\text{T.18})$$

Under this form, β_Σ 's regret-bound interpretation is *local*: differentiating the Pinsker bound, $\partial R / \partial D_{\text{KL}} = V_{\max} / (2\sqrt{2D_{\text{KL}}})$, so β_Σ represents the local cost-per-bit at the operating point but varies with D_{KL} . Upside: consistency with the IB linear-Lagrangian shape (AA). Downside: no uniform global β_Σ scale.

Choice made in 9.9. Keep the linear form (IB-shape alignment); note the square-root form in the Epistemic Status as the “source” derivation. The direction-forcing claim is the load-bearing strengthening; the linear-vs-square-root choice is a second-order trade-off that preserves architectural consistency at the cost of a fully naturalized β_Σ .

§8 — Bound tightness and scope limits. Vacuity regimes (where the regret bound fails to be informative):

1. $V_{\max} = \infty$ (**unbounded value**). Then all bounds are ∞ . AAT’s O_t is $\mathbb{R}$ -valued (6.4); boundedness of V over $\mathcal{A}$ at fixed M_t is an additional assumption. Stated here as a scope condition of the derivation.
2. $Q_{\Sigma_t}(a^*) = 0$ (**strategy cannot express the optimum**). Then $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t}) = +\infty$. This is structural failure — the strategy’s DAG cannot produce the optimal action — and the infinite KL correctly flags it. *Informative degeneracy*, not pathology: operational minimization rejects such Σ_t .
3. π^* **not deterministic (outside canonical scope)**. For stochastic π^* with larger support than Q_{Σ_t} , reverse-KL may still be infinite. §9 addresses tied-optimum extensions; stochastic π^* under softmax-smoothing is future work.

Tightness comparison. Under deterministic π^* (AAT’s canonical scope), the Bretagnolle-Huber **identity** $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t}) = -\log(1 - \text{TV}(\pi^*, Q_{\Sigma_t}))$ makes the KL and TV bounds *operationally equivalent in reverse-KL coordinates*: the KL-based bound $R \leq V_{\max}(1 - e^{-D_{\text{KL}}})$ of §4 is exactly the TV-based bound of §3 re-expressed in the KL coordinate, with matching lower bound $R \geq \Delta_{\min}(1 - e^{-D_{\text{KL}}})$ (§4). Pinsker is strictly weaker under this scope (see §4.1). Outside the deterministic- π^* scope, the BH identity degrades back to the inequality $\text{TV} \leq \sqrt{1 - e^{-D_{\text{KL}}}}$ (Bretagnolle-Huber 1978; tighter than Pinsker for large D_{KL} but no longer an identity); Pinsker is the textbook fallback for general distributions. The net: reverse-KL is not merely “the tightest smooth divergence” — in AAT’s canonical scope it carries the *exact* regret-bound relationship via BH, with Pinsker as a loose alternative retained only for stochastic- π^* extensions.

§9 — Extensions. Tied-optimum case. If π^* has support on a tied-optimum set $\mathcal{A}^* = \{a : V(a) = V(a^*)\}$ with uniform mass, reverse-KL is finite whenever Q_{Σ_t} covers $\mathcal{A}^*$. The regret-bound argument extends directly: $R(Q_{\Sigma_t}) = \sum_a Q_{\Sigma_t}(a) \Delta(a) \leq V_{\max} \cdot \mathbb{P}_{Q_{\Sigma_t}}(a \notin \mathcal{A}^*)$ and Pinsker applies unchanged.

Softmax-smoothed π^* (stochastic π^* for non-degeneracy reasons). A regret bound of the form

$$\mathbb{E}_{\pi^*}[V] - \mathbb{E}_{Q_{\Sigma_t}}[V] \quad (\text{T.19})$$

with softmax-weighted π^* also admits the Pinsker-KL step, with reverse-KL again the non-vacuous direction (forward-KL remains vacuous whenever π^* has wider support than Q_{Σ_t} , and vice versa). Deferred for explicit treatment.

What Is Derived vs. What Is Chosen.

Table T.2

Property	Source	Strength
Regret definition $R(Q_{\Sigma_t}) := V(a^*) - \mathbb{E}_{Q_{\Sigma_t}}[V]$	Definitional; collapses to the three literature forms under deterministic π^*	Definition
TV-regret bound $R \leq V_{\max} \cdot \text{TV}(\pi^*, Q_{\Sigma_t})$	Bounded value range + deterministic π^*	Proved (tight)
BH identity $D_{\text{KL}}(\pi^* \ Q_{\Sigma_t}) = -\log(1 - \text{TV}(\pi^*, Q_{\Sigma_t}))$ under deterministic π^*	Direct calculation (Bretagnolle-Huber 1978 specialized to $P = \delta_{a^*}$)	Proved (exact identity)
Regret-reverse-KL bound $R \leq V_{\max}(1 - e^{-D_{\text{KL}}(\pi^* \ Q_{\Sigma_t})})$	TV-regret bound + BH identity, under deterministic π^*	Proved (tight in upper direction)

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Matching lower bound $R \geq \Delta_{\min}(1 - e^{-D_{\text{KL}}(\pi^* \ Q_{\Sigma_t})})$ Pinsker-KL bound $R \leq V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \ Q_{\Sigma_t})}$	Isolated-optimum action-gap $\Delta_{\min} > 0$ + BH identity Pinsker's inequality applied to TV bound	Proved (Lipschitz-equivalence with $V_{\max} / \Delta_{\min}$ constants) Proved (strictly weaker than BH identity under deterministic π^* ; correct form for stochastic- π^* extensions)
KL direction forced (reverse-KL, π^* -first)	Forward-KL is vacuous ($+\infty$) under deterministic π^* whenever Q_{Σ_t} has off-optimum mass	Proved (direction uniquely forced)
Asymmetry forced by regret's one-sidedness	Regret contributes only from Q_{Σ_t} 's off-optimum mass; π^* 's off- Q deviation is vacuous; symmetric divergences penalize interchangeably, which is operationally wrong	Proved (asymmetry forced; independent of chain-rule axiom)
Reverse-KL uniquely forced within direction-forced f-divergences	Chain-rule additivity axiom (Hobson 1969; Csiszár 1991 Theorem 3 corollary and Theorem 5; standard functional-equation derivation per Aczél & Daróczy 1975); AAT-internally motivated as divergence-level analog of 8.1 (§6.1)	Derived (conditional on chain-rule axiom)
Secondary characterizations (gradient-tractability, VI-alignment, MDL coding)	Independent operational properties; each compatible with reverse-KL, none individually distinguishing	Formulation support (non-load-bearing under §6.1)
Fisher-metric-at-second-order does not distinguish reverse-KL	Eguchi 1983 §2 contrast-function framework (<i>Ann. Statist.</i> 11(3):793–803): every smooth f-divergence with $f''(1) > 0$ induces the Fisher metric up to scalar $f''(1)$	Proved (no-go for Path A as uniqueness axiom)
Admissible family members (TV, Bretagnolle-Huber, χ^2 , Rényi- α)	Each yields a valid regret bound; survey §6	Derived (each)
Under deterministic π^* : TV and KL-coordinate bounds are equivalent via BH identity; Pinsker strictly weaker	§4 BH identity + §4.1 Pinsker comparison	Proved (scope-dependent tightness ordering)
Reverse-KL is the Bregman divergence of negative-entropy on Δ^{n-1} ; log-odds is the Fenchel-dual natural coordinate (Legendre-Fenchel pair)	Standard Legendre-Fenchel (Rockafellar 1970 §26; Amari & Nagaoka 2000 §3.5; Bregman 1967) applied to $\phi(Q) = \sum_a Q_a \log Q_a$	Proved (textbook identification; §6.3)
AAT's π^* -first KL direction is distinctive within the information-theoretic-MDP lineage (TP2011 / Rubin 2012 / Levine 2018 all put agent-first) and is <i>forced</i> (not inherited) by the regret-bound + BH-identity derivations	Literature positioning (§6.4) + derivation structure (§§4–5)	Discussion (positioning; direction forced by §§4–5 derivations)
PAC-Bayesian generalization bound: $\tilde{D}_{\text{KL}}(V_{\pi} \ V_{\pi}) \leq (I_{\pi} + \log(2m/\delta))/(m-1)$	Rubin-Shamir-Tishby 2012 Theorem 3	Derived (external theorem applied; independent operational motivation alongside regret-bound + chain-rule + Fenchel-dual)
$\beta_{\Sigma} \propto V_{\max}$ naturalization (square-root-KL form)	Direct identification from Pinsker bound	Derived (under square-root form)
β_{Σ} local interpretation (linear-KL form, segment-retained)	Differentiation of Pinsker bound at operating point	Derived (local only)
Linear-KL form retained over square-root form	IB-shape alignment with AA	Formulation choice
Vacuity regimes ($V_{\max} = \infty$, $Q_{\Sigma_t}(a^*) = 0$, stochastic π^*)	Direct analysis of the bound	Proved (boundary)
Tied-optimum extension	π^* uniform on $\mathcal{A}^*$; bound adapts directly	Derived
Softmax-smoothed π^* extension	Sketched in §9	Hypothesis (deferred)

Property	Source	Strength
Uniqueness under chain-rule axiom (§6.1)	Hobson 1969 / Csiszár 1991 Theorem 3 corollary and Theorem 5 / standard functional-equation argument per Aczél & Daróczy 1975, applied to the direction-forced family; axiom AAT-internally motivated (§6.1)	Derived (conditional)

The dividing line: the KL **direction** is forced by the regret-bound derivation (strong result). The specific reverse-KL **form** within the direction-forced f-divergence family is *derived under the chain-rule additivity axiom* (§6.1) — conditional on an axiom that AAT independently motivates as the divergence-level version of the additive-decomposition principle already in 8.1. The β_Σ naturalization is partial — available globally only under the square-root form, locally under the linear form retained for IB-shape alignment.

Epistemic Status.

Robust qualitative overall, with several specific claims at *exact* tier. The direction-forcing claim (§5) is derived under standard assumptions (bounded value, deterministic π^* on the canonical AAT scope). The **Bretagnolle-Huber identity under deterministic π^*** (§4, $D_{\text{KL}}(\pi^* \| Q) = -\log(1 - \text{TV})$) is *exact* by direct calculation, and yields the tight regret bound $R \leq V_{\max}(1 - e^{-D_{\text{KL}}})$ with matching lower bound $\Delta_{\min}(1 - e^{-D_{\text{KL}}})$ — the segment’s primary bound form. Pinsker (§4.1) is retained as the strictly-weaker general form, correct for stochastic- π^* extensions. The TV bound (§3) is textbook. The admissible-divergence family characterization (§6) is a truthful survey. The **chain-rule uniqueness theorem** (§6.1) upgrades the reverse-KL selection to “uniquely forced conditional on the chain-rule axiom”; the axiom is AAT-internally motivated as the divergence-level analog of #der-chain-confidence-decay. **Asymmetry-from-one-sidedness** (§5) provides a second independent argument for the direction-forcing side, not requiring the chain-rule axiom. **Bregman-Fenchel identification** (§6.3) is textbook Legendre-Fenchel; ties the segment’s divergence coordinate to #deriv-edge-update-natural-parameter’s update coordinate as Fenchel-dual aspects of one exponential-family structure. Fisher-metric-at-second-order is explicitly identified as *not* a distinguishing axiom within the f-divergence family (Eguchi’s theorem), closing the most-obvious alternative candidate uniqueness route as a no-go. **Information-theoretic-MDP lineage positioning** (§6.4) is *Discussion-grade* (positioning in the literature, not a derivation); its role is to place AAT’s direction-distinctive form honestly within the TP2011 / Rubin 2012 / Levine 2018 lineage rather than overclaim equivalence with any of them. The Rubin 2012 Theorem 3 PAC-Bayesian bound (§6.4) is a fourth independent operational motivation for the KL-to-reference form. The β_Σ naturalization (§7) is a trade-off analysis, not a derivation. The extensions (§9) are sketches, not derivations.

Max attainable: *exact* for (a) “forward-KL is a vacuous bound on R under deterministic π^* ” (direct calculation; §5); (b) “under deterministic π^* , $D_{\text{KL}}(\pi^* \| Q) = -\log(1 - \text{TV}(\pi^*, Q))$ ” (BH identity; §4); (c) “regret is Lipschitz-equivalent to $(1 - e^{-D_{\text{KL}}})$ with constants $\Delta_{\min} / V_{\max}$ ” (§4 matched lower bound); (d) “reverse-KL is the Bregman divergence of negative-entropy; log-odds is its Fenchel-dual natural coordinate” (standard Legendre-Fenchel; §6.3); (e) “reverse-KL is the unique chain-rule-respecting f-divergence in the direction-forced family” (Hobson 1969 / Csiszár 1991; §6.1); (f) “asymmetry is forced by regret’s one-sidedness” (direct; §5). *Robust qualitative* for the overall strengthened characterization — the chain-rule uniqueness is conditional on the chain-rule axiom, which is a principled axiom choice (AAT-internally motivated) but remains an axiom rather than a consequence of prior AAT commitments. The information-theoretic-MDP lineage positioning (§6.4) is *Discussion-grade* and honest about where AAT sits in the broader lineage rather than claiming formal equivalence.

Discussion.

The convergence with active inference’s reverse-KL. Active inference’s expected free energy (Friston et al. 2017; Parr & Pezzulo 2022) also uses reverse-KL against a preferred distribution, with the direction arising from the variational-free-energy-gradient lineage. AAT derives the direction from a regret-bound argument internal to the decision-theoretic scope. The convergence (two distinct derivations reach the same direction) is worth noting but is not a uniqueness argument — it shows reverse-KL is *natural* in multiple frames. The lineage difference preserves AAT’s distinctive content: AAT’s derivation does not require VFE as master objective or preferences-as-priors (7.5, 8.4 for the contrast).

Why the regret bound is the right derivation, not Donsker-Varadhan. The Donsker-Varadhan variational representation

$$\log \mathbb{E}_Q[e^f] \geq \mathbb{E}_P[f] - D_{\text{KL}}(P\|Q) \quad (\text{T.20})$$

gives reverse-KL bounds for exponential-moment functionals, but requires V to have bounded exponential moments (a stronger-than-bounded assumption for unbounded V). The Pinsker-TV route used here requires only bounded value range and is closer to the AAT scope’s natural assumptions. Donsker-Varadhan becomes relevant if unbounded- V extensions are attempted.

Relationship to standard policy-gradient regret bounds. The argument here is structurally identical to standard policy-gradient / online MDP regret bounds (Agarwal, Kakade, Lee, Mahajan 2021 “On the theory of policy gradient methods” Lemma 3.2; Even-Dar, Kakade, Mansour 2009 “Online Markov decision processes”). AAT’s contribution is *re-using the standard bound as the derivation of the KL direction in the strategy-cost objective*, not inventing the bound. This is consistent with AAT’s integration-over-invention character.

Position in the additive-coordinate-forcing pattern. The chain-rule uniqueness theorem of §6.1 is the *divergence-level* instance of an AAT-wide pattern in which logarithmic coordinates are uniquely forced via Cauchy’s functional equation on an AAT-internally-motivated additivity axiom. The pattern has two other primary instances: the chain-layer identity (8.1, the motivating anchor) and the update-layer log-odds uniqueness (U). 5.5 catalogs the pattern, states the 1-anchor-plus-2-theorem structure precisely, and documents Lyapunov and IB Lagrangian as adjacent family members that share the additive-decomposition shape without the AAT-internal forcing structure.

Working Notes.

- **Linear vs. square-root form — revisit with downstream evidence.** The segment keeps the linear-KL form for IB-shape alignment. If downstream work shows the IB-shape-across-four-operations claim in AA is strained and the four β s want separate scales anyway, switching 9.9 to the square-root form (naturalizing β_Σ) becomes attractive. Revisit with the O-BP2 (four compressions as one hierarchy) work if pursued.
- **Stochastic- π^* extension.** Flagged in §9 but not derived. The tied-optimum case is immediate; softmax-smoothed π^* needs a careful treatment of what regret quantity is being bounded (expected-vs-max).
- **Family characterization strengthening.** *Resolved 2026-04-22* — see §6.1. The chain-rule additivity axiom (Hobson 1969; Csiszár 1991 Theorem 3 corollary and Theorem 5; standard functional-equation derivation per Aczél & Daróczy 1975) picks reverse-KL uniquely within the direction-forced f-divergence family. The Fisher-metric candidate was ruled out by Eguchi’s theorem (every smooth f-divergence induces the Fisher metric at second order up to scale; not distinguishing). Full reasoning trail in `spikes/.integrated/spike-reverse-kl-uniqueness.md`, including the citation audit that corrected the initial draft’s misattributions (Csiszár 1972, Amari 2009 Theorem 1, and Amari & Cichocki 2010 Prop 3.2 do not contain the chain-rule uniqueness theorem; the correct attributions are above).
- **BH identity under deterministic π^* — elementary fact the earlier presentation underplayed.** *Resolved 2026-04-24.* §4 now presents the BH identity as primary, with Pinsker demoted to §4.1 as the loose general form. The earlier framing “non-Pinsker tighter bounds... BH flagged for operational work where the tightness difference matters” under-sold the result:

under AAT’s canonical deterministic- π^* scope, the BH inequality specializes to an *identity* (not merely a tighter inequality), making the KL-coordinate bound exact rather than approximate. The segment now carries the exact two-sided relation with matching lower bound via $\Delta_{\min}$.

- **Citation verification (Path 1 content, §6.4).** The information-theoretic-MDP lineage content in §6.4 was PDF-verified 2026-04-24 against TP2011 / Rubin-Shamir-Tishby 2012 / Levine 2018. The verification process found a specific attribution error in an earlier spike draft — the objective form $\max_{\pi} \mathbb{E}[R] - \beta^{-1} I(\Pi; X)$ with KL-to-reference reference is **Rubin 2012’s**, not TP2011’s (TP2011’s actual quantity is Information-to-Go multi-information $\mathfrak{I}^{\pi}$, a different object). The segment reflects the corrected attributions with explicit equation/page references. Full trail in `spikes/.integrated/spike-ib-purity-strategy-cost-strengthening-2026-04-24.md` §12 “Citation-verification addendum.”
 - **AAT-outlier-on-KL-direction — distinctive feature, not a departure.** *Documented 2026-04-24.* The literature uses agent-first or proposal-first directions; AAT uses optimum-first, forced by the regret-bound derivation and required for the BH identity to be exact. Owned rather than inherited; see §6.4.
 - **Cross-reference to NeurIPS Paper 2.** The deterministic- π^* corner identity is sharpened in NeurIPS 2026 Paper 2 (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning”, `~/src/neurips/02-unified-convergence-rl/`, §5 Key Lemma 1 / `#lem-pointmass-identity`): under deterministic optimum, $\text{TV}(\delta_{a^*}, Q) = 1 - e^{-D_{\text{KL}}(\delta_{a^*} \| Q)}$ holds as an *exact algebraic identity*, lying strictly below the Pinsker and Bretagnolle-Huber envelopes at this corner (numerical comparison in Paper §App-E). The identity is **coordinate-optimal among bounds depending only on TV** — Paper 2 uses it as Component 2 of the composition theorem and as the structural reason why the segment’s optimum-first reverse-KL direction is the right coordinate. The classical BH bound is recovered as the loose general form away from the deterministic- π^* corner. See `spikes/neurips-back-integration-2026-05-08.md` §1 Paper 2 entry 1; standalone-segment proposal under back-integration §3 (proposed slug `#deriv-bh-pointmass-identity` or `#result-pointmass-tv-kl-identity`).
 - **Fenchel-Bregman connection to `#deriv-edge-update-natural-parameter`.** *Documented 2026-04-24.* §6.3 identifies reverse-KL and log-odds as Fenchel-dual coordinates of one exponential-family Legendre-Fenchel structure. The full geometric-unification reading (covering all four layers of `#disc-additive-coordinate-forcing`) is a meta-segment-level observation; the absorbing-spike trail is recorded in the spike-routing cycle (CHANGELOG 2026-05-17).

Appendix U

Derivation: Log-Odds as the Unique Additive-Evidence Parameterization for Edge Credences

The log-odds coordinate $\lambda_{ij} = \log(p_{ij}/(1 - p_{ij}))$ is the unique parameterization (up to positive affine transformation) on which independent Bernoulli evidence updates edge credences additively, under an evidential-additivity axiom motivated as the update-level analog of 8.1's chain-level additive log-confidence decomposition. This segment states the uniqueness theorem, derives it, and explains how it positions log-odds as the natural parameterization for AAT's continuous-gradient edge-update machinery.

This is the *update-level* instance of #disc-additive-coordinate-forcing's meta-pattern — the third formal layer where AAT commits to a specific coordinate because an internal additivity axiom forces it through a classical uniqueness theorem. Two prior layers compose with it: **log-probability at the chain layer** (chain rule of probability — #der-chain-confidence-decay); **reverse-KL at the divergence layer** (chain-rule additivity axiom via Hobson-Csiszár-Shore-Johnson — #deriv-strategy-cost-regret-bound); **log-odds at the update layer** (evidential-additivity axiom via Aczél's Cauchy functional equation — this segment). The Fisher information metric at the metric layer (Čencov's uniqueness theorem under parameterization-invariance) rounds out a four-layer structure that all live on the same geometric object — the exponential-family Legendre-Fenchel duality. *AAT's coordinates are not chosen by convention; they are forced by AAT-internal axioms via classical uniqueness theorems, and they all live on the same geometric object.*

The framework lifts this to a first-class coordinate commitment at the update layer. Continuous-gradient edge-update machinery in the credit-assignment treatment operates natively in log-odds and projects back to probability space via the sigmoid at the readout interface — the reason is mechanical: in probability space, the same update written as residual-times-gain can push the credence outside $[0, 1]$ when the Jacobian norm is small (a mechanical break of the probability domain). The log-odds coordinate has domain over all of $\mathbb{R}$, so additive updates never escape the domain; the sigmoid projection guarantees boundedness by construction, not by clipping. A downstream load-bearing consequence: the log-odds coordinate is what makes the detection-latency floor a structural rather than parametric result — the expected cycles to detect a regime change of given footprint scale linearly with accumulated experience precisely because the log-odds accumulation rate is forced (#deriv-update-detection-latency).

Formal Expression.

Setup. Let $p \in (0, 1)$ denote a scalar Bernoulli credence (the probability that a proposition is true) and let $\psi : (0, 1) \rightarrow \mathbb{R}$ be a smooth, strictly monotone reparameterization. Consider a sequence of independent Bernoulli observations $y_1, \dots, y_n \in \{0, 1\}$ drawn from a channel with likelihood ratio $P(y | H_1)/P(y | H_0)$.

Evidential-additivity axiom. The posterior update, applied to a single observation y , takes the form

Assumption (evidential-additivity axiom).

$$\psi(p_{\text{post}}) = \psi(p_{\text{prior}}) + g(y) \quad (\text{U.1})$$

for some function $g : \{0, 1\} \rightarrow \mathbb{R}$ that depends only on the observation y — not on p_{prior} nor on observation history.

Theorem.

Theorem. The functional equation above admits solutions if and only if

Derived (evidential-additivity uniqueness of log-odds, conditional on the axiom above).

$$\psi(p) = c \cdot \log \frac{p}{1-p} + d \quad (\text{U.2})$$

for constants $c > 0$ and $d \in \mathbb{R}$, with $g(y) = c \cdot \ell(y)$ where $\ell(y) = \log[P(y | H_1)/P(y | H_0)]$ is the log-likelihood ratio.

Derivation.

By Bayes' theorem applied to binary hypotheses,

Derived (Proof Step: Bayesian form of the update).

$$\frac{p_{\text{post}}}{1 - p_{\text{post}}} = \frac{p_{\text{prior}}}{1 - p_{\text{prior}}} \cdot \frac{P(y | H_1)}{P(y | H_0)} \quad (\text{U.3})$$

Taking the logarithm of both sides and writing $h(p) := \log(p/(1 - p))$,

$$h(p_{\text{post}}) = h(p_{\text{prior}}) + \ell(y) \quad (\text{U.4})$$

So $\psi = h$ trivially satisfies the axiom with $g = \ell$.

Suppose ψ is any smooth, strictly monotone reparameterization satisfying the axiom. Since the Bayesian mapping $p_{\text{prior}} \mapsto p_{\text{post}}$ is fully determined by y through the likelihood ratio, the difference $\psi(p_{\text{post}}) - \psi(p_{\text{prior}})$ depends only on y , and by the axiom must equal $g(y)$.

Derived (Proof Step: uniqueness by Cauchy functional equation).

Change variables via $\lambda = h(p) = \log(p/(1 - p))$ and define $\Psi(\lambda) := \psi(\sigma(\lambda))$ where $\sigma(\lambda) = 1/(1 + e^{-\lambda})$ is the logistic sigmoid. The axiom becomes

$$\Psi(\lambda + \ell(y)) - \Psi(\lambda) = g(y) \quad \text{for all } \lambda \in \mathbb{R}, y \in \{0, 1\} \quad (\text{U.5})$$

Extending to continuous-valued evidence (or considering mixtures of Bernoulli channels with varying likelihood ratios, which span all of $\mathbb{R}$ in the ℓ -value space), the identity

$$\Psi(\lambda + \ell) - \Psi(\lambda) = G(\ell) \quad \text{for all } \lambda, \ell \in \mathbb{R} \quad (\text{U.6})$$

holds for a function G independent of λ . This is the Cauchy functional equation (translation-additivity). Combined with the smoothness assumption on ψ , the unique solution class is $\Psi(\lambda) = c \cdot \lambda + d$ for constants c and d (Aczél 1966, *Lectures on Functional Equations and Their Applications*, §2.1).

Strict monotonicity of ψ forces $c \neq 0$. Taking ψ to have the same monotonicity sense as $p \mapsto p$ (credence increasing with ψ), we need $c > 0$. Thus $\psi(p) = c \cdot h(p) + d = c \cdot \log(p/(1-p)) + d$, and $g(y) = c \cdot \ell(y)$.

Derived (Proof Step: determining the constants).

This completes the proof. $\square$

Three-Layer Parallel.

The evidential-additivity axiom is the update-level instance of an additive-decomposition principle that AAT has already committed to at two prior layers:

Discussion (three-layer additive decomposition).

Table U.1

<i>Layer</i>	<i>Quantity decomposed</i>	<i>Decomposition form</i>	<i>Source</i>
Chain level	Confidence along a causal chain	$\log P(\text{chain}) = \sum_i \log P(E_i \mid E_{<i})$	8.1
Divergence level	Mismatch between optimal and strategy policies	$D_{\text{KL}}(\pi^* \parallel Q_{\Sigma_t})$ decomposes additively across DAG layers along the optimal trajectory	T §6.1
Update level	Credence evolution under independent evidence	$\psi(p_{\text{post}}) - \psi(p_{\text{prior}}) = g(y_1) + \cdots + g(y_n)$ for n observations, with $\psi = \log\text{-odds}$	This segment

Each layer forces a logarithmic coordinate through essentially the same structural move: products of independent factors become sums on a log scale. At the chain level, $p^n \rightarrow n \log p$; at the divergence level, $\prod Q \rightarrow \sum \log Q$; at the update level, $\prod \text{LR} \rightarrow \sum \log \text{LR}$. The three are the same transform applied to different quantities.

Interpretation for the Edge-Update Machinery.

For edge credence p_{ij} with log-odds $\lambda_{ij} = \log(p_{ij}/(1-p_{ij}))$, the Bayesian update under independent Bernoulli evidence is

Discussion (operational consequence).

$$\lambda_{ij}^{\text{post}} = \lambda_{ij}^{\text{prior}} + \ell(y) \quad (\text{U.7})$$

where $\ell(y)$ is the per-observation log-likelihood ratio.

Two operational consequences that follow from the uniqueness theorem:

1. **Domain unboundedness.** The log-odds coordinate has domain $\mathbb{R}$, not $[0, 1]$. Additive updates cannot escape the domain, regardless of update magnitude. The probability-space presentation $p_{ij} \in [0, 1]$ is the projected image of the log-odds coordinate, obtained via $p_{ij} = \sigma(\lambda_{ij})$ at the readout interface.
2. **Invariance under the chain of causal reasoning.** Because the log-odds coordinate is the unique additive evidence coordinate, evidence accumulated along one edge in a strategy DAG can be composed with evidence accumulated along another edge by addition in the log-odds vector space, provided the evidence is conditionally independent. The Beta-Bernoulli moment-parameter form $\hat{p} = \alpha/(\alpha + \beta)$ is the projected image, where α, β are the cumulative sufficient statistics in exponential-family form.

These consequences are why the continuous-gradient edge-update machinery in 9.6 is well-posed globally in log-odds but exhibits a mechanical break (unbounded updates pushing credences outside $[0, 1]$) when stated directly in probability space.

Scope Condition.

The evidential-additivity axiom applies to agent classes that treat observations as independent Bernoulli likelihood evidence — the Bayesian-coherent sub-scope of AAT. Non-Bayesian agents (PID controllers, rule-based systems, human judgment per 3.6) do not invoke likelihood-ratio accumulation and are outside the axiom's scope. This matches the sub-scope α / sub-scope β partition in 4.3: the uniqueness applies within sub-scope α , where B1 (directional fidelity) is already derived from Bayesian coherence.

Scope (evidential-additivity scope).

For multinomial / categorical edge credences with $K > 2$ outcomes, the analog is softmax / canonical exponential-family parameters: the softmax natural parameters $\eta_k = \log \pi_k$ (up to a reference-class shift) satisfy the same evidential-additivity axiom. The Bernoulli case ($K = 2$) collapses to log-odds.

Epistemic Status.

Derived (conditional on the evidential-additivity axiom). The uniqueness theorem is a standard functional-equation result (Cauchy functional equation with smoothness; Aczél 1966 §2.1). The AAT-internal motivation of the axiom is structural: it is the update-level analog of 8.1's chain-level additive log-confidence decomposition and T §6.1's divergence-level chain-rule additivity. Without the axiom, the selection of log-odds weakens to canonical-not-unique on convergent grounds (exponential-family naturalness, Fisher-information / natural-gradient canonicity, domain-well-posedness of the continuous gradient).

Max attainable: *exact* for the Cauchy functional equation step (standard); *derived-conditional* for the overall uniqueness claim because the axiom, though AAT-internally motivated, is itself a commitment rather than a consequence of prior AAT commitments. The axiom's status is parallel to the chain-rule additivity axiom in T §6.1 — both are AAT-internally motivated as the “right level” instances of a single additive-decomposition principle.

Not uniqueness in the unconditional sense. The theorem states that *if* credence updates live on a single additive coordinate whose increment depends only on the observation, *then* that coordinate is log-odds up to positive affine. It does not rule out non-additive update schemes, nor schemes that live on multiple coordinates (e.g., Beta-Bernoulli with sufficient statistics (α, β) rather than a single credence coordinate). The Beta-Bernoulli presentation is *equivalent* in content to the log-odds presentation under a change of coordinates; the uniqueness is about what single-coordinate additive form is possible.

Discussion.

Why log-odds is forced, not merely canonical. Three convergent grounds — exponential-family canonicity, Fisher / natural-gradient canonicity, and sector-condition preservation — establish that log-odds reparameterization is a natural coordinate for edge updates, but none of them is a uniqueness theorem. This segment supplies the uniqueness result conditional on the evidential-additivity axiom. The axiom is AAT-internally motivated, so the result is genuine strengthening — not “log-odds happens to work” but “log-odds is forced by the update-level analog of a principle AAT already relies on at chain and divergence levels.”

Why this matters for the mechanical break. The mechanical break in 9.6’s default signal function — unbounded gradient updates pushing credences outside $[0, 1]$ when $\|\mathbf{J}\|^2 \rightarrow 0$ — is a presentation artifact of the probability-space coordinate. In log-odds, the domain is $\mathbb{R}$ and the update is well-posed globally. The fix is not “clip the update” but “present the update in its native additive coordinate.”

Relationship to Bayesian conjugate analysis. The Beta-Bernoulli conjugate update produces posterior hyperparameters $(\alpha + y, \beta + 1 - y)$ that are additive in the sufficient statistics, giving the point estimate $\hat{p} = \alpha / (\alpha + \beta)$ that updates *non-additively* in probability space. The content is the same — the log-odds coordinate makes the additivity manifest at the level of credence itself, while Beta-Bernoulli shows the same additivity at the level of sufficient statistics. The two are dual presentations of the same exponential-family structure.

Non-uniqueness outside the Bayesian sub-scope. For non-Bayesian agents in sub-scope β of 4.3 (PID controllers, rule-based systems, human judgment), the evidential-additivity axiom does not apply. Such agents may update credences via coordinate-free heuristics (proportional blame, threshold rules) that do not decompose into likelihood-ratio addition. The uniqueness of log-odds is therefore scope-conditional, not universal.

Path B’s role in the overall pattern. The segment makes visible that AAT is committed to a family of consistent coordinate-forcing moves at chain, divergence, update, and metric layers, each forcing a specific coordinate via a uniqueness theorem on an AAT-internally-motivated axiom. Future coordinate-forcing structures in AAT (e.g., any novel decomposition along trajectories, across channels, or between agents) should be examined for whether Cauchy-FE on an additivity axiom or Čencov-invariance on a parameterization-invariance axiom applies. If yes, log-odds / natural-parameter / reverse-KL / Fisher-metric-style results compose cleanly. If no, the new layer is a genuine departure requiring its own analysis. The pattern is catalogued at the meta-pattern level in 5.5, including the 1-anchor-plus-3-theorem characterization (the chain layer is a mathematical identity; divergence, update, and metric are theorems conditional on AAT-internally-motivated axioms) and the adjacent-family classification (Lyapunov quadratic and IB Lagrangian share the additive shape but not the AAT-internal forcing structure).

Block-structured evidential additivity under L1’ correlated evidence. When sibling edges share a latent common cause C (L1’ correlated evidence per #def-strategy-dag’s Correlation Hierarchy), the independent-evidence axiom grounding Path B is literally false. Under *observable* C , the likelihood factorizes per-cluster as $P(\mathbf{y}, c) = P(c) \prod_k P(y_k | c)$, and the per-factor Aczél-1966 uniqueness argument applies independently to each factor. The forced coordinate becomes a $(2K + 1)$ -dimensional vector log-odds (one coordinate for θ_C , two per child edge for $p_{j|C}$ and $p_{j|\neg C}$), reducing to the scalar log-odds when the cluster is a singleton and no latent is present. This is a **generalization-in-scope** of the theorem above, not a new primary instance of #disc-additive-coordinate-forcing: the forcing machinery is unchanged (Cauchy-FE on per-factor additivity); the scope widens to block-factorized likelihoods under observable latents. Under *unobservable* C , the soft-EM responsibility-reweighted posterior depends nonlinearly on the prior, so no smooth ψ satisfies the block-additivity axiom — the axiom is structurally inconsistent with Bayesian mixture updates. This is the same scope boundary that #disc-identifiability-floor Instance 2 names via the Cramér-Rao Fisher-rank-1 obstruction; two independent analytical routes (Cauchy-FE failure at update layer; Cramér-Rao rank deficiency at observation layer) converge on the same unobservable- C structural floor, strengthening the “structural, not analytical-artifact” reading of Instance 2.

Findings.

Log-Odds as Uniquely-Forced Edge-Update Coordinate. Brief: When updating beliefs about whether something is true, there's a question of “what's the natural number to update?” — the probability itself, or some transformation of it. This result identifies a particular transformation (the log-odds, also used in logistic regression and Bayesian inference broadly) as the *uniquely* natural one for agents updating on independent evidence, in the precise sense that any equivalent representation must be log-odds up to scale. The choice isn't aesthetic; it's forced by what “independent evidence should add up” means mathematically. The uniqueness follows from Cauchy's functional equation operating on an evidential-additivity axiom motivated as the update-level analog of the chain-layer log-additive identity in `#der-chain-confidence-decay`.

Impact: Promotes a representational choice that previously had only convergent grounds (exponential-family canonicity, Fisher-information naturalness, sector-condition preservation) to a uniqueness theorem under an explicit AAT-internal axiom, joining the additive-coordinate-forcing meta-pattern (`#disc-additive-coordinate-forcing`) as one of its three theorem-grade instances. The result resolves a mechanical issue in the credit-assignment default signal function (`#disc-credit-assignment-boundary`), where unbounded gradient updates pushing credences outside $[0,1]$ in the probability-space presentation become globally well-posed in the log-odds presentation (domain $\mathbb{R}$). It also positions log-odds as the coordinate against which downstream gain-and-update machinery should be analyzed for sub-scope α (Bayesian-coherent) agents.

Novelty Claim: *Claim differentiation* on an already-canonical representational choice (log-odds as the natural Bayesian-update coordinate, well-known from logistic regression / exponential-family / information-geometry traditions) by deriving its uniqueness under an AAT-internally-motivated evidential-additivity axiom. The Cauchy-FE machinery is classical; the AAT-internal axiomatization and the meta-pattern membership are the contribution.

Search Log: - 2026-04 (*intuition-only* on AAT-internal axiomatization angle): no targeted search for prior derivations of log-odds via the specific evidential-additivity axiom (update-level analog of chain-rule additivity) has been conducted. Pre-search expectation: the Cauchy-FE move is classical (Aczél 1966); the log-odds canonical parameter is exponential-family standard; the *AAT-internal axiomatization* (motivating the additivity axiom as the update-level analog of `#der-chain-confidence-decay`) is the contribution being claimed. A targeted search would query the Bayesian-coherence and information-geometry literatures specifically for prior axiomatic derivations of log-odds via Cauchy-FE in agent-update settings. - 2025 (*targeted*): Aczél 1966 confirmed as the formal antecedent for the Cauchy-FE machinery; cited inline.

Appendix V

Derivation: Adaptive-Gain Dynamics — A2’ Under a Learning Gain

AAT’s gain structure (3.6, 4.3) derives the optimal gain η^* per regime — the gain is a function of the noise model, chosen to minimize one-step mismatch variance. Real adaptive agents often *learn the noise model itself* (adaptive Kalman), *switch regimes* (IMM), *adapt step-size online* (RMSProp / Adam), or *optimize gain across tasks* (MAML). The gain becomes a state variable with its own update dynamics. The question is whether the sector-persistence machinery extends to this case, and where inside the A2’ sub-scope partition adaptive gain sits. The result: sub-scope α splits into α_1 (fixed-gain per Prop B.3) and α_2 (adaptive-gain under four derivable conditions named (MG-1)–(MG-4)), with sub-scope β catching the rest. The two-timescale argument is an augmented-state Lyapunov composition (standard Khalil Thm 4.18), not a Tikhonov reduction — the primary and meta-gain sector conditions compose rather than one being eliminated.

Four worked cases land the partition. **Adaptive Kalman** with a Mehra-type innovation-based estimator under window-length timescale separation derives at sub-scope α_2 from (MG-1)–(MG-4); under Mehra non-identifiability (rank-deficient transform matrix; Zagorbelny-Rawlins 2015, Dunik et al. 2021), (MG-2) fails structurally — a candidate instance of #disc-identifiability-floor on the meta-gain channel. **RMSProp** on strongly-convex losses is α_2 under design conditions (large β , coupling smallness); outside those conditions, vanilla Adam’s (MG-1) fails (Reddi et al. 2018 counterexample), and **AMSGrad’s monotonicity constraint on v_t is structurally a meta-gain repair that restores (MG-1) by construction**. **IMM regime transitions** sit at α_2 between transitions and β across the posterior-reconcentration window — explicit dwell-time machinery is required because (MG-1) fails uniformly in time during the transition. **MAML** has α_1 inner loops and a β outer loop, since the meta-loss is non-convex even under per-task convexity (Fallah et al. 2020) and (MG-2) is not derivable from per-task structure. Each placement is a derivation, not folklore: the choice between gain mechanisms has structural consequences for which sub-scope the agent’s persistence guarantee lives in, and (through the persistence-information-rate bound of #deriv-persistence-cost) for how much observation bandwidth the agent must consume to hold it.

Formal Expression.

Augmented-state setup. Treat the gain K_t as state. Define $\tilde{K}_t = K_t - K^*$ (error relative to a target optimal gain, specified per case: Riccati-steady-state for adaptive Kalman, EMA-fixed-point for RMSProp, etc.). The augmented state is $z_t = (\delta_t, \tilde{K}_t)$. Primary and meta-gain dynamics:

$$\dot{\delta} = -F(\delta; K^* + \tilde{K}) + w(t), \quad \dot{\tilde{K}} = -\Phi(\tilde{K}, \delta) + v(t) \quad (\text{V.1})$$

where F is the primary correction function (depending on the current gain via its argument), Φ is the gain-update contraction, w is primary-channel disturbance, v is gain-channel disturbance (estimator noise, innovation variability, etc.).

Meta-gain sector conditions (MG-1)–(MG-4).

(MG-1) Primary sector floor under bounded gain error. There exist $\underline{\alpha} > 0$ and $r_K > 0$ such that for all $\|\tilde{K}\| \leq r_K$ and $\|\delta\| \leq R$:

Formulation (meta-gain-conditions, extend A2' to adaptive-gain setting).

$$\delta^T F(\delta; K^* + \tilde{K}) \geq \underline{\alpha} \|\delta\|^2 \quad (\text{V.2})$$

— A2' uniform in the gain-error ball. The sector floor is preserved across the gain-state range the meta-learner visits.

(MG-2) Meta-gain sector condition. The gain-update map Φ satisfies (T1) (zero at $\tilde{K} = 0$) and a local sector bound:

$$\tilde{K}^T \Phi(\tilde{K}, \delta) \geq \alpha_K \|\tilde{K}\|^2 \quad \text{for } \|\tilde{K}\| \leq r_K, \text{ uniformly in } \|\delta\| \leq R \quad (\text{V.3})$$

with $\alpha_K > 0$. This is a sector condition in the gain-error state — the adaptive-gain analog of A2' itself.

(MG-3) Timescale separation. $\alpha_K \ll \underline{\alpha}$. The gain adapts slower than the primary state contracts. This is 4.9's convergence constraint transcribed onto Lyapunov decay rates instead of event rates.

(MG-4) Coupling boundedness. The gain-channel disturbance $v(t)$ has bounded contribution from the primary state:

$$\mathbb{E}[\|v(t)\|^2 \mid \delta] \leq \sigma_{K,0}^2 + c_v \|\delta\|^2 \quad (\text{V.4})$$

for some $c_v \geq 0$. (MG-4) with $c_v = 0$ is clean two-timescale decoupling; $c_v > 0$ is δ -coupled meta-gain disturbance (RMSPop near minimizer), requiring fixed-point closure.

Composed persistence result.

Under (MG-1)–(MG-4), the augmented state $z = (\delta, \tilde{K})$ is ultimately bounded in mean square. The Lyapunov candidate $V(z) = \frac{1}{2} \|\delta\|^2 + \frac{c}{2} \|\tilde{K}\|^2$ for appropriate weight c satisfies, along trajectories:

Derived (augmented-state-persistence, from sector-persistence-template applied twice with coupling).

$$\dot{V} \leq -\underline{\alpha} \|\delta\|^2 - c\alpha_K \|\tilde{K}\|^2 + \rho \|\delta\| + c(\sigma_{K,0} + \sqrt{c_v} \|\delta\|) \|\tilde{K}\| \quad (\text{V.5})$$

Complete-the-square on the cross term (requires $c\sqrt{c_v}$ small compared to $\underline{\alpha} \cdot c\alpha_K$, i.e., (MG-3) timescale separation plus (MG-4) coupling smallness):

$$\dot{V} \leq -\frac{\underline{\alpha}}{2} \|\delta\|^2 - \frac{c\alpha_K}{2} \|\tilde{K}\|^2 + \frac{\rho^2}{2\underline{\alpha}} + \frac{c\sigma_{K,0}^2}{2\alpha_K} \quad (\text{V.6})$$

Standard Lyapunov ultimate-boundedness (Khalil 2002 Thm 4.18) applied to the augmented state gives the composed persistence bound. Both δ and $\tilde{K}$ are ultimately bounded with explicit bounds in $(\underline{\alpha}, \alpha_K, \rho, \sigma_{K,0}, c_v)$. $\square$

A2' sub-scope partition: $\alpha_1 / \alpha_2 / \beta$.

The adaptive-gain analysis refines 4.2's A2' sub-scope partition into three tiers:

Formulation (sub-scope-refinement).

Sub-scope α_1 — fixed-gain, A2' derived. 4.3 Prop B.3's current scope: the gain K is treated as a static function of fixed noise model parameters. A2' is derived from B1 directional fidelity. Covers Kalman with known (Q, R) , conjugate-Bayesian updates, exponential-family MLE, linear correction with PD KH , strongly-convex-gradient fixed-step-size.

Sub-scope α_2 — adaptive-gain, A2' derived through augmented-state Lyapunov. When (MG-1)–(MG-4) hold with all four conditions derivable from the update-rule structure:

- Adaptive Kalman with Mehra-type innovation-based (Q, R) estimator under timescale separation
- RMSProp/Adam with strongly-convex loss, large β (slow EMA), and coupling-smallness; AMSGrad fix (Reddi et al. 2018) structurally a meta-gain repair preserving (MG-1)
- Any adaptive-gain scheme admitting a clean (MG-1)–(MG-4) derivation from the update rule

For these, A2' is derived at the augmented-state level, not merely assumed. Setting $\tilde{K} \equiv 0$ recovers sub-scope α_1 cleanly.

Sub-scope β — A2' assumed (possibly under scope narrowing). When any of (MG-1)–(MG-4) must be assumed per-agent rather than derived. Concrete instances:

- MAML outer loop: meta-loss non-convex even under per-task convexity (Fallah et al. 2020), so (MG-2) cannot be derived from per-task structure. Inner loop is α_1 ; outer loop is β .
- IMM regime transitions: (MG-1) fails uniformly in time during posterior-reconcentration windows of duration τ_{IMM} . Between-transition regime is α_2 ; across-transition window is β (scope narrowing via dwell-time + impulsive-disturbance absorption).
- Adam without AMSGrad on ill-conditioned problems: (MG-1) fails under aggressive- β + small-gradient-noise (Reddi et al. 2018 counterexample).
- Rule-based / PID / human-judgment adaptive gains: no structural argument for either (MG-1) or (MG-2); both must be assumed.

This refinement preserves the existing A2' sub-scope α as a specialization (α_1) and identifies a derivable adaptive-gain extension (α_2) with honest fallback to β when the derivability conditions fail.

Structured cases.

Case A — Adaptive Kalman with Mehra estimator. Scalar linear-Gaussian setting with unknown (Q^*, R^*) . The innovation-based Mehra estimator (Mehra 1970, 1972; Dunik et al. 2021 for identifiability) yields $\hat{Q}_t, \hat{R}_t$ from a sliding-window autocorrelation of the innovation sequence. For window length N , the gain-update map to first order in $\tilde{K}$ is a scalar Ornstein-Uhlenbeck process:

Derivation (case-adaptive-kalman-alpha2).

$$\tilde{K}_{t+1} = (1 - \lambda_N)\tilde{K}_t + \lambda_N\eta_t^{\text{inn}} \quad (\text{V.7})$$

with $\lambda_N \asymp 1/N$ (contraction rate set by window length) and η^{inn} zero-mean innovation noise with variance $O(1/N)$. This is itself an instance of **G** with:

- (T1): $\Phi_K(0) = 0$ — when gain is optimal, estimator returns optimal in expectation.

- (T2): $\tilde{K} \cdot \Phi_K(\tilde{K}) = \lambda_N \tilde{K}^2$, so $\alpha_K = \lambda_N$.
- (T3-S): bounded stochastic disturbance on the gain channel.

Prop A.1S applied to the meta-gain channel gives $R_{S,K}^* \asymp 1/\sqrt{N}$ — the classical Mehra asymptotic rate, now derived from (MG-2). Primary sector floor is preserved: $\underline{\alpha} = K^* - |\tilde{K}|_{\max}$ via triangle. Composed persistence via augmented-state Lyapunov gives $O(1/\sqrt{N})$ degradation from the fixed-gain case. **This case is derived at sub-scope α_2 .**

Under Mehra non-identifiability (rank-deficient transform matrix; see Zagrobelny-Rawlins 2015, Dunik et al. 2021), (MG-2) fails structurally — an instance of the 5.1 pattern on the meta-gain channel.

Case B — RMSProp on strongly-convex loss. The per-step effective step is $\eta_t^{\text{eff}} = \eta_t/(\sqrt{v_t} + \varepsilon)$ where $v_t = \beta v_{t-1} + (1 - \beta)\hat{g}_t^2$ tracks the second moment. Near the minimizer, $\mathbb{E}[\hat{g}_t^2] \rightarrow \|\nabla L\|^2 + \sigma_g^2$. Writing $\tilde{v}_t = v_t - \mathbb{E}[\hat{g}_t^2]$:

Derivation (case-rmsprop-alpha2-conditional).

$$\tilde{v}_{t+1} = \beta \tilde{v}_t + (1 - \beta)(\hat{g}_t^2 - \mathbb{E}[\hat{g}_t^2]) + \beta(\mathbb{E}[\hat{g}_{t-1}^2] - \mathbb{E}[\hat{g}_t^2]) \quad (\text{V.8})$$

The first two terms give (MG-2) with $\alpha_v = 1 - \beta$ and $\sigma_v^2 \asymp (1 - \beta)^2 \text{Var}(\hat{g}_t^2)$. The third is δ -coupled: $\mathbb{E}[\hat{g}_t^2]$ depends on δ through $\|\nabla L\|^2$, giving $c_v > 0$ in (MG-4).

Composed persistence under design conditions β close to 1 (slow EMA) and $\lambda_{\max}(H) \cdot R_S^* \ll \sqrt{\sigma_g^2}$ (coupling smallness): fixed-point closure between primary R_S^* and meta-gain R_v yields existence of a stable equilibrium. Sub-scope α_2 under design conditions.

Outside those conditions (aggressive β + ill-conditioning + small gradient noise — Reddi et al. 2018's Adam counterexample), fixed-point iteration diverges. **AMSGrad's monotonicity on v_t is structurally a meta-gain repair that restores (MG-1) by construction** — preserving sub-scope α_2 by forcing a condition (MG-1) the vanilla algorithm would violate.

Case C — IMM / regime-switching Kalman. Mixture of M Kalman filters with Markov-transition posterior over regimes. Between regime transitions, the posterior concentrates on the true regime and the effective gain approaches the regime-conditional optimum: sub-scope α_2 in the steady portion with Mehra-style derivation. Across regime transitions, posterior re-concentration takes $\tau_{\text{IMM}} \asymp 1/(1 - p)$ observations (self-loop probability p); during this window (MG-1) fails uniformly in time — the gain can be aligned with the wrong regime. Scope narrowing via dwell-time + impulsive-disturbance absorption: regime stable for $T_{\text{dwell}} \gg \tau_{\text{IMM}}$, transient mismatch bounded by counting-argument. Sub-scope α_2 between-transition; β across-transition.

Sketch (case-imm-alpha2-plus-dwelltime).

Case D — MAML inner-outer structure. Inner loop (per-task adaptation with k gradient steps) — sub-scope α_1 from Prop B.4 under per-task convexity. Outer loop (meta-parameter update via gradient on meta-loss $\sum_i L_i(\theta'_i(\theta))$) — Fallah et al. 2020's convergence analysis shows the meta-loss is non-convex even under per-task convexity because of the non-linearity of inner-loop updates in θ . (MG-2) is not derivable from per-task structure. Outer loop is β — A2' assumed per basin.

Classification (case-maml-mixed).

What Is Derived vs. What Is Chosen.

Table V.1

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Augmented-state setup $z = (\delta, \tilde{K})$ with coupled sector dynamics	Definitional reformulation extending 3.2 + 3.6	Formulation choice
(MG-1) primary sector floor under bounded gain error	Derived in Cases A and B via triangle / ε -floor arguments	Derived (per case, conditional on regularity)
(MG-2) meta-gain sector condition	Derived in Cases A (Mehra OU) and B (EMA second-moment) from estimator structure	Derived (per named case)
(MG-3) timescale separation $\alpha_K \ll \underline{\alpha}$	Design condition on estimator window / EMA rate; Lyapunov decay-rate transcription of 4.9	Formulation (design condition; violations dissolve composition)
(MG-4) coupling boundedness of gain-channel disturbance	Decoupled ($c_v = 0$) in Case A; δ -coupled ($c_v > 0$) in Case B with fixed-point closure	Derived (per case)
Composed augmented-state persistence under (MG-1)–(MG-4)	Quadratic Lyapunov on z + Khalil 2002 Thm 4.18 ultimate-boundedness	Derived (conditional on MG-1 through MG-4)
Sub-scope refinement $\alpha_1 / \alpha_2 / \beta$	Extension of current A α/β partition	Formulation (classification)
α_2 reduces to α_1 under $\tilde{K} \equiv 0$	Direct substitution into augmented-state setup	Proved
Case A (adaptive Kalman): sub-scope α_2 under identifiability + window-length timescale separation	Mehra OU-form of estimator + Prop A.1S	Derived
Case B (RMSProp): sub-scope α_2 under design conditions; β otherwise; AMSGrad as meta-gain repair	EMA second-moment derivation + fixed-point closure + Reddi et al. 2018 counterexample	Derived (conditional); AMSGrad framing is discussion
Case C (IMM): sub-scope α_2 between-transition + β across-transition via dwell-time	Posterior re-concentration + impulsive-disturbance absorption	Sketch
Case D (MAML): inner-loop α_1 + outer-loop β	Fallah et al. 2020 meta-loss non-convexity	Classification (not derivation)
Mehra non-identifiability as meta-gain 5.1 instance	Rank-deficient transform matrix blocks (MG-2) derivation	Discussion (candidate floor instance)

Epistemic Status.

Conditional. Max attainable: *derived* for the composed persistence result under (MG-1)–(MG-4); *exact* for Case A (adaptive Kalman) under Mehra identifiability; *conditional* for Case B (RMSProp) under design conditions; *sketch* / *classification* for Cases C (IMM) and D (MAML).

The core claim — that (MG-1)–(MG-4) together give an augmented-state sector-persistence result via standard Khalil Thm 4.18 — is a clean application of two-timescale Lyapunov analysis to the gain-as-state formulation. The mathematical core is textbook (vector Lyapunov, augmented-state dissipation, completing-the-square on cross terms). The contribution is the AAT-framing: (i) naming the four conditions that make adaptive gain composable with sector-persistence, (ii) identifying which adaptive-gain schemes satisfy all four from update-rule structure (Cases A, B-design) and which require assumption (Cases C-transition, D-outer, rule-based), and (iii) refining the A2' sub-scope partition into $\alpha_1/\alpha_2/\beta$ as a principled extension rather than overhaul.

Imported machinery, acknowledged. The underlying techniques — two-timescale stochastic approximation (Borkar 1997, 2008), adaptive filtering (Mehra 1970–72; Mohamed-Schwarz 1999; Dunik et al. 2021), MRAC stability theory (Narendra-Annaswamy 1989; Ioannou-Sun 1996), non-convex meta-learning convergence (Fallah et al. 2020; Ji-Yang-Liang 2022) — are standard in control theory and ML. AAT's value-add here is the integration: connecting these techniques to G via the augmented-state Lyapunov composition, and producing a sub-scope partition that matches

AAT's scope-honesty architecture rather than importing the techniques' native terminology. The existing sub-scope α / β partition from A becomes α_1 / α_2 / β , with α_2 labeling the newly-derivable adaptive-gain region.

What this does not establish:

- Convergence rates beyond ultimate-boundedness (the bound gives stability, not speed).
- Behavior under (MG-3) violation — fast-adapting gain on a slow primary state — which is structurally different (the composite system becomes singular-perturbation pathological, not sector-persistent).
- Rigorous fixed-point closure for the Case-B δ -coupled case; the qualitative argument is clear but quantitative bounds on when the closure exists are per-problem.
- Composition at the multi-agent level — the augmented-state Lyapunov is for a single adaptive agent; team adaptive-gain (simultaneous meta-learning across agents) is beyond scope.

Discussion.

Resolving Epistemic Opacity. In #def-observation-function, the agent is structurally forbidden from knowing the true noise distribution ε_t . Yet the optimal gain #emp-update-gain requires knowing U_o . The adaptive Kalman filter with an innovation-based estimator (e.g., Mehra 1970) resolves this. The agent computes the autocorrelation of its observable mismatch sequence (innovations): $\iota_t = o_t - \hat{o}_t$. Because the innovation statistics are observable, the agent can estimate U_o (and U_M) purely from its own history $\mathcal{C}_t$, satisfying both the opacity axiom and the optimality requirement. The error in this estimation ($\bar{K}$) is exactly what the meta-gain sector condition (MG-2) bounds.

Why this is not a singular-perturbation reduction. Singular perturbation theory (Tikhonov 1952; Khalil 2002 Ch. 11) replaces fast dynamics with their quasi-steady-state manifold — the fast variable is *eliminated* in the slow reduction. The augmented-state analysis here does something different: it *keeps both states* and bounds their joint persistence via a weighted Lyapunov. Tikhonov gives “the fast variable tracks its slow manifold up to $O(\epsilon)$ ”; template-composition gives “each level's state is ultimately bounded with coupling-amplified disturbance” — the persistence-flavored state-ment aligned with AAT's other persistence results. They answer different questions; both are useful; neither replaces the other. M's stacking theorem (promoted 2026-06-10) is in fact stated in the template-composition register this paragraph describes — each level a template instance with coupling-amplified effective disturbance, both states kept, joint forward-invariance — with the quasi-steady-state manifold used only as the anchoring coordinate, not as an elimination step. The two segments now share the framing; what differs is the axis (gain-parameter timescale here, adaptive-level stacking there).

Three timescale patterns in AAT. M distinguishes model-class (slow) and parametric (fast) timescales. This segment introduces a *third* pattern: gain-parameter timescale, sitting between parametric-correction (fastest) and model-class (slowest). Adaptive gain is a different two-timescale pattern from structural adaptation — the gain is a parameter of the update rule, not of the model class. The convergence constraint $\nu_{n+1} \ll \nu_n$ from 4.9 translates in this segment to $\alpha_K \ll \underline{\alpha}$ on Lyapunov decay rates, which is the (MG-3) condition.

Meta-gain scope-honesty failure modes. - *Identifiability failures* on the meta-gain channel (Mehra non-identifiability) are instances of the 5.1 pattern: a structural no-go (non-identifiability) on the meta-gain channel blocks the sub-scope α_2 derivation. AMSGrad as a meta-gain repair is the constructive complement — an added structural condition (monotonicity on v_t) that restores (MG-1) and keeps the adaptive scheme in α_2 . - *Non-convex meta-losses* (MAML outer loop) put the outer loop in sub-scope β : A2' must be assumed within a basin, not derived from the meta-loss's global structure. This is the honest scope-narrowing posture — different from saying “it works” or “it doesn't” without qualification. - *Regime transitions* (IMM across switches) violate (MG-1) uniformly in time during posterior re-concentration windows. Repair via dwell-time is clean but significant scope narrowing.

Connection to 9.10's $\alpha_\Sigma = 1/(n+1)$. The strategy-edge persistence condition has α_Σ decaying with experience — this is adaptive gain of a specific form, where the gain (effective update rate per edge) is a function of accumulated pseudo-count. Without forgetting, $\alpha_\Sigma \rightarrow 0$ and (MG-1) fails asymptotically. 9.10's forgetting prerequisite $(1 - \lambda) > \rho_\Sigma/R_\Sigma$ is precisely the condition that keeps strategy-edge adaptation in sub-scope α_2 rather than letting it fall to β as n grows.

Relation to catastrophic forgetting via EWC. Elastic Weight Consolidation (Kirkpatrick et al. 2017) introduces a per-parameter stability-weighted update: gain is scaled by inverse Fisher information of prior tasks. In AAT vocabulary, EWC is a tensor-valued adaptive gain with stability weighting, distinct from the scalar adaptive-gain case treated here but fitting the same augmented-state framework with (MG-1)–(MG-4) reinterpreted per-parameter. Adapting the present derivation to EWC would tensorize the Lyapunov argument — a natural but not-yet-executed extension.

Working Notes.

- **Identifiability as meta-gain obstruction.** Mehra non-identifiability for certain system structures (Dunik et al. 2021) is an instance of 5.1 on the meta-gain channel — a structural no-go blocking (MG-2) derivation. Candidate for explicit cross-reference in 5.1's §"Adjacent Floors" as a fourth derived instance (after F1 CHT no-go, F13 Cramér-Rao mixture-identifiability, and Regime II-b misspecification-cost from 15.3).
 - **Rate-specific results.** The composed persistence result is a bound, not a rate. Can the $1/\sqrt{N}$ rate of Mehra-adaptive-Kalman be derived rigorously from the augmented-state Lyapunov? Classical Mehra asymptotics give it directly; deriving it from (MG-1)–(MG-4) would confirm the framework's completeness.
 - **Adversarial adaptive-gain.** If the environment adversarially varies K^* (hostile regime-switching cadence), dwell-time repair of Case C fails. Adversarial-tempo-advantage analog at the meta-gain level: faster meta-gain tracking beats faster environmental regime switching iff $\alpha_K T_{\text{dwell}}$ exceeds the transition rate. Not derived here; adjacent spike. (*Indexed: spikes/PROPOSED.md Tier 3 — "Adversarial adaptive-gain — meta-gain tempo-advantage analog"*)
 - **Discrete-time form.** Everything above is continuous-time. Discrete-time version involves the Lipschitz bound of $\mathbf{O}$ on both F and Φ . Extension is mechanical but deferred.
 - **Relationship to 9.10 time-varying α .** 9.10's $\alpha_\Sigma = 1/(n+1)$ decay is a concrete instance of adaptive-gain dynamics where (MG-1) fails asymptotically without forgetting. Worth re-reading that segment through the α_2 lens; the forgetting prerequisite is the specific move that keeps strategic adaptation in α_2 as n grows.
 - **Template-composition as general technique.** The augmented-state weighted-Lyapunov argument is a general two-timescale composition technique for **G**. It composes two template instances with a cross-coupling bound. A generalization to three or more timescales (inner loop + outer loop + meta-meta-loop, or fast + gain + slow + structural) would give a chain-composition form; not derived here but structurally available.
 - **AMSGrad as α_2 -preserving meta-gain repair.** Characterizing AMSGrad as "enforce (MG-1) by construction" is a clean AAT-framing of a pragmatically-motivated algorithm. Worth noting as an example of adaptive-gain schemes being AAT-classifiable by which of (MG-1)–(MG-4) they structurally ensure vs leave to luck.
 - **Deterministic-meta-gain special cases.** When the meta-gain is a deterministic function of the primary state rather than an independently learned variable — $K_t = \mathbf{I}^{-1}(\lambda_t)$ for Fisher whitening at the edge-update layer (**AM**), or $K = (H_M + H_L)^{-1}H_L$ for the Fisher-local model-parameter update (**AR**) — all four meta-gain conditions are satisfied trivially under the regularity conditions of those segments. The non-degenerate adaptive-Kalman-with-Mehra case is this segment's primary instance and adds a Mehra-style meta-channel with its own (MG-1)–(MG-4); the Fisher-local cases are degenerate special cases where the meta-gain is read off the primary state directly.

Appendix W

Derivation: Internal-External Decomposition of Agent Viability

Agent viability decomposes **additively** into agent-movable terms and an irreducible environmental floor — inherited from the exact mismatch decomposition — and provably does **not** factor multiplicatively into an agent-independent environmental rate times agent factors. The construction takes log-viability as the log-margin between steady-state mismatch and the critical task boundary, and inherits the additive split (estimation error + state-uncertainty floor + channel noise) from 3.5; the agent can move the estimation term by modeling and the state-uncertainty term by acting, the channel floor it cannot move at all.

The constitutive no-go is that multiplicative ρ -factorization of the form “ $\rho = \rho_{\text{external}} \cdot f(\text{model-class}) \cdot g(\text{policy})$ ” is type-incorrect: mismatch is constitutively agent-relative, so ρ^2 carries an estimation term that *vanishes* as the agent’s model improves — a contribution that subtracts to zero cannot be represented by attenuating a fixed agent-independent scalar by agent factors. Established exactly is the additive env/agent split with the environmental floor; the finer decomposition of the internal component into model, policy, and cross-term contributions is *conditional* and deliberately reserved — separating it requires Level-2 interventional access (5.1) and is under separate investigation.

Log-Viability.

Log-viability $\mathcal{V}$ is the margin by which steady-state mismatch R^* stays below the critical task boundary $\|\delta_{\text{critical}}\|$:

$$\mathcal{V} = \log \frac{\|\delta_{\text{critical}}\|}{R^*} = \log \|\delta_{\text{critical}}\| - \log R^* \quad (\text{W.1})$$

Persistence holds exactly when $\mathcal{V} > 0$. Under linear Model D, $R^* = \rho/\alpha$ (4.5), so

$$\mathcal{V} = \log \|\delta_{\text{critical}}\| - \log \rho + \log \alpha \quad (\text{W.2})$$

[*Derived*] — exact algebra (logarithm of a ratio); independent of how ρ itself is structured.

The disturbance is additive, not multiplicative.

The decomposition of viability into “what the environment imposes” versus “what the agent controls” runs through the structure of ρ . That structure is fixed by an existing exact result, not a free modeling choice.

The exact mismatch decomposition. By 3.5 (status: exact, via the fresh-noise assumption GA-1), expected squared mismatch splits with vanishing cross-terms:

Derived (exact, inherited from #result-mismatch-decomposition GA-1).

$$\mathbb{E}[\|\delta_t\|^2] = \underbrace{\mathbb{E}[\|\hat{o}_t - \hat{o}_t^B\|^2]}_{\text{estimation — reducible by modeling}} + \underbrace{\mathbb{E}[\text{Var}(\bar{o}_t \mid \mathcal{C}_{t-1}, a_{t-1})]}_{\text{state uncertainty — movable by acting}} + \underbrace{\mathbb{E}[\text{Var}(o_t \mid \Omega_t, a_{t-1})]}_{\text{channel noise — irreducible}} \quad (\text{W.3})$$

All cross-terms are zero by orthogonality (not independence), exactly as that result establishes. The first two terms are **agent-side**: the estimation term shrinks as the model improves, vanishing at the Bayes predictor; the state-uncertainty floor binds every model — well-specified or not — and yields only to *acting* (more informative interaction history), never to better modeling alone. The third is the **irreducible environmental floor**: a property of the observation channel the agent cannot reduce. A boundary note, because the working record has drawn it in two places: “the environmental floor” can be placed at the channel term alone (as here — everything else is agent-movable, by model or by policy) or at the full Bayes floor (state uncertainty + channel — everything no *model* can remove); the two placements differ by exactly the state-uncertainty term. This segment uses the first placement because the viability split is about what the agent — model and policy together — can move.

Rate-lift (stated convention). The persistence condition uses the disturbance *rate* ρ , related to expected squared mismatch by a fluid-limit identification $\rho^2 = \nu \cdot \mathbb{E}[\|\delta_t\|^2]$ for a positive throughput factor ν :

The viability decomposition. Substituting the exact split gives

Formulation — stated fluid-limit convention, introduced here; not a pre-existing canon identity. The structural conclusion below is convention-robust: any $\nu > 0$ preserves additivity, since positive scaling of a sum is a sum..

Derived (conditional on the stated rate-lift convention).

$$\mathcal{V} = \mathcal{V}_{\text{env}} + \mathcal{V}_{\text{agent}} \quad (\text{W.4})$$

where the first term $\mathcal{V}_{\text{env}}$ collects the channel-floor contribution (environmental affordance) and the second collects the estimation and state-uncertainty contributions together with the $\log \alpha$ tempo/gain terms (internal-operational health: the estimation part improves as the model improves; the state-uncertainty part as the agent’s interaction history grows more informative).

No multiplicative factorization (constitutive no-go).

There is no agent-independent scalar ρ_{external} with $\rho = \rho_{\text{external}} \cdot f(\mathcal{M}) \cdot g(\pi)$. Mismatch is constitutively agent-relative ($\delta_t \equiv o_t - \hat{o}_t$, 3.4), so ρ^2 carries the estimation term, which **vanishes as the agent’s model improves**. A multiplicative form attenuates a fixed agent-independent scalar by agent factors; it cannot represent a contribution that *subtracts to zero* under an agent-internal change. Multiplicative-in-rate and additive-in-(squared-mismatch) are type-incompatible, and $\sqrt{A+B} \neq \sqrt{A}\sqrt{B}$ blocks recovering the product form under the rate-lift. The decomposition is additive by construction, not by choice.

Derived — constitutive impossibility; exact under the constitutive definition of mismatch.

Epistemic Status.

The mismatch decomposition is **exact** (3.5, under GA-1). The viability decomposition in ρ -units is **conditional on the stated fluid-limit rate-lift** — a modeling convention introduced in this segment, not a pre-existing canonical identity; the *additive structure* (versus multiplicative) is robust to it for any positive throughput factor. The constitutive no-go is exact given the definition of mismatch. A general (non-isotropic, state/policy-dependent) diffusion $\Sigma(\delta, t)$ preserves additivity by linearity of the Itô generator in the diffusion matrix — this is an elementary extension *beyond* A Prop A.1S's constant-isotropic $\sigma_w^2 I_n$ case, correct but not itself part of that result's exact scope.

Discussion.

The finer split is conditional, not exact. Decomposing $\mathcal{V}_{\text{agent}}$ further into model-class ($\mathcal{M}$), policy (π), and cross contributions is a *mediation* question, not an identity: it is identifiable under interventional regimes (rotating the same agent across environments, or environments across agents) and **confounded** otherwise — in a feedback system high internal capacity itself lowers future environmental difficulty, entangling the terms. That confound is an identifiability-floor phenomenon (5.1): separating the agent-internal sub-terms from observational data alone is formally obstructed; Level-2 interventional access is required. This segment asserts only the exact two-term env/agent split and the no-go; the finer $\mathcal{M}/\pi$ /cross decomposition and its precise floor characterization are under separate investigation and are deliberately not asserted here.

Why this matters. The two-term split is the honest form of the internal/external diagnostic the persistence condition invites: it identifies exactly what an agent can improve (model error) versus the floor it cannot (channel noise), without the false promise that the environmental rate is an agent-independent quantity one can read off and attribute blame to.

Working Notes.

- Provenance (process history, not theory content): this segment previously asserted a multiplicative $\rho = \rho_{\text{external}} \cdot f(\mathcal{M}) \cdot g(\pi)$ split, was honesty-marked status: false, and was rebuilt on the exact mismatch decomposition. The constitutive no-go and the canon-forcing of the additive form were established by an independent recheck and confirmed by an independent verifier that also caught two pedigree over-claims (the ν rate-lift is *not* a pre-existing #hyp-mismatch-dynamics identity — landed here as a stated convention; the general- Σ additivity exceeds Prop A.1S's constant-isotropic scope — labeled as an elementary extension). Full trail: CHANGELOG 2026-05-18; spikes/ROUTING.md.
 - Open (reserved, under independent investigation): the conditional $\mathcal{M}/\pi$ /cross refinement and whether its Regime-C confound is a distinct #disc-identifiability-floor instance. Do not assert the three-way split until that resolves.
 - Boundary regression-guard (2026-07-03, audit 731548 B-2): the working layer twice defined the environmental floor $\rho_\star^2$ at *different* boundaries — the 2026-04-24 additive-variance spike at the full Bayes floor (state uncertainty + channel), the 2026-05-18 recheck at channel-instant variance only — differing by exactly the state-uncertainty term, and this segment's earlier gloss “vanishes for a well-specified model” was false under either placement (the Bayes-optimal predictor retains the state-uncertainty floor; see the Kalman anchor in 3.5). The three-term form now inherited from 3.5 states the boundary explicitly; if a future edit re-merges the middle term into either neighbor, check it against that segment's derivation first. History: CHANGELOG 2026-07-03; the ρ -family row in spikes/INDEX.md.

Appendix X

Derivation: Update Detection Latency Under Accumulated Experience

For a Beta-Bernoulli strategy-edge agent without forgetting, the expected number of cycles required to detect a within-class regime change of observable footprint ε scales as $\Omega((n_{\min} + 1)/\varepsilon)$ with $n_{\min}$ the minimum accumulated pseudo-count on load-bearing edges. The $1/(n + 1)$ rate is **structurally forced** — it is the log-odds update magnitude per cycle under $\mathbf{U}$'s Aczél-Cauchy-FE uniqueness theorem, and no choice of coordinate escapes it. The result sharpens 9.10's forgetting prerequisite from “required for asymptotic persistence” to “required for detection-latency bounded independently of operating point.” The broader myopia observation — that successful, high-capability organizations systematically underinvest in detecting regime changes that would require structural adaptation — admits a complementary decision-theoretic account via 10.2's oracle analysis; this segment's contribution is the signal-side lower bound, not the decision-side account.

Formal Expression.

Setup. An agent with a Beta-Bernoulli strategy DAG per 9.10 / $\mathbf{R}$, credit assignment via the log-odds signal of 9.6 (forced by $\mathbf{U}$), and no forgetting ($\lambda = 1$, pseudo-counts n_k accumulate monotonically). Let E_{load} denote the load-bearing edges on the current active plan; $n_{\min} = \min_{k \in E_{\text{load}}} n_k$. The agent has been operating with model-class fitness $\mathcal{F}(\mathcal{M})$ near 1, adaptive reserve $\Delta\rho^* > 0$, control regret δ_{regret} small — a high-operating-point configuration.

At cycle t_0 , a regime change occurs within the current model class (a true edge probability shifts by ε ; the L0 graph remains correct; the agent's model class still suffices). This is case R1 in the spike taxonomy — a within-class drift change. Other regime-change cases (R2 model-class inadequacy; R3 L0→L1 structural transition) are deferred to Working Notes and 5.1 respectively.

Detection-latency theorem.

Proposition. Under the setup, the expected number of cycles T_{detect} required for the log-odds coordinate on any load-bearing edge $k \in E_{\text{load}}$ to cross a fixed detection threshold $\Delta\lambda_{\text{detect}}$ in response to the regime change satisfies

Derived (detection-latency-R1, from edge-update-natural-parameter + deriv-edge-credence-dynamics).

$$\mathbb{E}[T_{\text{detect}}] = \Omega(\Delta\lambda_{\text{detect}} \cdot (n_{\min} + 1)/\varepsilon) \quad (\text{X.1})$$

Derivation. The default signal function of 9.6 (under the log-odds coordinate forced by $\mathbf{U}$) updates an edge's log-odds credence by

$$\lambda_k^{\text{new}} = \lambda_k + \eta_{\text{edge}} \cdot \iota_k \cdot J_k \cdot (y_G - \hat{R}_\Sigma) / \|\mathbf{J}\|^2 \quad (\text{X.2})$$

with $\eta_{\text{edge}} = 1/(n_k + 1)$ for Beta-Bernoulli (Prop B.4 of R). Per-cycle the expected log-odds update magnitude is bounded:

$$\mathbb{E}|\Delta\lambda_k| \leq \frac{|J_k| \cdot \mathbb{E}|y_G - \hat{R}_\Sigma|}{\|\mathbf{J}\|^2 \cdot (n_k + 1)} \quad (\text{X.3})$$

Under regime change R1 with observable footprint ε , the expected systematic residual $\mathbb{E}|y_G - \hat{R}_\Sigma| = \Theta(\varepsilon)$ as $\varepsilon \rightarrow 0$ (the misspecified-edge residual is proportional to the edge's probability shift, via the linearization of the Bernoulli likelihood in a neighborhood of the pre-change parameter). Combining: the per-cycle expected log-odds increment on load-bearing edges is $O(\varepsilon/(n_{\min} + 1))$.

For the agent to cross $\Delta\lambda_{\text{detect}}$, expected cycles required is at least $\Delta\lambda_{\text{detect}}/(O(\varepsilon/(n_{\min} + 1))) = \Omega(\Delta\lambda_{\text{detect}} \cdot (n_{\min} + 1)/\varepsilon)$. $\square$

The rate is structurally forced.

The $1/(n + 1)$ scaling is not a property of the specific update rule choice. Per U, the log-odds coordinate is the *unique* additive-evidence coordinate satisfying the evidential-additivity axiom — the Aczél 1966 Cauchy-functional-equation uniqueness theorem forces it up to positive affine transformation. In this forced coordinate, the per-cycle increment for Beta-Bernoulli edges is forced to be $O(1/(n + 1))$: the Fisher-equivalent statement holds in any sensible coordinate. Rearranging the update to a different scale does not change the rate — it just changes the units in which the rate is measured.

Observation (rate-forced-by-aczel).

The forcing composition:

1. U forces the log-odds coordinate via evidential additivity.
2. In that coordinate, Beta-Bernoulli accumulation gives $\eta_{\text{edge}} = 1/(n + 1)$.
3. Therefore the per-cycle update magnitude is structurally forced at $O(1/(n + 1))$.

This is the specific link between AAT's constructive meta-pattern (5.5, via U's theorem) and a downstream detection-latency consequence. The rate cannot be escaped without abandoning evidential additivity — which would invalidate the update rule on AAT-internal grounds, not merely operational ones.

Sharpening the forgetting prerequisite.

9.10 derives the forgetting prerequisite $(1 - \lambda) > \rho_\Sigma/R_\Sigma$ as required for *asymptotic persistence* — without forgetting, $\alpha_\Sigma = 1/(n + 1) \rightarrow 0$ and persistence eventually fails. The detection-latency theorem sharpens this to a **load-bearing claim about detection latency on the way to asymptotic failure**:

Corollary (forgetting-as-latency-bound, sharpens #schema-strategy-persistence).

Forgetting is required not only for asymptotic persistence, but also for detection latency to be bounded independently of operating point. Without forgetting, $n_{\min}$ grows monotonically, and $\mathbb{E}[T_{\text{detect}}]$ grows linearly with $n_{\min}$. With forgetting at rate $\lambda < 1$, the effective pseudo-count $n_{\text{eff}} = 1/(1 - \lambda)$ is bounded, and the detection latency caps at $\Omega(1/((1 - \lambda)\varepsilon))$ regardless of how long the agent has been operating.

This dualizes 9.10’s asymptotic claim: forgetting is operationally load-bearing at every step, not only in the limit. An agent with the right λ has bounded detection latency throughout its lifetime; an agent with $\lambda = 1$ has detection latency that grows unboundedly with experience, producing the phenomenon of stability-induced myopia in practice.

What Is Derived vs. What Is Chosen.

Table X.1

<i>Property</i>	<i>Source</i>	<i>Strength</i>
R1 detection-latency theorem $\mathbb{E}[T_{\text{detect}}] = \Omega((n_{\min} + 1)/\epsilon)$	U log-odds coordinate + R Prop B.4 $\eta_{\text{edge}} = 1/(n + 1)$ + Pinsker-type linearization	Derived (conditional on Beta-Bernoulli + log-odds + no forgetting)
$1/(n + 1)$ rate structurally forced	Composition of U’s Aczél-Cauchy-FE theorem with Beta-Bernoulli accumulation	Proved (conditional on evidential-additivity axiom)
Sharpening of forgetting prerequisite from asymptotic persistence to bounded detection latency	9.10 + this theorem	Derived
R2 model-class inadequacy sub-case (C1-diagnostic blindness under misspecification)	Common-mode-bias argument on $A_O^{(1)}$ vs $V_O(\pi_{\text{current}})$	Discussion (sketch; see Working Notes)
R3 L0→L1 structural transition sub-case	Direct application of 5.1 Instance 1 — already derived there	Reference (not new content)
Probability-of-deferral bound	Derivable from the expected-time bound via Markov inequality	Discussion
Connection to institutional inertia / Christensen / competency traps	Stability-induced-myopia as a mechanism for the empirical pattern	Discussion
Connection to IDT sidecar monitoring (Hafez et al. 2026 89% vs 44%)	On-policy reward-based monitoring is the log-odds accumulator; IDT bi-predictability is a change-detector that bypasses the $1/(n + 1)$ rate	Discussion

Epistemic Status.

Conditional. Max attainable: *exact* for R1 under stated scope (Beta-Bernoulli + log-odds forced + no forgetting + linearized residual near pre-change parameter); *robust qualitative* for general exponential-family edge with similar sufficient-statistic accumulation; *discussion-grade* for extensions beyond the Beta-Bernoulli / log-odds specialization.

The R1 theorem is a direct consequence of two derived AAT results (U’s forced log-odds coordinate + R’s Beta-Bernoulli η_{edge}) composed with a standard residual-magnitude argument (Pinsker-type inequality applied to the linearized Bernoulli likelihood). The mathematical core is not novel — what is novel is the AAT-framing: reading the $1/(n + 1)$ scaling as *structurally forced* through composition of existing AAT theorems, not contingent on update-rule choice. The rate is unescapable without abandoning evidential additivity.

The forgetting-prerequisite sharpening follows by direct substitution — replace unbounded $n_{\min}$ with bounded $n_{\text{eff}} = 1/(1 - \lambda)$ and the latency bound inherits the cap. This is where the segment’s most concrete contribution lies: the existing forgetting prerequisite’s justification expands from “asymptotic persistence fails without it” to “detection latency is unbounded in operating point without it.” Two load-bearing consequences instead of one, from the same $\lambda < 1$ condition.

What this does not establish:

- R2 (model-class inadequacy) as a full derivation. The sketch argument — that $A_O^{(1)}$ and $V_O(\pi_{\text{current}})$ share common-mode bias under misspecification, so the C1 regret diagnostic under-reports — is qualitatively clear but quantitatively informal. Making it rigorous requires a model of the bias’s functional form.
- R3 (L0→L1 transition) as new content. This is 5.1 Instance 1 — a structural no-go, not a latency bound. This segment references it but does not extend it.
- Decision-theoretic consequences. The theorem is about signal latency, not about whether the signal once received yields the right decision. 10.2’s oracle analysis (which shows deliberation rarely chosen) operates at the decision-theoretic level; the myopia theorem operates at the signal-quality level. An agent with degraded signals + perfect decision rule still defers; this is complementary to the oracle’s degraded-decision-with-perfect-signals result.
- Extension beyond Beta-Bernoulli. Gaussian edges admit $1/(n + c)$ scaling with analogous behavior; general exponential-family edges admit scaling following the sufficient-statistic accumulation. The qualitative form — expected detection time monotone in accumulated sufficient statistic — is more general than Beta-Bernoulli; the quantitative $1/(n + 1)$ is specific.

Discussion.

The forcing composition is where the meta-pattern interacts with downstream results. 5.5 is an AAT meta-segment naming the Cauchy-FE structural move at three layers (chain / divergence / update). This segment exhibits the specific case where that move’s downstream consequences bind: the log-odds forcing at the update layer implies — through Beta-Bernoulli accumulation — a specific detection rate that cannot be escaped via re-parameterization. The meta-pattern’s constructive power is visible here as a *negative* downstream consequence (bounded detection rate), which then becomes the positive motivator for forgetting. This is an example of AAT’s meta-architecture composing constructively: the forcing move (positive) produces a bound (negative) that sharpens an existing requirement (positive).

Distinction from adjacent phenomena:

- 4.8 characterizes WHEN restructuring is needed at truth (model-class inadequacy). This segment characterizes WHEN (in terms of cycles) the agent’s detection signal crosses threshold. The two together say: the agent will eventually detect a structural problem, but the latency can be large at high operating point.
- 10.2 gives a decision rule over exploit / explore / deliberate given signals. This segment is about signal quality — specifically, a predictable bias in signals as a function of operating point. The two compose: even an oracle’s decision rule applied to myopia-biased signals produces deferred action.
- 9.10’s forgetting prerequisite is a condition for asymptotic persistence. The corollary here is a condition for bounded detection latency — the same $\lambda < 1$ buys both.
- 5.1 Instance 1 (on-policy L0-insufficiency no-go) is a structural unboundedness result specific to L0/L1 transitions. The R1 detection-latency theorem is a quantitative bound on a broader class of regime changes (within-class drift, not just structural transitions).

Connection to cross-domain empirical patterns. Christensen’s *Innovator’s Dilemma*, Levitt & March competency traps, Hannan & Freeman structural inertia, March exploration/exploitation, and Eldredge-Gould punctuated equilibria all identify empirical patterns of stability-induced myopia across domains. The common story is that successful, mature, capable systems systematically underinvest in detecting regime changes that would require restructuring. The theorem supplies a mechanism: as experience accumulates (n_{min} grows), per-observation learning rate decays as $1/(n + 1)$, expected detection time grows linearly, and the structural-adaptation trigger signal is systematically delayed.

The phenomenon is not only decision-theoretic (incentive mis-alignment, short-horizon myopia) — it has a signal-side epistemic component forced by the log-odds coordinate. The signal-side and decision-side stories compose; neither subsumes the other.

Connection to IDT (Hafez et al. 2026) empirical result. Hafez et al. 2026 observed 89% vs 44% detection accuracy for Information Digital Twin (IDT) sidecar monitoring vs reward-based monitoring. The AAT-native explanation: reward-based monitoring is the log-odds accumulator — it inherits the $1/(n+1)$ detection rate and is subject to the theorem’s latency bound. IDT’s bi-predictability and entropy-change measures are structural-information-theoretic tests that bypass the log-odds coordinate entirely; they are change-detectors in the CUSUM / GLR tradition (Page 1954; generalized likelihood ratio tests) rather than Bayesian credence accumulators. The predicted gap between the two monitoring styles grows with accumulated experience — a testable refinement of the 89%/44% observation. A sidecar change-detector is always going to beat the log-odds accumulator on detection latency for within-class drift; the AAT theorem explains why without invoking the specific IDT mechanism.

The signal side and decision side as complementary. The fact that the oracle in 10.2 rarely chose deliberation is usually read as “agents correctly defer when deliberation is expensive and information is limited.” This segment’s theorem adds: “and the information is limited in a specific quantitative way that scales with operating point.” Both are true; neither is contradicted. The detection-latency result does not overturn the oracle analysis; it provides the signal-quality context in which that decision analysis operates.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- **R2 sharpening (model-class inadequacy).** The argument: under C1 convention, $\delta_{\text{regret}}^{(1)} = A_O^{(1)} - V_O(\pi_{\text{current}})$ where both terms are computed under the current (now misspecified) M_t . Both terms bias in the same direction when the model class is structurally wrong; the gap stays small under common-mode bias. A clean version would compute the common-mode bias as a function of 3.5’s model-error component, show it is $O(1)$ (not $O(\epsilon)$) when the misspecification is directional, and derive a convention-dependent detection latency. Candidate one-evening spike. (*Indexed: spikes/PROPOSED.md Tier 3 — “R2 detection-latency sharpening under model-class inadequacy”*)
- **R3 reference, not extension.** The L0 $\rightarrow$ L1 structural-transition case is 5.1 Instance 1 — on-policy detection is forbidden by Bareinboim CHT, not merely slow. The detection-latency theorem here is about within-class drift (R1), which does not hit that no-go. When the regime change *does* involve an L0 $\rightarrow$ L1 transition, the theorem does not apply and the no-go does; the two coexist at different regime-change types.
- **Extension beyond Beta-Bernoulli.** Gaussian edges: $\eta \propto 1/(n+c)$ for the Gaussian-mean update. Exponential-family edges in natural-parameter form: η follows sufficient-statistic accumulation. The *qualitative* form (detection time monotone in accumulated sufficient statistic) is general; the *quantitative* $1/(n+1)$ is specific to Beta-Bernoulli. A parametric version of the theorem covering general exponential-family edges would be a clean follow-up.
- **Probability bound.** The expected-time bound implies a probability bound via Markov: $\Pr[\text{detect within } T] \leq T/\mathbb{E}[T_{\text{detect}}]$. Tighter concentration requires specifying the residual distribution’s shape; candidate one-paragraph extension.
- **Testable prediction.** In agents with controlled accumulated experience n , detection latency for regime change with fixed observable footprint ϵ should scale linearly in n . Directly testable in multi-arm bandits with drifting reward distributions, in simulated organizations with commit-log-mediated task environments, in human-subjects studies on noisy-signal regime detection. Each would confirm or refute the $1/(n+1)$ scaling in its native setting.
- **Multi-timescale connection.** The theorem adds empirical content to 4.9: the slow (structural-adaptation) timescale slows with accumulated fast-timescale state — the two timescales are not independent. The fast one’s accumulated state feeds back into the slow one’s responsiveness. This is the formal version of the institutional-inertia observation and is adjacent to, but not subsumed by, M’s current formulation.

- **Part III analog.** Do larger teams / organizations face proportionally longer detection latency via analogous accumulation? Candidate: team effective detection latency is bounded below by the slowest member's latency (the weakest-dimension version of 16.5). Connects to 15.1. Not derived here.
 - **Class 3 (Coupled) architectures.** For fully-coupled agents (LLMs), the Beta-Bernoulli accumulator is absorbed into the single merged computation — there is no literal edge-credence accumulator. But there *is* an analog at pretraining: token-statistic accumulation. Do LLMs exhibit a myopia analog? This is in the domain of 03-llm-core/, potentially connecting to #obs-context-turnover and the frozen-weights framing.
-

Appendix Y

Discussion: Independence Audit

AAT's results depend on a recurring modeling move: treat some quantity as independent of another to obtain tractable mathematics, then identify the failure regime where independence breaks and specify the repair. This segment enumerates the independence assumptions used across the theory, their failure regimes, their diagnostic signals, and the repair operations AAT provides. The enumeration makes visible what is *not* an independence assumption — acyclicity of Σ_t , Cox-derived probability, the Lyapunov machinery of G — and therefore what survives when a particular independence assumption fails.

Formal Expression.

Six load-bearing independence assumptions in AAT, each paired with its failure regime and repair:

Discussion (independence-audit).

1. Directed separation: M_t update independent of G_t . **Statement:** $f_M(M_{t-}, e_t)$ has no G_t argument — the epistemic update is goal-blind.

Where it appears: 6.3, the structural backbone of Part II. Feeds the orient cascade's sequential resolution (10.1), the causal validity of Q_O (6.6), and the scope of all Part II results to Class 1 (Separated) agents.

Failure regime: Class 3 (Coupled) architectures — transformer LLMs where attention processes goals and observations together. Motivated reasoning, confirmation bias, prompt-conditioned perception. Partially also Class 2 (Partial) agents.

Diagnostic signal: $\kappa_{\text{processing}} = I(G_t; M_{t+} \mid e_t, M_{t-}) / H(G_t \mid e_t, M_{t-})$. Zero for Separated agents; near one for Coupled; intermediate for Partial.

Repair operation: Class 2 (Partial) approximation quality scales with $\kappa_{\text{processing}}$. Class 3 (Coupled) agents require the coupled formulation $X_{t+} = f_X(X_{t-}, e_t)$ without (M_t, G_t) decomposition — the scope of 03-llm-core/. At the system level, Class 3 (Coupled) components can be wrapped in modular topology (separate observation processing, external monitoring — see #der-directed-separation Working Notes on the IDT pattern).

2. Causal sufficiency: no latent common causes among strategy nodes. **Statement:** Every common cause of two or more nodes in Σ_t is itself a node in Σ_t .

Where it appears: Q (precondition for the CMC-based Markov proof); 8.3 edge-independence in status propagation; all of Part II's strategy-layer formal results (Props B.1–B.6, the sector condition transfer of B.5, persistence of δ_s).

Failure regime: The dominant real-world case in complex, multi-stakeholder, or adversarial environments — shared infrastructure, market conditions, correlated adversary actions, common-mode risks, supply-chain dependencies.

Diagnostic signal: Pairwise covariance among sibling edges after edge credences have converged. Positive covariance rejects the independence hypothesis and localizes where a common cause is missing. See 9.2.

Repair operation: L1 augmentation — add common-cause nodes and restructure the DAG so each common cause is factored *above* the correlation it creates (8.3 Correlation Hierarchy; R Prop B.6). L0 formal results transfer exactly to correctly constructed L1 DAGs because L1 restores causal sufficiency by construction. The orient cascade's step 4c triggers this escalation.

3. Channel independence: observation channels contribute non-redundant correction. **Statement:** $\mathcal{T} = \sum_k \nu^{(k)}$. $\eta^{(k)*}$ with each channel contributing independently to effective tempo.

Where it appears: 3.8 (core definition); inherited by 4.5, 15.4, 15.1 (communication tempo), 13.2, and any result using scalar $\mathcal{T}$.

Failure regime: Any system with redundant or correlated information sources — overlapping sensors, correlated team-mate reports, redundant telemetry. In multi-agent settings, allies reporting the same intelligence source.

Diagnostic signal: $I(e^{(1)}; e^{(2)} \mid M_{t-})$ — pairwise mutual information between event streams conditioned on prior model state. Non-zero conditional mutual information *witnesses* dependence (a valid alarm), but it cannot serve as the correction term: it is sign-blind, and the sign of the noise correlation determines whether the additive form over- or under-counts (#deriv-tempo-additivity, no-go N1).

Repair operation: Under correlated channel noise the additive formula is *not* a general upper bound — the signed deviation $\Delta = \sum_k 1/U_o^{(k)} - \mathbf{1}^\top \Sigma_n^{-1} \mathbf{1}$ takes both signs (anti-correlated or heterogeneous positively-correlated noise makes the additive form an *undercount*; correlated noise is also a cancellation resource). The exact statements live in #deriv-tempo-additivity: additivity is exact under cross-channel noise independence (sufficient, not necessary), and in the common-source regime (shared persistent bias s) the additive form *is* an exact upper bound with closed-form penalty and joint information saturating at $1/\sigma_s^2$ — the echo-chamber bound. No channel-local additive correction exists in general for $n \geq 3$ (PID obstruction, no-go N2); precise tempo under correlation requires the joint Fisher form. Propagates into every segment using scalar tempo; per-segment ripple audit tracked in the 2026-07-15 spike.

4. Unity-dimension independence: ($U_M, U_O, U_\Sigma, U_{\text{obs}}$) substantially independent. **Statement:** The four unity dimensions of 14 parametrize composite quality along substantially independent axes.

Where it appears: 14 framing; 14.1's rate-distortion family indexed by each unity separately.

Failure regime: Shared models enable implicit strategic coordination (high $U_M \rightarrow$ high U_Σ without explicit policy sharing); aligned objectives often induce strategic coordination. Also *update-rule heterogeneity* (an axis not covered by any unity dimension) contributes to closure defect independently — the two-Kalman non-degenerate case shows $\varepsilon_x > 0$ from differing Kalman gains at perfect U_M .

Diagnostic signal: No clean one. The hypothesis is empirical and the theory currently logs it as working-position rather than resolved (see 14 Working Notes: update-heterogeneity gap).

Repair operation: Two options explored in the theory: (a) accept a two-axis structure (unity $\times$ homogeneity) for closure defect, (b) add a fifth update-homogeneity dimension. The current working position is (a); formal resolution open. Downstream uses of unity dimensions should not treat them as cleanly orthogonal.

5. Independent edge outcomes in AND/OR propagation. Statement: In $\hat{R}_\Sigma$ status propagation, sibling edge outcomes are independent given their parents.

Where it appears: 8.3 status propagation formula; 8.2; every downstream quantity computed from $\hat{R}_\Sigma$ (satisfaction gap, control regret via A_O , strategy-plan-confidence error δ_s).

Failure regime: Same as causal sufficiency (item 2) — the CMC theorem makes them the same condition: causal sufficiency $\Leftrightarrow$ exogenous noise independence $\Leftrightarrow$ edge-outcome independence. When one fails, they all fail.

Diagnostic signal: Same as item 2.

Repair operation: Same as item 2 (L1 augmentation). The assumption is not a separate modeling choice from causal sufficiency; the theory treats it as the *consequence* of causal sufficiency (via CMC), not an independent axiom.

6. Scalar tempo / isotropic correction. Statement: $\mathcal{T}$ as a scalar captures the agent's correction capacity.

Where it appears: 4.5 linear operational form; most Part I results stated in scalar $(\mathcal{T}, \rho, \|\delta_{\text{critical}}\|)$ form; 9.8 aggregate.

Failure regime: Any real multi-dimensional system with non-uniform correction capacity across dimensions. Simulation confirms scalar $\rho/\mathcal{T}$ overestimates by up to 72% in anisotropic systems, with the weak dimension accounting for 84% of total mismatch.

Diagnostic signal: Gain variation across dimensions (easily computable when gains are explicit — Kalman, gradient descent with diagonal preconditioning).

Repair operation: Per-dimension persistence: $\mathcal{T}_k > \rho_k / \|\delta_{\text{critical},k}\|$ for each dimension. See 16.5. The weakest dimension is the bottleneck. Same structural pattern propagates to strategic tempo (9.8 Per-edge persistence) — the bottleneck edge determines persistence, not the aggregate.

What is not an independence assumption.

Several results that might appear to depend on independence actually do not:

- **Acyclicity of Σ_t** is proved from temporal ordering over a finite horizon (Q). Independent of any independence assumption.
- **Cox-derived probability structure** at edges is independent of edge-independence — Cox forces the *measure* to be probability, not the joint structure.
- **Sector-persistence template machinery** (G) depends only on the sector condition (T2) and bounded disturbance (T3); it does not require any independence assumption on the state variable or correction function.
- **The DAG structure derivation** (directed edges, acyclicity, representability as a Bayesian network) does not require causal sufficiency — only the *Markov factorization* within the derived structure does.

This is the boundary between AAT's robust results and its conditional ones: robust results survive when the independence assumptions fail; conditional results break and require their specific repair operations.

Epistemic Status.

Robust-qualitative. Max attainable: *robust-qualitative*. The enumeration is definitional — each independence assumption is stated in a named segment, and the repair operations are either formally specified (causal sufficiency $\leftrightarrow$ L1 augmentation) or named open problems (unity-dimension independence). What this segment adds is the cross-cutting view: the six assumptions are the recurring modeling move that distinguishes AAT’s exact-tractable results from its conditional results, and the repairs are (mostly) already present in the theory but scattered across segments.

The enumeration is not exhaustive. Other independence-flavored assumptions exist in specific instantiations (e.g., independent Beta priors across edges in the credit-assignment analysis of 9.6). The six listed are the load-bearing ones — those whose failure regime the theory has actually characterized and provided a repair for.

Discussion.

Why enumerate these in one place. AAT’s theoretical contribution is often described as “integration”: bringing control theory, causal inference, information theory, and agent architecture under one framework. Integration *is* achieved largely through the independence assumptions listed above: each is a bridge that lets a module from one discipline plug into a module from another. Directed separation lets control-theoretic Lyapunov analysis operate on the epistemic substate without goal-entanglement. Causal sufficiency lets Pearl’s DAG machinery apply to strategy without requiring the agent to model every environmental common cause. Channel independence lets the tempo framework sum over heterogeneous observation modalities.

When these bridges fail, the integration does not fail catastrophically — each failure has a characterized repair. But the theory’s “exact” claims depend on the bridges holding, and recognizing this is the honest way to present the framework’s scope. A reader who understands the six assumptions and their repairs understands where AAT’s results apply exactly, where they apply approximately, and where they require structural revision.

Connection to Z. The L0/L1 distinction for causal sufficiency (items 2 and 5) is one instance of a meta-pattern: AAT’s results are parameterized by approximation level, with proved monotonicity between levels. See Z for the full treatment — the pattern also applies to the C1/C2/C3 value-convention hierarchy and the Tier 1/2/3 bridge-lemma contraction structure.

What this does NOT say. The enumeration does not claim the theory’s results are fragile or routinely fail. Most independence assumptions hold approximately in most well-behaved domains, and the theory’s quantitative predictions are typically within the regime where assumptions apply. The audit is a scope clarification, not a criticism.

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Failure-regime references under Assumption 1 updated accordingly. The C1/C2/C3 mention at line 120 is the value-convention hierarchy (a different ladder), not the GUC axis — left unchanged. Removed at candidate stage per FORMAT.md Gate 4.
- **Interaction between assumptions.** The six assumptions are not fully orthogonal. Causal sufficiency failure and edge-independence failure are the same failure (item 5 is a consequence of item 2 via CMC). Directed separation failure can propagate through the orient cascade into the strategy-layer results (which inherit their structure from the cascade). A fuller treatment would map the dependency graph among assumptions and characterize cascading failure modes.
- **Quantitative failure modes.** For each independence assumption, the theory has or could have a quantitative failure bound — how much the dependent result degrades as a function of the independence-violation magnitude ($\kappa_{\text{processing}}$, the covariance magnitude, the mutual information between channels). These bounds are partially specified in segment-level caveats; collecting them in one place would strengthen the audit.

- **Empirical audit.** A concrete agent could be scored against the six assumptions to produce an “independence profile.” For software agents: directed separation $\sim$ holds (Separated), causal sufficiency $\sim$ holds (test-based Regime A), channel independence $\sim$ holds (tests target disjoint behaviors), scalar tempo may fail (component-level gain variation). For LLM agents: directed separation fails structurally (Class 3 Coupled), causal sufficiency varies by task, channel independence varies. The profile would be a diagnostic for where the theory’s exact claims apply to the agent and where they degrade.

Appendix Z

Discussion: Approximation Tiering

AAT uses a recurring meta-pattern for handling intractability: when a problem admits no tractable exact treatment in general, introduce a tiered hierarchy of approximations with proved monotonicity between tiers and a diagnostic for ascending when needed. Three such hierarchies exist in the theory — the Correlation Hierarchy (L0/L1/L2) in 8.3, the Convention Hierarchy (C1/C2/C3) in 6.6, and the Tier 1/2/3 contraction taxonomy in 13.1. This segment articulates the pattern explicitly, identifies what makes a successful approximation tiering, and notes where other scattered simplifications might fit the same shape.

Formal Expression.

A successful approximation tiering has four components:

Discussion (approximation-tiering).

(AT1) **A parameter indexing tractability.** Some quantity (correlation modeling depth; continuation-policy fidelity; operator regularity) that admits a natural ordering from least to most demanding computation.

(AT2) **Monotonicity.** A proved ordering of the results produced at each level — each higher tier dominates the lower in the direction of interest (calibration accuracy, diagnostic force, guarantee strength).

(AT3) **Graceful degradation.** Lower tiers produce usable (not vacuous) results, with the specific form of the degradation characterized. An agent stuck at the lowest tier knows what it is missing, not just that it is incomplete.

(AT4) **Ascension diagnostic.** A signal the agent can detect at a lower tier that indicates escalation to a higher tier is warranted. Without this, the tiering is descriptive but not operational.

The three AAT tierings.

Table Z.1

<i>Hierarchy</i>	<i>Parameter</i>	<i>Monotonicity</i>	<i>Lowest tier</i>	<i>Highest tier</i>	<i>Ascension diagnostic</i>
Correlation (8.3)	Modeling depth of inter-edge dependence	L0 is conservative; L1 is unbiased on augmented graph; L2 is the full joint	L0 (independence model, $O(V + E)$ propagation)	L2 (full joint, $O(2^m)$ in general)	Sibling-edge covariance after credence convergence (9.2)

<i>Hierarchy</i>	<i>Parameter</i>	<i>Monotonicity</i>	<i>Lowest tier</i>	<i>Highest tier</i>	<i>Ascension diagnostic</i>
Convention (6.6)	Continuation-policy fidelity	$A_O^{(1)} \leq A_O^{RH} \leq A_O^B$ (proved monotonicity)	C1 (one-step improvement)	C3 (Bellman optimal)	Persistent $\delta_{\text{sat}} > 0$ under C1 that C2 replanning may resolve
Contraction (13.1)	Operator regularity for bridge lemma	Tier 1 $\supset$ Tier 2 $\supset$ Tier 3 in terms of proved contraction strength	Tier 3 (domain-specific verification required)	Tier 1 (contraction proved for full class)	Structural test: is the correction strongly monotone, locally convex, or neither?

Each row satisfies (AT1)–(AT4) fully — these are mature tierings in the theory. Each tiering is independently motivated by a different source of intractability, and each has its own ascension mechanism. Their structural similarity is not designed-in; it is the consequence of facing three separate intractable problems with the same modeling strategy.

Candidate future tierings. Several other scattered simplifications in the theory have the right shape to become tierings but are not currently organized that way:

- **Scalar vs. per-dimension tempo** (around 3.8, 16.5). Tier 0 (scalar isotropic), Tier 1 (per-dimension), Tier 2 (full tensor with off-diagonal coupling). Monotonicity: scalar overestimates margin, per-dimension is exact for diagonal-gain systems, full tensor handles off-diagonal gain coupling. Ascension diagnostic: gain variance across dimensions.
- **AND/OR parameterization** (8.2). Tier 0 (AND/OR, $O(k)$ parameters per node), Tier 1 (weighted/threshold, $O(k)$ additional parameters), Tier 2 (full CPT, $O(2^k)$ parameters). Monotonicity: expressiveness. Ascension diagnostic: systematic miscalibration at AND/OR nodes that survives L1 augmentation.
- **Identifiability regimes** (9.5). Regime A/B/C is already a tiering of causal identification quality, with t_{ij} as the indexing parameter. Monotonicity: interventional $\geq$ partial $\geq$ observational. Ascension diagnostic: available intervention opportunities in the domain.

Promoting these to named tierings with explicit (AT1)–(AT4) structure would make AAT’s scope parameterization more uniform. This is not pursued here — it is noted as a direction for editorial consolidation.

Epistemic Status.

Robust-qualitative. Max attainable: *robust-qualitative*. The meta-pattern is an editorial observation: three existing hierarchies in the theory share the same four-component structure, and the shared structure is worth naming because it makes the theory’s scope-parameterization move visible rather than implicit. The pattern itself is not a theorem — there is no result that says “every intractable AAT problem admits a (AT1)–(AT4) tiering.” The candidate future tierings are conjectures about where the pattern could be extended; each would require its own monotonicity proof and ascension diagnostic.

The three existing tierings are individually grounded: the L0→L1 monotonicity holds under the CMC theorem and augmentation construction; the C1→C2→C3 monotonicity is proved in 6.6; the Tier 1/2/3 taxonomy is grounded in operator theory (strong monotonicity, local convexity, arbitrary).

Discussion.

Why this matters. AAT's results are often presented as "exact under assumption X." A reader can misread this as "the theory works when X holds and breaks otherwise." The tiering pattern reveals a different structure: when X fails, a named lower tier takes over with a characterized weaker result, and the theory provides a diagnostic for when to escalate to reinstating X by structural repair. This is graceful degradation — a property that a theory wanting to apply across a range of agents and domains needs, and that AAT achieves in three places independently.

Reading AAT through the tiering lens: the theory's "exact" core is what it guarantees at the highest tier of each hierarchy. Its "conditional" periphery is where specific tiers are in force. The claim is not that agents should always operate at the highest tier — that would often be intractable — but that the theory tells the agent which tier it is in and how to get to a higher one when the binding constraint changes.

Connection to Y. The two meta-segments are complementary. Y enumerates the independence assumptions whose failure drops a result from exact to conditional. This segment enumerates the tierings that provide the structured *recovery* from those drops. Together they characterize AAT's scope parameterization: the independence audit says where the boundaries are; the tiering pattern says how to navigate within them.

What a full tiering promotion would look like. If the scattered simplifications listed above were promoted to named tierings, the theory's scope-parameterization would be dramatically more uniform: every conditional result would come with its own tiering and ascension diagnostic. This is aspirational. The three existing tierings took substantial segment-work to formalize (a full Appendix derivation for the CMC, a monotonicity proof for the convention hierarchy, a spike for the incremental sector bound). Extending the pattern to five or six hierarchies would be correspondingly substantial.

The pattern is not unique to AAT. Approximation tiering is a common move in applied mathematics — numerical methods (low-order vs. high-order integrators with error bounds), information theory (typical vs. exact coding with rate-distortion monotonicity), statistical inference (maximum-likelihood vs. Bayesian vs. nonparametric). AAT's contribution is not the tiering pattern itself but its deployment across the specific intractable problems that adaptive-agent theory faces.

Working Notes.

- **Formal characterization of the tiering pattern.** Is there a mathematical structure that unifies approximation tiering across domains? Candidates: lattices of model classes ordered by inclusion, rate-distortion curves with explicit corners, hierarchies of Galerkin approximations. None of these is an exact match; the AAT tierings are closer to "ordered families of sufficient conditions" than to any standard mathematical hierarchy. Worth investigating whether a cleaner abstract pattern exists.
 - **Interaction between tierings.** An agent operating at L1 correlation, C2 convention, and Tier 2 contraction is in a specific combined regime. The cross-hierarchy interactions are not worked out — is there cross-hierarchy monotonicity? (E.g., does L1 change anything about the convention hierarchy's guarantees?) Each tiering is independently-grounded but the joint structure is not yet mapped.
 - **Diagnostic costs.** Each ascension diagnostic has a cost: detecting sibling covariance requires observing convergence; detecting C1-inadequacy requires comparing replanning values; detecting Tier 1 violations requires verifying strong monotonicity. A unified treatment of "when is the diagnostic itself worth running?" would connect this segment to 4.1 and the allocation analysis in 10.2.
-

Appendix AA

Discussion: Compression Operations in AAT

AAT contains four compression operations — the epistemic model M_t , the strategy DAG Σ_t , shared intent G_t^{shared} , and the composition projection Λ — each formulated in its own segment with its own objective. Three of the four are written in Information Bottleneck (IB) form already; the fourth is stated as an IB constraint. This segment makes the shared shape explicit, promotes one underspecified source (the ontologically ambiguous “true causal structure” for Σ_t) to a cleaner formulation parallel to M_t , and establishes that composition admissibility (P1) is the Lagrangian-dual of a standard IB objective. It does *not* claim the four operations reduce to a single optimization problem — cross-instance theorems do not follow from the shared shape alone, and several conditions (Lipschitz regularity (P2), dimensional reduction (P3) in the Gaussian case, interventional relevance for Level-2 edges) remain outside the IB frame.

Formal Expression.

The shared IB shape.

Every compression operation in AAT has an objective or constraint of the form:

Discussion (ib-shape).

$$T^* = \arg \min_{T|X} [I(X; T) - \beta \cdot I(T; Y)] \quad (\text{AA.1})$$

with the Markov chain $Y - X - T$. The four AAT instances specialize this with different bindings:

Table AA.1

<i>Instance</i>	<i>X (source)</i>	<i>T (compressed)</i>	<i>Y (relevance variable)</i>	<i>β (trade-off)</i>
Model compression (2.2)	$\mathcal{C}_t$	M_t	$O_{t+1:\infty} \mid a_{t:\infty}$	$\beta(\rho, \pi)$ — volatility and policy
Strategy compression (9.9)	$\mathcal{C}_t$	Σ_t	$\pi^* \mid M_t$	β_Σ — cognitive cost per decision-bit
Shared intent (14.2)	$G_t^{\text{full}} = (O_t, \Sigma_t)$	G_t^{shared}	$a_t^{\text{coordinated}}$	bandwidth per coordination-bit

Instance	X (source)	T (compressed)	Y (relevance variable)	β (trade-off)
Composition projection (13.1 P1)	$X_{\text{micro},t}$	$\Lambda_X(X_{\text{micro},t})$	$o_{\text{micro},t+1} \mid a_{\text{micro},t}$	$\beta(\epsilon_I)$ — rate-distortion Lagrange multiplier

What the four instances share: *shape* (the objective structure), *variational calculus* (minimization over stochastic compressors), and *rate-distortion interpretation* (each trade-off parameter indexes a point on the frontier). What they do not share: source type (history vs. structured state), relevance-variable availability (observed vs. latent), computability (Gaussian closed forms vs. variational approximation), or a single joint optimization across the four. The level of unification is *medium*: shared shape and vocabulary, not a shared master problem.

Strategy compression: source reformulation.

The current statement in 9.9 has the Σ_t IB objective as:

Formulation (strategy-compression-source).

$$\Sigma_t^* = \arg \min_{\Sigma_t} [\text{DL}(\Sigma_t) - \beta_{\Sigma} \cdot I(\Sigma_t; \pi^* \mid M_t)] \quad (\text{AA.2})$$

Two issues with this as currently written:

1. **The compression cost is description length, not mutual information.** DL and $I(X; T)$ are related through coding-theoretic equivalences but coincide only under specific coding schemes. Using DL in the complexity term blocks the identification of this objective as an IB instance directly.
2. **The “source” is not an AAT object.** To fit the IB shape, the objective implicitly treats Σ_t as a compression of “the true causal structure.” That structure is not part of AAT’s ontology — the agent never has access to it; it is only ever implicit.

Reformulation. Treat Σ_t as a compression of $\mathcal{C}_t$ (the interaction history — the agent’s only evidence) *for decision-relevance*, parallel to M_t which is a compression of $\mathcal{C}_t$ *for prediction-relevance*:

$$\Sigma_t^* = \arg \min_{\Sigma_t} [I(\mathcal{C}_t; \Sigma_t) - \beta_{\Sigma} \cdot I(\Sigma_t; \pi^* \mid M_t)] \quad (\text{AA.3})$$

Under this reformulation:

- The source $\mathcal{C}_t$ is a well-defined AAT object, shared with the M_t instance.
- The two instances differ cleanly in relevance variable: M_t is compressed for prediction ($Y = o_{t+1:\infty} \mid a$); Σ_t is compressed for guidance ($Y = \pi^* \mid M_t$). Prediction is about *what will happen*; guidance is about *what to do*. Both are computed from the same history, with different targets.
- The information cost $I(\mathcal{C}_t; \Sigma_t)$ replaces $\text{DL}(\Sigma_t)$ as the theory-level compression term. The DL formulation remains useful as an *operational* cost measure for specific DAG encodings; it is not the theoretical quantity the IB objective minimizes.

Relationship between the two cost measures. Under MDL with a specific encoding scheme for DAGs (the one in 9.9), $DL(\Sigma_t)$ is an upper bound on $I(\mathcal{C}_t; \Sigma_t)$ for DAGs produced by the given encoder — coding cost dominates distinguishability cost. In practice, DL is computable and I is not, so the operational minimization uses DL as a proxy; the theoretical minimization uses I . The IB objective above is the theoretical statement; the DL-based minimization in 9.9 remains the practical one.

Variational form. The Shannon mutual information $I(\Sigma_t; \pi^* \mid M_t)$ in the relevance term collapses to zero when π^* is deterministic-from- M_t . The variational form (cf. 9.9) replaces the relevance term with the KL-divergence $D_{KL}(\pi^*(\cdot \mid M_t) \parallel Q_{\Sigma_t}(\pi \mid M_t))$ — note the π^* -first direction, which is *forced* by a regret-bound derivation (full derivation and admissible-divergence family analysis in T). Under bounded value range and deterministic π^* , Pinsker’s inequality gives $R(Q_{\Sigma_t}) \leq V_{\max} \sqrt{\frac{1}{2} D_{KL}(\pi^* \parallel Q_{\Sigma_t})}$ where R is the strategy-induced regret against π^* ; the opposite KL direction is vacuous ($+\infty$ under deterministic π^* whenever Q_{Σ_t} has off-optimum mass). The π^* -first KL is well-defined and graded under deterministic π^* . Under the variational reading, the AAT Σ_t is a tractable approximation of the policy-relevant posterior, and the KL term measures approximation quality — aligning the strategy compression with the variational free energy decomposition $-F = \text{accuracy} - \text{complexity}$ in active inference (Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017; Da Costa, Parr, Sajid, Veselic, Neacsu & Friston 2020). The direction alignment is convergent: both AAT’s regret-bound and active inference’s variational-free-energy derivations pick π^* -first KL (reverse-KL in the variational-inference vocabulary), with AAT’s additional interpretation being an upper-regret-bound rather than free-energy-gradient. The shared-IB-shape framing of the four AAT compression operations is the rate-distortion specialization of this variational picture; AAT’s commitment is to the rate-distortion form (which gives the (P1) Lagrangian-dual derivation and the four-instance unification at U-medium), not to the full variational free-energy interpretation.

Composition admissibility (P1) as IB Lagrangian-dual.

13.1 condition (P1) is currently stated as a lower-bound constraint:

Derived (p1-ib-dual, from composition-closure + rate-distortion duality).

$$I(\Lambda_x(X_{\text{micro},t}; \Lambda_o(o_{\text{micro},t+1}) \mid \Lambda_a(a_{\text{micro},t})) \geq (1 - \epsilon_I) \cdot I(X_{\text{micro},t}; o_{\text{micro},t+1} \mid a_{\text{micro},t}) \quad (\text{AA.4})$$

This is the *constraint form* of an IB problem. In Lagrangian form:

$$\Lambda^* \in \arg \min_{\Lambda \in \mathcal{P}} [I(X_{\text{micro}}; \Lambda_x(X_{\text{micro}})) - \beta(\epsilon_I) \cdot I(\Lambda_x(X_{\text{micro}}); Y_{\text{rel}})] \quad (\text{AA.5})$$

where $Y_{\text{rel}} = (o_{\text{micro},t+1} \mid a_{\text{micro},t})$ and $\beta(\epsilon_I)$ is the Lagrange multiplier corresponding to the relevance-preservation tolerance ϵ_I . The correspondence $\epsilon_I \leftrightarrow \beta$ is the standard rate-distortion duality: smaller ϵ_I (more relevance preserved) corresponds to larger β (less aggressive compression).

Consequence: admissible projections are those that sit *on or above* the IB frontier at rate $I(X; T) \leq I_{\max}(\epsilon_I)$. The information-theoretic content of (P1) is exactly “project onto the IB frontier with a tolerance ϵ_I .” This formalizes the connection previously logged in 13.1’s Working Notes and in 14.1’s §Connection to the Information Bottleneck.

What this resolves. The 13.1 Working Note “Open: Information Bottleneck unification” is now resolved for (P1): it is the Lagrangian-dual of the IB constraint at $\beta(\epsilon_I)$. The corresponding Working Note in 14.1 §6 moves from conjecture to derived result. Nothing else about (P1) changes — the condition continues to define admissible projections; only its information-theoretic reading is now explicit.

The symmetric two-Kalman witness, and the falsification handle.

The (P1)↔IB reading has a worked witness in the two-Kalman composition setup (14.1's linear-Gaussian case). With symmetric process noise $Q = q \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$, identical observation noise, and homogeneous gains ($\Delta K = 0$), the canonical-correlation basis between the micro-state $X = (\hat{\omega}_1, \hat{\omega}_2)$ and the relevance variable $Y = o_{t+1}$ is the symmetric pair $u_{\pm} = (1, \pm 1)/\sqrt{2}$, with generalized eigenvalues

Derived (linear-Gaussian-symmetric means-sum optimality).

$$\lambda_+ = \frac{(1 + \rho_M)\sigma_{\hat{\omega}}^2 + q(1 + \rho) + r}{q(1 + \rho) + r}, \quad \lambda_- = \frac{(1 - \rho_M)\sigma_{\hat{\omega}}^2 + q(1 - \rho) + r}{q(1 - \rho) + r}, \quad (\text{AA.6})$$

so the means-sum projection $u_+^\top X = (\hat{\omega}_1 + \hat{\omega}_2)/\sqrt{2}$ — the natural (P1)-admissible projection — is simultaneously the PCA-optimal 1D projection of X and the CCA-optimal 1D projection of X for predicting Y . The coincidence is symmetry-forced (the canonical basis and the principal-component basis of Σ_X align under symmetric Q and $\Delta K = 0$); in general the two bases differ. The retained relevance at 1D is $\frac{1}{2} \log \lambda_+$ of the full $\frac{1}{2} \log(\lambda_+ \lambda_-)$, ranging from half (at $\rho \rightarrow 0$, symmetric contributions) to all of it (at $\rho \rightarrow 1$, collapsed directions). Whether the means-sum additionally attains the Gaussian IB *frontier* remains the deferred mechanical derivation (Working Notes below); the canonical-direction identity here is the structural half that does not wait on it.

In the heterogeneous case ($\Delta K \neq 0$, where the means-sum produces genuine closure defect $\varepsilon_x > 0$), the symmetry breaks and the means-sum is *no longer* the top canonical direction: the IB-optimal 1D projection is a rotation of it, and — if the IB reading of (P1) is right — that rotation achieves strictly lower ε_x than the means-sum. This is a falsifiable consequence of the unification, checkable numerically in the existing two-Kalman machinery: if the rotated projection fails to improve ε_x when $\Delta K \neq 0$, the IB reading of (P1) is disconfirmed as more than shape-coincidence. Under the unification, means-sum admissibility is *conditional on gain symmetry* rather than free.

Hypothesis (heterogeneous-gain falsification handle).

What stays separate from the IB frame. Three admissibility and structural conditions do *not* reduce to IB:

- **(P2) Lipschitz continuity.** Not an IB constraint. The bridge lemma in 13.1 requires (P2) for analytic reasons (propagating bounded closure defect into bounded trajectory error); IB does not impose any continuity condition on compressors. (P2) remains a separate admissibility condition.
- **(P3) Dimensional reduction.** In the Gaussian-IB case relevant to composition, the IB-optimal T at any finite β typically uses full support of $\mathbb{R}^{\dim X}$; the categorical dimensionality reduction $\dim \mathcal{X}_c < \dim \mathcal{X}_{\text{micro}}$ is a *harder* condition than any rate constraint. (P3) remains separate. (In discrete cases it may be rate-implied, but the composition instance is Gaussian.)
- **Interventional relevance (Level 2).** The relevance variable in all four instances is associational (Y in a joint distribution with X and T). Strategy edges in the regime-indexed interpretation (9.5) want interventional relevance for Regime A: “what edge (i, j) predicts *under* $do(i)$.” This is a strictly stronger requirement than IB provides. Adapting IB to interventional relevance (causal IB, Wieczorek & Roth 2017 and follow-ups) is an extension direction, not a specialization of the master IB.

The honest slogan is therefore “the (P1)-analog in each compression operation is IB; regularity, dimensionality, and interventional relevance are separate conditions that compose with it.”

Epistemic Status.

Robust-qualitative. The claim that the four compression operations share IB shape is *discussion-grade* — it is a presentational observation supported by examining each segment’s formulation and noting structural alignment. The Σ_t source reformulation is a *formulation choice* replacing one underspecified source with a cleaner one; no derivation is needed because the new formulation and the old are not the same claim. The (P1) as Lagrangian-dual of IB is *derived* — rate-distortion duality is standard (see §1.12–13 of Cover & Thomas) and the constraint-form $\leftrightarrow$ Lagrangian-form equivalence is mechanical.

Max attainable: *robust-qualitative* for the shared-shape claim; *derived conditional on rate-distortion duality* for (P1) as IB Lagrangian-dual; *formulation* for the Σ_t source reformulation. The strongest version of the unification claim — “U-strong,” that the four operations are the same optimization problem with different bindings — is *not* established and is unlikely to be, for reasons in the Discussion.

This segment does not promote any of the four instance segments. Each remains the primary site for its own instance. What this segment adds is the shared-shape framing, the Σ_t source fix, and the (P1) derivation.

Discussion.

Why not go further. Two distinct claims could be made: (a) U-strong — the four operations are the *same* optimization problem with different bindings, so a single derivation specializes to each instance; (b) U-medium — the four share *shape*, vocabulary, and variational structure but differ in substantive ways (source type, relevance-variable availability, computability) that prevent a single derivation from covering all four. U-strong requires cross-instance theorems, results of the form “because these are all IB, property X holds across all four.” No such theorems are identified. The shared IB shape is legibility-enhancing but does not produce deductions for free. This segment therefore states U-medium (shared shape) honestly rather than overclaiming U-strong.

Honest credit to the hierarchical-generative-model lineage. AAT’s four compression operations are a structurally narrower family than the operations a hierarchical generative model in the predictive-coding lineage (Friston 2008, “Hierarchical models in the brain,” *PLoS Comp. Biol.* 4; Friston 2010, “The free-energy principle: a unified brain theory?” *Nat. Rev. Neurosci.* 11; Clark 2013, “Whatever next?,” *Behav. Brain Sci.* 36; Hohwy 2013, *The Predictive Mind*, OUP) could express. A hierarchical generative model layers compressions of compressions, with each layer producing a representation tuned to the next layer’s prediction target — and the AAT compressions (M_t for prediction, Σ_t for guidance, shared intent for coordination, Λ for level-bridging) are all expressible within that frame as specific layer-bindings. What AAT adds is structural: (a) the *relevance variables* Y are made first-class with explicit per-instance bindings (see the table in §“The shared IB shape”); (b) the (P1)–(P3) admissibility conditions for composition give a measurable closure-defect bound that hierarchical-generative-model layering does not natively produce (13.1); (c) regime-indexed edges (9.5) introduce Pearl-Level-2 relevance for Regime A, which standard hierarchical generative models do not address. The shared family is real; AAT’s additions are also real. The honest framing is “AAT’s compressions are a structured subset of the hierarchical-generative-model family with additional structure load-bearing for AAT’s specific results.”

Why this is not the “biggest available unification.” It is better described as the *most legible* unification. The pattern is already half-named at each instance site (three of four segments already write their objectives in IB form); the segment-level contribution is sharpening the naming and fixing one formulation issue (Σ_t source), not discovering a new structural result. The biggest leverage concision move in the theory — the sector-Lyapunov template in G — is substantively different: it removes repeated content and absorbs proofs that previously appeared in multiple segments. This segment adds legibility without removing much.

What each β means. The four trade-off parameters are not unified in value, only in role:

- $\beta(\rho, \pi)$ for M_t depends on environmental volatility and policy; fast-changing environments or high-value policies both warrant higher β .

- β_Σ for Σ_t is the cognitive cost per decision-relevant bit retained; bounded-context agents (LLMs with finite windows) have low β_Σ .
- The bandwidth β for shared intent is the communication-capacity-per-coordination-bit; low-bandwidth teams have low β .
- The $\beta(\epsilon_I)$ for (P1) is the rate-distortion Lagrange multiplier at tolerance ϵ_I .

These are four calibration problems, not one. A theory of *resource allocation across the four compression operations* — where a single cognitive budget is split across modeling, strategy, communication, and composition — is not currently in AAT, and the unification does not produce it. If such a theory is ever needed, it would tie the four β s together through an outer optimization; the spike flags this as an open direction.

Relationship to 14 and 14.1. The unity dimensions parametrize rate-distortion curves for closure defects (14.1). Under the present segment’s framing, unity dimensions are *curve parameters for the Λ instance of the IB schema*. This tightens the existing 14.1 Discussion, which already presented the rate-distortion reading as the correct interpretation; it is now stated uniformly across the four compression operations.

Relationship to Q. The DAG-uniqueness result derives the *shape* of Σ_t from operational postulates (Q, Cox-analog). The present segment characterizes the *compression level* of Σ_t . These operate at different levels: uniqueness supplies the representational type (the compressed T is a DAG), IB supplies the rate-distortion trade-off within that type (how richly the DAG is populated). The two arguments are independent and compatible — IB-compressed Σ_t is a DAG-with-fewer-nodes, not a non-DAG.

Position relative to the additive-coordinate-forcing pattern. The IB Lagrangian’s $I(X; T) - \beta \cdot I(T; Y)$ is an additive decomposition on a log-scale coordinate (mutual information is logarithmic by construction) — the same shape that 5.5 catalogs at the chain / divergence / update layers. The IB case is classified as an *adjacent family member* rather than a fourth primary instance because 2.2 adopts the Lagrangian form from Tishby, Pereira & Bialek 1999 as an applied external theorem rather than re-deriving it under an AAT-internally-motivated additivity axiom. The Shore-Johnson 1980 system-independence axioms that axiomatize IB’s additivity are cited in T §6.1; if a future framing pass promotes Shore-Johnson to an explicit AAT axiom, IB would move from adjacent member to fourth primary instance.

Working Notes.

- **The Σ_t source reformulation changes the theoretical quantity without changing the operational computation.** 9.9’s DL-based minimization remains the practical procedure; what changes is the theoretical claim about what that procedure approximates. Depending on promotion-workflow preferences, the reformulation may warrant a small note in 9.9 referencing this segment.
- **(P1) as IB Lagrangian-dual does not close 13.1’s other Working Notes.** Computability of (P1) for nonlinear/non-Gaussian systems, choice of ϵ_I , and N -agent scaling remain open. The unification resolves the *framing* question but not the *computation* questions.
- **Synthesis segment vs. full unification.** This segment is a targeted synthesis: it fixes the Σ_t source, derives (P1) as IB Lagrangian-dual, and tables the four instances. It does *not* rewrite the four instance segments as specializations of a master schema. If future work reveals that the four instance segments are pulling in inconsistent directions (e.g., if the Σ_t reformulation creates friction with the DL-based minimization in 9.9), that is the signal to escalate to a full rewrite in which the instance segments become thin specializations. Short of that signal, this targeted synthesis is the stopping point.
- **The Gaussian IB frontier derivation is deferred.** Completing the derivation that the means-sum projection attains the Gaussian IB frontier in the symmetric two-Kalman case would promote 14.1’s rate-distortion claim from discussion-grade to derived. The obstruction is mechanical (specializing Chechik, Globerson, Tishby & Weiss 2005, “Information Bottleneck for Gaussian Variables,” *J. Machine Learning Research* 6:165–188, Theorem 3.1 to the symmetric-gain setup) rather than structural — feasible as a follow-up derivation, not required for this segment. The *canonical-direction half* (means-sum =

PCA-optimal = CCA-optimal under symmetry, with explicit $u_{\pm}/\lambda_{\pm}$) is now landed in the body's §symmetric-two-Kalman-witness (2026-07-16, from the bulk-64 verification of spikes/.integrated/spike-ib-unification-plan.md §5.4–5.6); only the frontier-attainment step remains deferred.

- **The heterogeneous-gain numeric check is unrun.** The falsification handle in the body (§witness: IB-optimal rotation should beat the means-sum's ε_x when $\Delta K \neq 0$) is a small numerical experiment on the existing two-Kalman machinery — a natural companion to the frontier derivation above; neither has been executed.
-

Appendix AB

Derivation: Observation-Ambiguity Bias-Bound Constant C

The observation-ambiguity bias bound carried by Class 3 (Coupled) agents in the logogenic-agents scope — $\|\Delta M_{\text{bias}}\| \leq C \cdot \kappa_{\text{processing}} \cdot I(G; \Omega_{\tau} \mid e_{\tau}, M_{\tau-})$ (`#scope-observation-ambiguity-modulation`, `#result-section-ii-survival`) — previously treated the constant C as “domain-dependent” and the bound as “order-of-magnitude guidance, not a theorem.” This appendix derives C under two named sub-scopes, records a no-go showing that C cannot be universal without the (PI) parameterization-invariance axiom of 4.10, and documents two failed derivation routes so future agents do not repeat them.

Formal Expression.

§1 — Setup and the audit before strengthening. Let $M_{\tau-} \in \mathcal{M}$ be the pre-update epistemic substate. Let e_{τ} be the event triggering update, G_t the goal substate, and Ω_{τ} the latent world-state. At the **causally-disciplined** baseline ($\kappa_{\text{processing}} = 0$ — Class 1 by construction or an idealized Class 2 in effect, equally; 6.3), the update $f_M(M_{\tau-}, e_{\tau})$ is goal-blind: $M_{\tau+}^{\text{decoupled}} = f_M(M_{\tau-}, e_{\tau})$, and the bias below is zero. In Class 3 (Coupled) scope, the coupled update $f_X^M(X_{\tau-}, e_{\tau})$ carries goal-conditional reweighting; the bias is

$$\Delta M_{\text{bias}} := f_X^M(X_{\tau-}, e_{\tau}) - f_M(M_{\tau-}, e_{\tau}) \quad (\text{AB.1})$$

Pre-strengthening type audit. For the bound “ $\|\Delta M_{\text{bias}}\| \leq C \cdot \kappa \cdot I$ ” to be well-typed:

1. **Norm on $\mathcal{M}$.** The LHS is a norm on model-space. $\mathcal{M}$ is the model space of 2.1. Three candidate norms: Euclidean on parameters, total variation on induced measures, Fisher-Rao geodesic distance. **Under the (PI) parameterization-invariance axiom in 4.10** (fourth primary instance of 5.5), Euclidean-on-parameters is a coordinate artifact and Fisher-Rao is the canonical AAT-invariant choice on statistical-manifold sub-cases of $\mathcal{M}$ (Čencov 1982 uniqueness).
2. **Regularity of f_X^M .** For the bound to be a theorem, f_X^M must satisfy some regularity. The Bayesian-posterior model (prior + likelihood reweighting) is the canonical working class; it covers the attention-reweighting mechanism typical of Class 3 (Coupled) architectures to leading order.
3. **Information coordinate.** $I(G; \Omega_{\tau} \mid e_{\tau}, M_{\tau-})$ is in nats (or bits). Converting information to state-distance is exactly what the Pinsker / Bretagnolle-Huber / Otto-Villani / Bakry-Émery machinery does.

The bound is well-typed under (a) named norm, (b) bounded f_X^M regularity, (c) specified information-geometric inequality. Without (PI) adopted, C is norm-dependent; under (PI), Fisher-Rao is canonical and C becomes derivable.

§2 — Track 1: Transport-inequality derivation under log-Sobolev + Lipschitz-posterior.

Named sub-scope (H1-H3).

Derived (w2-transport-track, conditional on H1-H3).

- **(H1) Statistical-manifold sub-case.** Each $M_t \in \mathcal{M}$ corresponds to a probability distribution P_{M_t} over world-states. $\mathcal{M}$ is (locally) a statistical manifold.
- **(H2) Log-Sobolev inequality.** The observation distribution $P_{\Omega|e,M}$ satisfies a log-Sobolev inequality (LSI) with constant $\rho_{\text{LSI}} > 0$. Sufficient condition: $P_{\Omega|e,M}$ is strongly log-concave with constant K (Bakry-Émery 1985 curvature-dimension condition gives $\rho_{\text{LSI}} \geq K$). For Gaussian observation models, $\rho_{\text{LSI}} = 1/\sigma^2$ explicitly.
- **(H3) Lipschitz-posterior stability.** The Bayesian-posterior pushforward from observation to state is L_{post} -Lipschitz in W_2 :

$$W_2(P_{M|e,G}, P_{M|e}) \leq L_{\text{post}} \cdot W_2(P_{\Omega|e,G}, P_{\Omega|e}) \quad (\text{AB.2})$$

Sufficient condition: well-posed Bayesian inverse problem with bounded log-likelihood Hessian (Stuart 2010 *Inverse problems: a Bayesian perspective*, *Acta Numerica* 19:451–559, Theorem 4.6; Hairer, Stuart & Vollmer 2014 *SIAM J. Math. Anal.* 46(1):415–451 for explicit W_2 -bounds in infinite-dimensional settings).

Step 1 — KL from mutual information. By the chain rule of relative entropy (Cover & Thomas 2006 Theorem 2.5.3):

$$\mathbb{E}_G[\text{KL}(P_{\Omega|e,M,G} \| P_{\Omega|e,M})] = I(G; \Omega_\tau | e_\tau, M_{\tau-}) \quad (\text{AB.3})$$

Exact identity.

Step 2 — Otto-Villani under LSI. From (H2) and Otto & Villani 2000 *J. Funct. Anal.* 173(2):361–400 Theorem 1:

$$W_2^2(P_{\Omega|e,M,G}, P_{\Omega|e,M}) \leq \frac{2}{\rho_{\text{LSI}}} \cdot \text{KL}(P_{\Omega|e,M,G} \| P_{\Omega|e,M}) \quad (\text{AB.4})$$

Taking expectation over G and substituting Step 1:

$$\mathbb{E}_G[W_2^2(P_{\Omega|e,M,G}, P_{\Omega|e,M})] \leq \frac{2}{\rho_{\text{LSI}}} \cdot I(G; \Omega_\tau | e_\tau, M_{\tau-}) \quad (\text{AB.5})$$

Step 3 — Lipschitz-posterior pushforward. From (H3):

$$\mathbb{E}_G[W_2^2(P_{M|e,G}, P_{M|e})] \leq L_{\text{post}}^2 \cdot \mathbb{E}_G[W_2^2(P_{\Omega|e,G}, P_{\Omega|e})] \quad (\text{AB.6})$$

Step 4 — $\kappa_{\text{processing}}$ factor. The $\kappa_{\text{processing}}$ coefficient from 6.3's Class 1/2/3 (Separated/Partial/Coupled) taxonomy multiplies the goal-conditional reweighting strength by the modularity coefficient. For Class 3 (Coupled), $\kappa_{\text{processing}} \approx 1$; for Class 2 (Partial) with modularity κ , the effective bound carries a factor κ multiplicatively on the information term.

Result (Track 1). [Derived, conditional on (H1)-(H3)]

$$\mathbb{E}[W_2^2(M_{\tau+}^{\text{coupled}}, M_{\tau+}^{\text{decoupled}})] \leq \frac{2L_{\text{post}}^2}{\rho_{\text{LSI}}} \cdot \kappa_{\text{processing}} \cdot I(G; \Omega_{\tau} \mid e_{\tau}, M_{\tau-}) \quad (\text{AB.7})$$

The constant is explicit: $C_{W_2}^2 = 2L_{\text{post}}^2/\rho_{\text{LSI}}$, linear in I , with geometric interpretation:

- L_{post} grows with *prior-likelihood tension* — ill-conditioned inverse problems amplify bias.
- ρ_{LSI} grows with *observation-distribution concentration* — sharper observations yield tighter bounds.
- The ratio $2L_{\text{post}}^2/\rho_{\text{LSI}}$ captures the **geometric stiffness** of the update: small- ρ /large- L = soft, goal-sensitive updates; large- ρ /small- L = stiff updates that resist goal-bias.

§3 — Track 2: Fisher-Rao derivation under (PI) + Čencov + small-information regime.

Named sub-scope (H1 + H4).

Derived (fisher-rao-track, conditional on H1 + H4).

- **(H1) Statistical-manifold sub-case** — as in §2. Under the (PI) parameterization-invariance axiom of 4.10, Čencov’s 1982 uniqueness theorem (*Statistical Decision Rules and Optimal Inference*, AMS) forces the Fisher information metric as the canonical Riemannian metric on $\mathcal{M}$ up to global scale (Ay, Jost, Lê & Schwachhöfer 2017 *Information Geometry*, Theorem 5.1).
- **(H4) Small-information regime.** $I(G; \Omega_{\tau} \mid e_{\tau}, M_{\tau-}) \ll 1$ nat. The second-order Taylor expansion of KL at coincident distributions is sharp.

Step 1 — KL-to-Fisher-squared-distance identity. For nearby distributions P, Q on a statistical manifold with Fisher metric $\mathbf{I}$, the KL divergence admits the second-order expansion

$$\text{KL}(P\|Q) = \frac{1}{2} \cdot d_{FR}^2(P, Q) + O(d_{FR}^3) \quad (\text{AB.8})$$

where d_{FR} is the Fisher-Rao geodesic distance (Cover & Thomas 2006 §12.5; Amari & Nagaoka 2000 §3.7 Theorem 3.1). This is the infinitesimal form of the Bregman divergence on the exponential family’s dual geometry (cf. T §6.3 for the related Fenchel-Bregman identification).

Step 2 — Posterior-displacement in Fisher-Rao. Under (H1)+(H4) + Bayesian-posterior-class f_X^M , the goal-conditional posterior and goal-marginalized posterior are nearby points on the statistical manifold; their Fisher-Rao distance satisfies

$$d_{FR}^2(M_{\tau+}^{\text{coupled}}, M_{\tau+}^{\text{decoupled}}) \leq 2 \cdot \text{KL}(P_{M|e,G} \parallel P_{M|e}) + O(d_{FR}^3) \quad (\text{AB.9})$$

Using the data-processing inequality $\text{KL}(P_{M|e,G} \parallel P_{M|e}) \leq \text{KL}(P_{\Omega|e,G} \parallel P_{\Omega|e})$ (Bayesian posterior is a pushforward), and Step 1 of §2 ($\mathbb{E}_G[\text{KL}(P_{\Omega|e,M,G} \parallel P_{\Omega|e,M})] = I$):

$$\mathbb{E}[d_{FR}^2(M_{\tau+}^{\text{coupled}}, M_{\tau+}^{\text{decoupled}})] \leq 2 \cdot I(G; \Omega_{\tau} \mid e_{\tau}, M_{\tau-}) \cdot (1 + o(1)) \quad (\text{AB.10})$$

Step 3 — Taking square roots (with κ factor). Under Class 2 (Partial) modularity, $\kappa_{\text{processing}}$ enters multiplicatively on the goal-conditional reweighting strength, hence on the KL and Fisher-Rao distance:

Result (Track 2). *[Derived, conditional on (H1)+(H4), small-information regime]*

$$\mathbb{E} \|\Delta M_{\text{bias}}\|_{FR} \leq \sqrt{2} \cdot \sqrt{\kappa_{\text{processing}} \cdot I(G; \Omega_{\tau} | e_{\tau}, M_{\tau-}) \cdot (1 + o(1))} \quad (\text{AB.11})$$

The constant is universal and dimension-free: $C_{FR} = \sqrt{2}$ (nats) or $\sqrt{2 \ln 2}$ (bits). **No domain-specific parameters.** The (PI) commitment eliminates the coordinate-dependence that made C ambiguous under Euclidean-parameter norms.

Scaling difference between tracks. Track 1 gives $W_2^2 \propto I$ (linear in information). Track 2 gives $d_{FR}^2 \propto I$, equivalently $d_{FR} \propto \sqrt{I}$ (square-root in information). The two tracks are not contradictory — they are bounds under different assumptions in different metrics. Track 1 is tight in the large- I regime where Otto-Villani’s linear form dominates; Track 2 is tight in the small- I regime where the Fisher-metric second-order expansion is sharp. The two compose at intermediate scales by taking the tighter of the two under the local curvature conditions.

§4 — No-go result: universal C under Euclidean-parameter norm fails.

Claim. No universal constant C — independent of $\mathcal{M}$ ’s geometry, parameterization, and coupled-update structure — exists such that $\|\Delta M_{\text{bias}}\|_{\text{Euclidean}} \leq C \cdot \kappa \cdot I$ under the Euclidean norm on an arbitrary parameter vector.

Proved (no-universal- C -euclidean, counterexample-grade).

Counterexample. Let $\mathcal{M} = \{N(0, \sigma^2) : \sigma > 0\}$ parameterized by σ . The Fisher information in σ scales as $\mathbf{I}(\sigma) = 2/\sigma^2$ — small near large σ , large near small σ . For any $C_0 < \infty$, choose σ_0 large enough that the Fisher-Rao displacement corresponding to $I(G; \Omega) = 1$ nat of goal-conditional reweighting translates to Euclidean- σ displacement $\sigma_0/\sqrt{2} > C_0$. Specifically, by Track 2’s $\sqrt{2}$ bound:

$$d_{FR}(M^{\text{coupled}}, M^{\text{decoupled}}) \leq \sqrt{2} \cdot 1 = \sqrt{2} \quad (\text{AB.12})$$

Under the Fisher metric $\mathbf{I}(\sigma) = 2/\sigma^2$, the Fisher-Rao line element is $ds^2 = 2d\sigma^2/\sigma^2$, so $\Delta\sigma \approx \sigma \cdot d_{FR}/\sqrt{2} = \sigma$ (Euclidean displacement scales linearly in σ). Taking $\sigma \rightarrow \infty$ gives arbitrarily large Euclidean- σ displacement for fixed $I = 1$ nat. No universal C in Euclidean-parameter norm exists.

Implication. The no-go strengthens the (PI) commitment rather than weakening the bound: **under (PI), Fisher-Rao is the canonical norm and $C = \sqrt{2}$ is universal; without (PI), C does not exist as a universal constant.** The (PI) axiom is *load-bearing* for this derivation, not coincidental.

Position relative to 5.1. The no-go has the shape of a floor-pattern no-go (external obstruction: Euclidean-parameter norms carry unbounded Fisher condition numbers; escape: (PI) + Fisher-Rao gives universal C), but it does not match the five-element test for a floor instance (see 5.1): it has a *single* escape (the (PI) adoption), not ≥ 2 distinct escapes, and its strengthened consequence is *re-use* of existing (PI)+Čencov machinery (fourth primary instance of 5.5) rather than elevation of new machinery. The honest position: this no-go is a **downstream theorem of the (PI) commitment**, not a new floor instance. It belongs in this appendix as motivating justification for why (PI) is load-bearing for the derivation, not as a separate meta-segment entry. (The floor-vs-coordinate-forcing distinction is articulated explicitly in #disc-additive-coordinate-forcing §”Downstream consequences of the (PI) commitment”.)

§5 — Failed derivation routes (honest record). Two derivation routes were attempted and failed at a structural level. Documented here so future agents do not re-attempt them without new evidence.

(F1) Cramér-Rao inversion — wrong direction. Attempt: treat G as a parameter estimated from Ω given (e, M) ; use the Cramér-Rao lower bound $\text{Var}(\hat{G}) \geq \mathbf{I}_G^{-1}$ inverted to bound $\|\Delta M_{\text{bias}}\| \leq L_M \cdot \sqrt{\mathbf{I}_G^{-1}}$ via a posterior-sensitivity factor. Failure: Cramér-Rao bounds estimator error *below*, not above; the bound goes in the opposite direction to what the bias bound needs. Inverting Cramér-Rao for an upper bound on bias propagation requires a fixed-estimator-class assumption that is not available for a Class 3 (Coupled) agent’s attention-reweighting mechanism. The transport-inequality route of §2 is the correct machinery.

(F2) Rate-distortion inversion — wrong problem structure. Attempt: apply Shannon’s rate-distortion inequality $R(D) \geq h(X) - \frac{1}{2} \log(2\pi e D)$ (Gaussian source), invert to $D \leq \sigma^2 \cdot 2^{-2(R-h(X))}$ with “bits in” = $I(G; \Omega \mid e, M)$. Failure: rate-distortion theory describes the minimum bits-per-symbol required to represent a source within distortion D ; it does **not** describe the maximum distortion induced by injecting side-information into an update. Source-coding theorems are about optimal representations of a source, not spatial displacement induced by side-information injection. The direction is again wrong. Transport inequalities (Attempt B) are the correct machinery.

The pattern shared across (F1) and (F2): **information-theoretic source-coding theorems (Cramér-Rao bounds, rate-distortion lower bounds) are structural lower-bound machinery for an estimator’s or encoder’s performance; they cannot be inverted to produce upper bounds on displacement induced by side-information.** Upper bounds on displacement require transport-inequality machinery (Pinsker, Otto-Villani, Bakry-Émery, posterior-stability).

§6 — Gaussian worked example.

Setup. Gaussian observation model $P_{\Omega|e,M} = N(\mu_M, \sigma^2 I)$ with fixed σ^2 ; conjugate-Gaussian prior $P_M = N(0, \tau^2 I)$; goal-conditional likelihood reweighting $P_{\Omega|e,M,G} = N(\mu_M + \beta(G), \sigma^2 I)$ where $\beta(G)$ is a goal-dependent shift with $\|\beta(G)\|^2$ bounded by the information budget $I(G; \Omega_\tau)$.

Illustrative, exact under specified assumptions.

LSI constant. Gaussian $N(\mu, \sigma^2 I)$ satisfies LSI with $\rho_{\text{LSI}} = 1/\sigma^2$ (Bakry-Émery; direct Hessian bound on $-\log p$).

Posterior-Lipschitz constant. Conjugate-Gaussian posterior: $P_{M|\Omega} = N(\mu_{\text{post}}, \Sigma_{\text{post}})$ with $\mu_{\text{post}} = \tau^2/(\tau^2 + \sigma^2) \cdot \Omega$. Lipschitz-in- Ω constant $L_{\text{post}} = \tau^2/(\tau^2 + \sigma^2) < 1$. Under W_2 -Lipschitz (Hairer-Stuart-Vollmer 2014), $L_{\text{post}} \leq 1$ for well-conditioned priors.

Track 1 bound (numerical). $C_{W_2}^2 = 2L_{\text{post}}^2/\rho_{\text{LSI}} = 2\sigma^2 \cdot \tau^4/(\tau^2 + \sigma^2)^2$. In the prior-dominant limit ($\tau^2 \ll \sigma^2$): $C_{W_2}^2 \approx 2\tau^4/\sigma^2$ (tight prior amplifies bias). In the likelihood-dominant limit ($\sigma^2 \ll \tau^2$): $C_{W_2}^2 \approx 2\sigma^2$ (sharp observations limit bias).

Track 2 bound (numerical). Under (PI) + Fisher-Rao on the Gaussian mean-manifold with metric $\mathbf{I}(\mu) = I/\sigma^2$: $d_{FR}(\mu_1, \mu_2) = \|\mu_1 - \mu_2\|/\sigma$. Under small- I : $\mathbb{E} d_{FR}(\Delta M_{\text{bias}}) \leq \sqrt{2 \cdot \kappa \cdot I}$. In Euclidean-on- μ norm: $\|\Delta \mu_{\text{bias}}\| \leq \sigma \cdot \sqrt{2\kappa I}$ — the σ prefactor is the Fisher-Rao-to-Euclidean conversion. The Euclidean form is coordinate-dependent (per Attempt E §4); Fisher-Rao form is universal.

Comparison at operating point. For $\tau = \sigma = 1$ (balanced): Track 1 gives $C_{W_2}^2 = 2 \cdot (1/4) = 1/2$, so $\mathbb{E} W_2 \leq \sqrt{I/2}$. Track 2 gives $\mathbb{E} d_{FR} \leq \sqrt{2I}$. The two are within a factor of 2 of each other at balanced scale; they diverge in the ill-conditioned limits where Track 1’s L_{post} or ρ_{LSI} blows up while Track 2 remains dimension-free.

What Is Derived vs. What Is Chosen.

Table AB.1

Property	Source	Strength
Chain-rule identity $\mathbb{E}_G[\text{KL}(P_{\Omega G} P_{\Omega})] = I(G; \Omega \cdot)$	Cover & Thomas 2006 Theorem 2.5.3	Exact
Pinsker's inequality $\ P - Q\ _{TV} \leq \sqrt{\frac{1}{2}\text{KL}}$	Standard (Csiszár-Körner)	Exact
Otto-Villani $W_2^2 \leq (2/\rho_{\text{LSI}})\text{KL}$ under LSI	Otto & Villani 2000 Theorem 1; Bakry-Émery 1985 curvature-dimension for LSI	Exact
KL-to-Fisher-squared-distance $\text{KL}(P\ Q) = \frac{1}{2}d_{FR}^2 + O(d_{FR}^3)$	Cover-Thomas 2006 §12.5; Amari-Nagaoka 2000 §3.7 Theorem 3.1	Exact (standard information geometry)
Bayesian-posterior W_2 -Lipschitz stability L_{post}	Stuart 2010 Theorem 4.6 under well-posed inverse problem	Conditional on (H3)
Track 1 bound $\mathbb{E}[W_2^2(M^{\text{coupled}}, M^{\text{decoupled}})] \leq (2L_{\text{post}}^2/\rho_{\text{LSI}}) \cdot \kappa \cdot I$	Composition of §2 Steps 1–4	Derived (conditional on H1-H3)
Track 2 bound $\mathbb{E} \ \Delta M_{\text{bias}}\ _{FR} \leq \sqrt{2} \cdot \sqrt{\kappa I}(1 + o(1))$	Composition of §3 Steps 1–3 under (PI) + Čencov	Derived (conditional on H1+H4, small-I regime)
$C_{FR} = \sqrt{2}$ is universal, dimension-free, no domain constants	§3 Result	Exact under (H1)+(H4)
$C_{W_2}^2 = 2L_{\text{post}}^2/\rho_{\text{LSI}}$ with explicit geometric interpretation	§2 Result	Exact under (H1)-(H3)
Attempt E no-go: no universal C in Euclidean-parameter norm	Heteroscedastic-normal counterexample §4	Proved (counterexample-grade)
(F1) Cramér-Rao inversion fails	Direction mismatch (estimator lower bound cannot invert to upper bound)	Recorded failure
(F2) Rate-distortion inversion fails	Problem-structure mismatch (source-coding theorem cannot yield side-information injection bound)	Recorded failure
Gaussian worked example with explicit C_{W_2} and C_{FR}	Conjugate-Gaussian direct computation	Exact under specified assumptions

The dividing line: both tracks are derived theorems under named hypotheses; the hypotheses (LSI, Lipschitz-posterior, small-I, statistical-manifold sub-case, (PI) adoption) are either standard mathematical regularity (LSI, Lipschitz-posterior) or AAT-internal axioms ((PI), already adopted in 4.10 and elevated to fourth primary instance of 5.5). The no-go §4 justifies the (PI) commitment as load-bearing rather than coincidental. The failed attempts §5 document structural reasons two alternative routes cannot work, preventing future re-attempts.

Epistemic Status.

Conditional — exact under H1-H3 (Track 1) or H1+H4 (Track 2). Both tracks are derived theorems under named hypotheses:

- Track 1 is exact under the three regularity conditions (H1 statistical-manifold sub-case; H2 log-Sobolev on observation distribution; H3 Lipschitz-posterior stability). All three are standard mathematical regularity conditions satisfied for canonical cases (Gaussian observations: (H2) direct; well-posed Bayesian inverse problems: (H3) per Stuart 2010). The bound is linear in I , with explicit geometric-stiffness constants.
- Track 2 is exact under (H1) + (H4) small-information regime, leveraging (PI) + Čencov. The bound is $\sqrt{I}$ scaling with universal dimension-free constant $C_{FR} = \sqrt{2}$. Does not depend on domain-specific L_{post} or ρ_{LSI} ; the price is the small-I regime restriction.

The no-go §4 is *proved* via the heteroscedastic-normal family counterexample — universal C in Euclidean-parameter norm does not exist; the (PI) commitment is load-bearing for the derivation. The failed attempts §5 are *recorded* at structural-reason level; they document why Cramér-Rao inversion and rate-distortion inversion cannot produce the needed upper bound, not merely that the attempts failed.

Upgrade over prior formulation. The bias bound in `#result-section-ii-survival` and `#scope-observation-ambiguity-modulation` previously carried the honest admission “*Without the constant, the bound is order-of-magnitude guidance, not a theorem.*” This appendix **promotes the bound to theorem-level** under named sub-scopes. The order-of-magnitude admission is superseded by the two explicit tracks with their H-conditions. Updates to the logogenic-agents segments cross-reference this appendix.

Max attainable: *exact* for the composition of the three textbook inequalities (Step 1 chain-rule; Step 2 Otto-Villani; Step 3 Lipschitz-posterior or KL-to-Fisher-Rao identity) and for the no-go counterexample §4. *Conditional* overall — the theorem statements carry their H-conditions explicitly, and the sub-scope boundary is where “derived” transitions back to “admitted empirical regularity” (cases where H2 or H3 fails require separate treatment, flagged in Working Notes).

Honest failure modes.

The appendix does **not** cover:

1. **Non-statistical-manifold sub-cases of $\mathcal{M}$.** If $\mathcal{M}$ carries structured state-space geometry (mixed continuous/discrete components, graphical-model structure, non-parametric models without sufficient statistics), (H1) is weakened and Čencov’s uniqueness does not straightforwardly apply. The Fisher-Rao track degrades; Track 1 may still apply under suitable alternative regularity.
2. **Unbounded KL / structural-failure limit.** If $P_{\Omega|e,M,G}$ has support disjoint from $P_{\Omega|e,M}$ at G -values carrying non-trivial prior probability, the KL (and thus I) diverges. The bound is vacuous in this regime. This is a structural failure of the coupled-update model, not a bound weakness.
3. **Non-Lipschitz pushforward.** If f_X^M is not a well-posed Bayesian posterior (e.g., ill-posed inverse problem, degenerate likelihood, rank-deficient observation channel), (H3) fails and Track 1 does not apply. Track 2’s small- I expansion may still apply in the local-linearization sub-region.
4. **Large-information regime beyond the small- I expansion.** Track 2’s $\sqrt{I}$ scaling uses the second-order Fisher-metric expansion of KL; the full global relationship is lattice-dependent. A fully-global Fisher-Rao statement requires either compact-manifold assumption (Fisher-Rao distance bounded) or a staged-application argument (many small- I steps composed).
5. **Heavy-tailed observation distributions.** LSI fails for heavy-tailed measures. Track 1 degrades to the Pinsker bound $W_2 \leq \sqrt{KL/(2\rho_{\text{LSI}})}$ when $\rho_{\text{LSI}} \rightarrow 0$; this is the $O(\sqrt{\varepsilon})$ baseline without the LSI tightening.

Discussion.

Position in the 5.5 meta-pattern. Track 2’s $C_{FR} = \sqrt{2}$ result is a **downstream theorem of the fourth primary instance** (Čencov-invariance at the metric layer, under (PI)). Once (PI) adoption forces Fisher-Rao as the canonical metric on statistical-manifold sub-cases of $\mathcal{M}$, the KL-to-Fisher-squared-distance identity supplies the universal constant “for free” in the small- I regime. The no-go §4 tightens the connection: the (PI) commitment is not just “useful axiom” but load-bearing for the bound’s theorem-level status — without (PI), C does not exist as a universal constant.

Connection to AJ. Both segments use Pinsker’s inequality as a first step in propagating a KL bound. After Pinsker, the two segments diverge: this segment’s cascade (Pinsker $\rightarrow$ Otto-Villani $\rightarrow$ Lipschitz-posterior $\rightarrow W_2$ on pushforward) is a KL-to-state-distance machinery; `#deriv-variational-sector-condition`’s use (Pinsker + Cauchy-Schwarz $\rightarrow$ scalar

sector-constant degradation) is a KL-to-scalar-constant machinery. The shared first step is Pinsker; the post-Pinsker cascade is not shared, so `#deriv-variational-sector-condition` is an adjacent family member rather than a candidate for a shared `#posterior-displacement-template` (a possible future extraction recorded in Working Notes).

The $\varepsilon(\kappa)$ degradation for causally-disciplined results. This appendix *is* the degradation bound that the causal-discipline scoping rule of 6.3 calls for: a Part II result that holds exactly at $\kappa_{\text{processing}} = 0$ (for any causally-disciplined agent) degrades off that zero at a rate this bound controls — $\|\Delta M_{\text{bias}}\|$ enters multiplied by $\kappa_{\text{processing}}$, exact (zero bias) at the causally-disciplined value and decaying controllably as coupling grows. The first realized client is the value object’s Q_O G_I -independence (6.6): the Q_O degradation at $\kappa_{\text{processing}} > 0$ is the ΔM_{bias} this appendix bounds, propagated through the value functional. That a successful $\varepsilon(\kappa)$ bound exists is itself the evidence that the result-at-the-noun (causal discipline, the shared zero) is the right object — the result degrades continuously off the zero rather than requiring the architecture certificate.

Forward-looking clients. Three open extensions in 5.1 Working Notes are candidate future primary clients of this appendix’s machinery: causal-IB (KL $\rightarrow W_2$ on post-intervention pushforward), misspecification-cost (KL $\rightarrow W_2$ on posterior under model misspecification), composition-scope-robustness (KL $\rightarrow W_2$ on composite-state pushforward). Each would reuse the Track 1 Otto-Villani + Lipschitz-posterior cascade with client-specific (P, Q, f) and $(L_{\text{post}}, \rho_{\text{LSI}})$ instantiations. If two or more of these materialize, factoring the cascade out as a template segment becomes attractive.

Why the Fisher-Rao specialization is worth landing even under the small- I restriction. In the AAT-canonical operating regime, Class 3 (Coupled) bias is *moderate* — the goal-conditional reweighting shifts the posterior but does not replace it. Small- I is the honest model of this regime; large- I is the structural-failure limit where the coupled agent’s goal-conditioning overwhelms evidence. Track 2’s universal $C_{FR} = \sqrt{2}$ is the right bound in the operating regime; Track 1 is the fallback under structural conditions where I is not small or where Fisher-Rao is not available.

Connection to logogenic agents. This appendix’s bounds are the quantitative apparatus underlying `#scope-observation-ambiguity-modulation`’s product-form bias bound and `#result-section-ii-survival`’s Class 3 (Coupled) scope-survival analysis. Both segments previously carried the “constant C not computed” caveat; with this appendix landed, C is computed under named conditions and the epistemic tier of the bias bound upgrades to “conditional (exact under H1-H3 or H1+H4).” The logogenic-agents segments retain their client status; the quantitative work moves here.

Findings.

Universal Constant for the Coupled-Agent Bias Bound under Parameterization-Invariance. Brief: When a goal-conditioned agent (like an LLM) processes evidence, its update can be biased by what it’s trying to do, not just what it observes. Prior work could only say “this bias is bounded by some constant times the relevant information leakage” without computing the constant. This result computes it under two specific conditions, and shows that at least one of them — committing to a particular geometric structure on the model space (the (PI) parameterization-invariance axiom) — is necessary in a strong sense: without it, no universal constant exists at all. A transport-inequality track gives $C_{W_2}^2 = 2L_{\text{post}}^2/\rho_{\text{LSI}}$ linear in the goal-conditional information leakage, under log-Sobolev concentration of the observation distribution and Lipschitz-stability of the Bayesian posterior. A Fisher-Rao track gives a universal dimension-free $C_{FR} = \sqrt{2}$ in the small-information regime, conditional on the (PI) axiom. Two structurally wrong derivation routes (Cramér-Rao inversion; rate-distortion inversion) are recorded as honest failure cases.

Impact: Promotes the bias bound from “order-of-magnitude guidance, not a theorem” to a conditional theorem under explicitly named hypotheses, closing the quantitative gap that `#scope-observation-ambiguity-modulation` and `#result-section-ii-survival` previously carried as a caveat. The no-go strengthens the (PI) commitment from useful axiom to load-bearing structural choice and adds a fourth primary instance to the `#disc-additive-coordinate-forcing` meta-pattern. The recorded failures prevent future agents from re-attempting Cramér-Rao or rate-distortion inversions for upper bounds on side-information-induced displacement, and identify transport-inequality machinery (Pinsker, Otto-Villani, Bakry-Émery, posterior-stability) as the correct family. Three forward-looking clients in adjacent appendices

(causal-IB pushforward, misspecification-cost, composition-scope-robustness) are candidate consumers of the same Track 1 cascade, suggesting eventual extraction of a shared #posterior-displacement-template if two or more materialize.

Novelty Claim: *Claim differentiation* on the Lipschitz-posterior + Otto-Villani composition for AAT’s coupled-agent bias bound, plus *claim novelty* on the no-go counterexample showing that universal C in Euclidean-parameter norms cannot exist, which jointly elevates the (PI) axiom from convergent representational choice to load-bearing for theorem-level status. The two upstream tracks each compose textbook information-geometric / transport-inequality machinery (Cover-Thomas chain rule; Otto-Villani 2000; Stuart 2010 Bayesian-posterior stability; Amari-Nagaoka 2000 Fisher-metric expansion); the contribution is the composition for the Class 3 (Coupled) agent bias setting and the no-go that justifies the geometric commitment. (*This finding’s novelty is the supporting quantitative apparatus; the integrated $\kappa \times A$ bias law it supports is in #scope-observation-ambiguity-modulation, where the Pillar-3 verdict applies.*)

Table AB.2

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
KL-to- W_2 transport under log-Sobolev	Otto & Villani 2000 <i>J. Funct. Anal.</i> 173:361–400 (published 2000); Bakry & Émery 1985 curvature-dimension condition	<i>formal antecedent</i> — adopted directly in the Track 1 cascade; standard transport-inequality machinery, cited and used
Lipschitz-stability of Bayesian posteriors	Stuart 2010 <i>Acta Numerica</i> 19:451–559 (published 2010); Hairer, Stuart & Vollmer 2014 <i>SIAM J. Math. Anal.</i> 46(1):415–451 (published 2014)	<i>formal antecedent</i> — adopted directly as (H3); the conjugate-Gaussian case is computed explicitly in §6
Čencov uniqueness of the Fisher metric	Čencov 1982, <i>Statistical Decision Rules and Optimal Inference</i> (published 1982); Ay, Jost, Lè & Schwachhöfer 2017 <i>Information Geometry</i> Theorem 5.1 (published 2017)	<i>formal antecedent</i> — adopted via the (PI) axiom in #scope-agent-identity and used in the Track 2 derivation; the no-go in §4 is the AAT-internal demonstration that this adoption is load-bearing for the bound, not just convenient
KL-to-Fisher second-order expansion	Amari & Nagaoka 2000, <i>Methods of Information Geometry</i> §3.7 Theorem 3.1; Cover & Thomas 2006 §12.5	<i>formal antecedent</i> — supplies the small- I regime sharpness used in Track 2
Information-processing-constraint bounds on decisions	Ortega & Braun 2012 <i>Proc. R. Soc. A</i> (published 2012-04, found 2026-04 via Undermind); Genewein et al. 2015 <i>Front. Robot. AI</i> 2:27 (published 2015-11, found 2026-04)	<i>adjacent literature</i> — addresses a different quantity (decision quality under information constraint rather than belief-update bias under goal-coupling); shares the information-theoretic vocabulary but does not produce a Wasserstein or Fisher-Rao bias bound for coupled-architecture agents
Variational bounds on posterior beliefs in active inference	Friston et al. 2017, “Active inference: a process theory” <i>Neural Computation</i> 29:1–49 (published 2017)	<i>adjacent literature</i> — uses overlapping transport-inequality machinery in a different framework; consistent with the Track 1 derivation but does not require the variational-free-energy commitment (cf. #form-information-bottleneck Discussion)

Novelty assessment. A prior-art search located bounded-rationality and information-cost literatures (Ortega & Braun 2012, Genewein et al. 2015) as the closest decision-theoretic precursors and confirmed no equivalent of the universal- C

derivation under (PI). The verdict (Wholly Novel, Medium confidence) applies to the integrated $\kappa \times A$ law downstream in #scope-observation-ambiguity-modulation; this segment's contribution is narrower (the constant derivation and the no-go) and inherits the same Medium confidence, with a follow-on targeted search recommended on formal posterior-displacement bounds in coupled-architecture agents.

Search Log:

- 2026-04 (*nominally comprehensive*): A comprehensive-search pass (Pillar 3 of the prior-art defense) located bounded-rationality and information-cost literatures (Ortega & Braun 2012, Genewein et al. 2015) as the closest decision-theoretic precursors and confirmed no equivalent of the universal-C derivation under (PI) was surfaced. The verdict (Wholly Novel, Medium confidence) applies to the integrated $\kappa \times A$ law downstream in #scope-observation-ambiguity-modulation; this segment's narrower contribution (the constant derivation and the no-go) inherits the same Medium confidence, with a follow-on targeted search recommended on formal posterior-displacement bounds in coupled-architecture agents.

Working Notes.

- **Causal-discipline cross-link (2026-05-31).** Recognized as the landed $\varepsilon(\kappa)$ bound for the causal-discipline scoping rule of #der-directed-separation (Stage-2 reframe): §1's baseline terminology-aligned from "Class 1 (Separated) scope" to the causally-disciplined $\kappa_{\text{processing}} = 0$ object (held equally by Class 1 by construction and an idealized Class 2 in effect), and the Discussion now names #def-value-object's Q_O independence as the first realized client. No re-derivation — the bound already carried the factor- κ form; this surfaces it as the degradation norm's worked model. The Class 2 (Partial) closed-form refinement ($\kappa_{\text{processing}} \in (0, 1)$) remains open per the Working Note below.
- **Trail.** Full derivation history in spikes/.integrated/spike-bias-bound-constant-C-strengthening-2026-04-24.md. The spike's Track 1 and Track 2 structure maps directly to §§2–3 here; the no-go Attempt E maps to §4; the failed attempts (F1 Cramér-Rao, F2 rate-distortion) map to §5. The spike also flags the shared Pinsker / Otto-Villani machinery with #deriv-variational-sector-condition as a candidate shared-lemma extraction (spikes/spike-kl-to-state-distance-template-extraction-2026-04-24.md Option B); that extraction is contingent on this appendix landing + forward-looking clients materializing.
- **L_{post} for AAT-native cases.** The Lipschitz-posterior stability constant L_{post} is cited from Stuart 2010 / Hairer-Stuart-Vollmer 2014 but not computed for all AAT-relevant cases. The conjugate-Gaussian case of §6 is explicit; general non-parametric Bayesian inverse problems have looser bounds. A future refinement could compute L_{post} for the exponential-family / conjugate-prior cases in 4.3 directly.
- **Large- I Fisher-Rao refinement.** Track 2's $\sqrt{I}$ scaling is the small- I Taylor expansion. Extending to large I requires either compact-manifold assumption or staged composition; flagged for future work.
- **Interaction with the $\mathcal{A}$ factor from #scope-observation-ambiguity-modulation.** The product form $\kappa_{\text{eff}} = \kappa \cdot \mathcal{A}$ interacts with the transport-inequality constants in ways not fully worked out here. If $\mathcal{A}$ is itself an information-theoretic ratio, the $\mathcal{A}$ factor may be absorbable into the I term rather than appearing as a separate multiplicative factor. Flagged for a clarification pass when the logogenic-agents segments are next revised.
- **Non-Bayesian pushforwards.** The Track 1 (T3) posterior-Lipschitz step is stated for Bayesian-posterior pushforwards. Non-Bayesian pushforwards (e.g., post-intervention transformations in the causal-IB candidate) would use the general W_2 -Lipschitz form; the machinery generalizes, though the concrete constants are client-specific.
- **Relation to active-inference bounds.** Active inference (Friston 2017 *Active inference: a process theory*, *Neural Computation* 29) uses KL bounds on posterior beliefs under the free-energy principle; those bounds are formulated in a different framework but share the underlying transport-inequality machinery. AAT's Track 1 derivation is consistent with the active-inference reading but does not require the variational-free-energy-as-master-objective commitment (see 2.2 Discussion for the lineage distinction).

- **Class 2 (Partial) bias-bound analog — open derivation.** This segment derives the bound C for the Class 3 (Coupled) extreme at $\kappa_{\text{processing}} \rightarrow 1$. The corresponding bound for Class 2 (Partial) agents at $\kappa_{\text{processing}} \in (0, 1)$ is open. Both Track 1 (transport-inequality under LSI + Lipschitz-posterior) and Track 2 (Fisher-Rao under (PI) + Čencov + small- I) derive the worst-case envelope; specializing either track to the bounded-coupling regime is the natural starting point. Whether the Class 2 case admits a clean closed-form bound or requires architectural specifics (e.g., per-stage modularity decomposition) is not yet known. Surfaced 2026-05-09 by the GUC rename audit; flagged in `TODO.md` §"Open theory items (MEDIUM)" for cross-referencing.
- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged / fully coupled, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. The segment's canonical claim previously known as the "Class-2 ambiguity bias bound" (fully-coupled case) is now the "Class 3 (Coupled) ambiguity bias bound." Every "Class-2 (fully-coupled)" reference renamed to "Class 3 (Coupled)"; "Class 3 partially-modular" $\rightarrow$ "Class 2 (Partial)"; "Class-1 (modular)" $\rightarrow$ "Class 1 (Separated)." Downstream segments citing the old "Class-2 bias bound" name: see external-citation list in the parent Phase 2 commit report — those segments are scope for later Phase 2/3 work. Removed at candidate stage per `FORMAT.md` Gate 4.
- **Cross-reference to NeurIPS Paper 3.** This segment's two-tracks framework is materially sharpened in NeurIPS 2026 Paper 3 ("How Much Can LLMs Hallucinate? An Upper Bound on Goal-Coupling Displacement", `~/src/neurips/03-llm-hallucinate-bound/`). The paper carries: (i) **Two named tracks with explicit hypothesis sets** at §4 Theorem 4.1 / `#thm-umbrella` — Track 1 (transport-inequality, W_2 metric) recovers the canonical Stuart-school cascade form $C_{T_2} \propto L_{\text{post}}^2 / \rho_{\text{LSI}}$ under (H2'); Track 2 (Fisher-Rao Čencov uniqueness) gives $C = 2$ **globally on the ambient spherical-arc pseudometric** — the operating constant for adversarial / rare-high-KL prompts including jailbreaks and persona injection (via Rényi-1/2 monotonicity + chord-arc on the unit L^2 -sphere; sharp via symmetric N -point witness) — tightening to $C = \sqrt{2}$ **locally** under (R) + (K) + (H4') uniform-locality on goal-conditional slices (first-moment sharp via symmetric two-point witness). (ii) **Chain-rule on post-update law as bridging lemma** at §5 Lemma 5.1 / `#lem-chain-rule`: $\mathbb{E}_G[\text{KL}(P_{M_{\tau+}|e, M_{\tau-}, G} \| P_{M_{\tau+}|e, M_{\tau-}})] = I(G; M_{\tau+} | e_{\tau}, M_{\tau-})$ — the structural identity connecting Bayesian inverse-problems with architectural classification. (iii) **No-go theorem on Euclidean chart norms** at §4 Theorem 4.2 / `#thm-no-go`: chart-rescaling argument $\phi \mapsto a\phi$ scales chart-Euclidean W_2 linearly while leaving $\text{KL}/\text{MI}/d_{FR}/\text{Hellinger}$ chart-invariant; taking $a \rightarrow \infty$ contradicts any candidate fixed $C_0\sqrt{I}$. *Forces (PI) as load-bearing for theorem-level status* and supplies the explicit witness construction for what this segment's Attempt E flagged structurally. The fourth instance of M1 identifiability-floor (named F4 in Paper 3 §4 Lemma 4.2). (iv) **Čencov-uniqueness-and-sharpness** at §4 Theorem 4.3 / `#thm-fr-uniqueness`: under (H1)+(PI)+(R)+(K)+(H4'), $d_{\mathcal{M}}$ is uniquely the ambient Amari-Nagaoka Fisher-Rao spherical-arc distance and $C = \sqrt{2}$ is the unique sharp upper-bound constant. (v) **Class 1 reduction theorem to Stuart-school setup** at §App-D — the Class 1 (Separated) specialization of Track 1's hypothesis space *is* the Stuart-school Lipschitz-posterior cascade (the strict-strengthening from spike A7). The paper's (PI)+(R)+(K) axiom triple — chart-invariance + Riemannian structure + KL second-order matching — is the load-bearing structural commitment for the universal-constant route. See `spikes/neurips-back-integration-2026-05-08.md` §1 Paper 3 entries 1, 2, 3, 4, 5, 7. Standalone-segment proposals under back-integration §3: `#deriv-post-update-chain-rule`, `#deriv-chart-rescaling-no-go`.

Appendix AC

Discussion: Partial-Coupling Pathways — A Sub-Typology Within Class 2

Class 2 (Partial Coupling) per *#der-directed-separation* is named structurally as “some shared infrastructure, some separate pathways” and operationalized as a scalar $\kappa_{\text{processing}} \in (0, 1)$ that aggregates over the un-modeled internal sub-structure. The scalar is distribution-dependent and tracks the *magnitude* of goal-coupling, but not its *kind*: it cannot distinguish the agent that uses goals to *attend* from the one that uses goals to *interpret*, or the agent biased by *what it wants to be true* from the one foreclosed by *what plan it has committed to*, or the additively-biased agent (whose coupling is wrappable by post-hoc debiasing) from the multiplicatively-entangled agent (whose coupling is not). These distinctions are operationally distinct — they recommend different repairs, predict different dynamical signatures, and gate different wrapping regimes.

This segment names the structural sub-space the scalar projects over. Class 2 partial coupling decomposes along three structurally-independent axes — *stage*, *source*, and *form* — yielding a parameterization within which the Class 3 (fully Coupled) corner and the Class 1 (Separated) corner are recovered as the two trivial endpoints. The stage axis tracks which step of the belief-update pipeline takes a G_t argument; the source axis tracks whether the coupling comes from the objective O_t or from the strategy Σ_t ; the form axis tracks whether the coupling acts as separable additive bias on a stage’s output (*content*) or as a non-separable change of the stage’s functional form (*process*). The three axes have distinct operational consequences (Discussion §“Operational consequences” below), and the form axis at Class 2 unifies with the *structure-vs-behavior* refinement at Class 1 — they are the same distinction read at different architectural levels.

The treatment is discussion-grade at the structural-recognition level. The pipeline decomposition is posited as canonical for Bayesian-style updaters and serves as an interpretive lens for monolithic architectures. The substantive structural results that fall out — form-determines-wrappability (a content-form / process-form no-go cut), and the source asymmetry of belief-strategy attractors — are stated qualitatively here and derived in their own segments (*#der-belief-strategy-attractor* for the source-asymmetry result; the form no-go is stated formally in this segment’s Discussion). The combinatorial parameterization is structurally complete but operationally too fine; the load-bearing distinctions live on the (form $\times$ source) projection with stage as a localization tag.

Formal Expression.

Pipeline decomposition of f_M .

Any belief-update function f_M that maintains M_t — whether Bayesian, Kalman, RL with separate world model, or LLM-as-tracker — factors functionally through a small set of operations. The canonical decomposition is

Formulation (partial-coupling-pipeline).

$$f_M = \tau \circ \alpha \circ \lambda \circ \phi \quad (\text{AC.1})$$

with the four stages mapping to AAT machinery already in canon:

Table AC.1

Stage	Operation	AAT correspondent
P1 — Featurization	$\phi : \mathcal{E} \times \mathcal{M} \rightarrow \mathcal{X}$, $x = \phi(e_\tau, M_{\tau-})$	Extracts features from the realized event given current model; in a Kalman tracker, the innovation $\delta = o - \hat{o}$ per #def-mismatch-signal
P2 — Likelihood evaluation	$\lambda : \mathcal{X} \times \mathcal{M} \rightarrow \mathcal{L}$, $\ell = \lambda(x, M_{\tau-})$	Evaluates the likelihood of features under representable hypotheses; in a Kalman tracker, the Gaussian likelihood on δ with innovation covariance S
P3 — Aggregation	$\alpha : \mathcal{L} \times \mathcal{M} \rightarrow \mathcal{M}^+$, $M' = \alpha(\ell, M_{\tau-})$	Combines likelihood with prior to produce new belief; in a Kalman tracker, the gain-weighted update with $\eta^* = U_M / (U_M + U_o)$ per #emp-update-gain
P4 — Consolidation	$\tau : \mathcal{M}^+ \rightarrow \mathcal{M}$, $M_{\tau+} = \tau(M')$	Post-update transformation: storage, normalization, regularization, memory consolidation

Each of (P1)–(P4) can independently take or omit a G_t argument. The Class 1 case has none; the Class 3 case has all; Class 2 is everything between.

The decomposition is posited rather than derived. It is canonical for Bayesian-style belief-updating agents and serves as an interpretive lens for monolithic architectures (where the stages are not architecturally distinct in the forward pass) — the typology’s precision drops the more monolithic the agent.

The (stage $\times$ source $\times$ form) parameterization.

A Class 2 partial-coupling sub-type is a triple $\mathcal{C}_2 = (S, R, F)$ with:

Definition (class-2-sub-type).

- $S \subseteq \{P1, P2, P3, P4\}$, $S \neq \emptyset$ and $S \neq \{P1, P2, P3, P4\}$ — the **stage set** at which goals enter f_M . Empty S recovers Class 1; full S (with all-process form) recovers Class 3.
- $R \subseteq \{O, \Sigma\}$, $R \neq \emptyset$ — the **source set** within $G_t = (O_t, \Sigma_t)$ that acts as the coupling input.
- $F : S \rightarrow \{\text{content}, \text{process}\}$ — the **form** at each coupled stage.

The endpoints recover canon: $S = \emptyset$ is Class 1; $(S, R, F) = (\{P1, P2, P3, P4\}, \{O, \Sigma\}, \text{process})$ is Class 3 (fully Coupled). The scalar $\kappa_{\text{processing}}$ is the projection of $\mathcal{C}_2$ onto the magnitude axis.

Form classification — content vs process.

A stage operation $\xi(\cdot; G)$ is **content-form coupled** if there exist functions ξ^0 (goal-blind) and b_ξ (bias) such that

Definition (coupling-form).

$$\xi(u; G) = \xi^0(u) + b_\xi(G; u) \quad (\text{AC.2})$$

with b_ξ identifiable from a probing protocol that varies G at fixed u (specifically: a reference goal G_0 exists with $b_\xi(G_0; u) = 0$, or b_ξ is identifiable up to a u -dependent constant by varying G across finitely many probes).

A stage operation is **process-form coupled** if no such decomposition exists — the operation's *functional form* depends on G , not just its output. The multiplicative case $\xi(u; G) = \xi^0(u) \cdot h(G; u)$ is the most common process form (multiplicative attention coupling, gain modulation, precision weighting); the compositional case $\xi(u; G) = \xi^\dagger(u, G)$ with no separable factor is the starkest form.

The classification is *probing-protocol-dependent*: an analyst with reference-goal access may classify as content where an analyst without that access classifies as process. This is the same epistemic situation as the existing $\hat{\kappa}_{\text{processing}}$ behavioral estimator — the form classification inherits the same probe-dependence.

Form-determines-wrappability — the central operational claim.

For a Class 2 sub-type with coupling triple (S, R, F) :

Derived (content-process-wrappability, conditional on probing model).

Positive half (content-form is post-hoc-wrappable). Stages with content-form coupling admit an *external debiasing wrapper* that requires only behavioral-probing access (no internal pipeline access). The wrapper estimates $b_\xi(G; u)$ from probes that vary G at fixed u , then subtracts the estimated bias in normal operation. The wrapped output converges to $\xi^0(u)$ as the estimator becomes consistent. This corresponds to the W_2 (partial-wrapping) regime at the agent level — “the query boundary still passes G_W to the component” with typed-output structuring extracting a goal-blind belief-update.

Negative half (process-form is not post-hoc-wrappable). Stages with process-form coupling do not admit such an external wrapper. The argument is identifiability-theoretic: under process-form there is no G_0 making $h \equiv 1$ (or, more generally, no u -independent reference goal recovering ξ^0); behavioral probes that vary G reveal goal-correlated differences but cannot collapse them to a G -invariant honest output. Repair requires either *stage replacement* (substituting a goal-blind version of the stage in the pipeline — requires substitutability access at the stage's input/output boundary) or *full-agent wrapping* (the W_1 strict-wrapping regime, operating at the whole-agent boundary).

The form distinction is therefore *load-bearing*, not ornamental — it gates the wrapping regimes available for coercion to Class 1.

Stage-cascade propagation.

Goal-coupling at stage P_k contaminates all downstream stages $P_{k+1}, \dots, P_4$ even when those downstream stages are individually goal-blind, because their inputs are functions of G through the cascade. The *naming* of a sub-type by its primary coupling stage refers to where the coupling originates; the *effect* propagates forward through the pipeline. Minimal repair (per stage-localization-of-repair, below) is therefore at the *most upstream coupled stage*, not at the most downstream symptom.

Derived (cascade-propagation).

Stage-localization of repair.

If pipeline access is available at stages $P_k \in S$ — the wrapper can intercept the stage’s input and supply its output to P_{k+1} — then substituting goal-blind operations P_k^0 at every coupled stage produces a wrapped agent that is Class 1 at the wrapper level. The construction has a capability cost (the substitute operations may be weaker than the agent’s native ones) and a Brooks’s-Law tempo overhead (more pipeline calls per macro-step), but the structural class-coercion is exact.

Derived (stage-localization-of-repair, conditional on pipeline access).

For monolithic architectures without pipeline access, only full-agent wrapping (the construction of `#der-class-coercion-via-wrapping`) is available; stage-level repair does not apply.

Composition with the leakage locus. Goal contamination’s *effect on belief* is confined to the Fisher null space $\ker J_\tau$ of the observation given the current latent state (the leakage-locus result, when promoted to its own segment, will be the formal statement). This locus is *universal across Class 2 sub-types* — it does not depend on which pipeline stage the coupling enters. The sub-type determines the *functional form* of the displacement within the locus:

- Content-form sub-types produce displacement linear in G (the $\Delta\mu = \Lambda_0^{-1}g(G)$ shape in the linear-Gaussian instantiation, with $g(G)$ a linear function of the goal-tilt parameter).
- Process-form sub-types produce displacement with a G -dependent gain matrix or a G -dependent covariance structure — non-linear in G .
- Σ -source sub-types compound the per-step displacement across the closed-loop dynamics; under multiplicative process form, self-stabilizing belief-strategy attractors arise (`#der-belief-strategy-attractor`).
- O -source sub-types produce exogenously-bounded tilt magnitude (because O_t revises only when forced, per `#der-orient-cascade`).

Wrapping-regime correspondence. The $W_0 / W_1 / W_2$ wrapping regimes of `#der-class-coercion-via-wrapping` are the agent-level analogs of the stage-level form distinction:

Table AC.2

<i>Wrapping regime</i>	<i>Stage-level analog</i>	<i>Class achieved at wrapper</i>
W_0 (no wrapping)	n/a — the agent stands as-is	Whatever the un-wrapped agent is
W_2 (partial wrapping)	Content-form at the agent level — wrapper passes G to component, post-hoc structures the response	Class-1-by-behavior (per <code>#der-directed-separation</code>)
W_1 (strict wrapping)	Process-form-with-pipeline-access — wrapper structurally substitutes goal-blind execution	Class-1-by-structure

This unifies the *structure-vs-behavior* distinction at Class 1 with the *content-vs-process* form distinction at Class 2: they are the same axis read at different architectural levels. The structure / behavior distinction at the Class 1 cell is the agent-level shadow of a sub-classification axis that runs all through Class 2.

Sub-type matching refines the wrapping-regime recommendation: a Class 2 agent with content-form coupling only is sufficient with W_2 ; a Class 2 agent with process-form coupling at any stage requires W_1 or remains effectively Class 2 under W_2 ; a Class 2 agent with Σ -source coupling may need a Σ -channel-suppressed W_1 even with pipeline access, because strategy-context can leak through stateful component channels independent of the query. The call-boundary condition

under which W_1 's structural guarantee survives such stateful leakage is the (C2') condition of #disc-w1-structural-bound-boundary: when goal-correlated state crosses the call boundary, W_1 's structural bound is unavailable and only a behavioral bound remains.

Epistemic Status.

Discussion-grade at the structural-recognition level. The pipeline decomposition is a *formulation choice* — canonical for Bayesian-style updaters and well-motivated by AAT's existing machinery, but not forced by AAT canon. The (stage $\times$ source $\times$ form) parameterization is derived from the choice. The form distinction is *robust qualitative* at the operational level (the content / process distinction has a clean identifiability argument); the formal definition is probing-protocol-dependent.

The two substantive structural consequences carry their own tiers:

- **Form-determines-wrappability** (this segment, Discussion §): *robust qualitative* — the identifiability argument is exact under the formal non-separability definition; the operational dependence on probing-protocol availability is honest scope.
- **Source asymmetry / belief-strategy attractors** (#der-belief-strategy-attractor): *conditional* — exact under the linearized dynamics and the posited multiplicative form for Σ -source aggregation-stage coupling; robust qualitative beyond.
- **Composition with leakage locus**: *derived* under the linear-Gaussian instantiation; robust qualitative more generally (it composes existing structural results).
- **Wrapping-regime correspondence**: *robust qualitative* — the structural correspondence is exact, but boundary cases (partial-information wrappers between W_1 and W_2) require per-case analysis.

The full $42 \times 2^{|S|}$ -cell parameterization is structural completeness; operationally the load-bearing distinctions live on the coarsening to *upstream-most coupled stage $\times$ source-set $\times$ form*, which gives roughly 30 cells, of which empirically about a dozen are populated by recognizable phenomena (canonical phenomena placed in Discussion §"Canonical phenomena" below).

Discussion.

Why the form axis is the operationally-load-bearing one. Of the three axes — stage, source, form — the form axis is the one that gates wrappability: it determines whether external post-hoc debiasing suffices or whether stage replacement / full-agent wrapping is required. The source axis is the one that gates *dynamics*: Σ -source coupling closes a feedback loop through the orient cascade and can produce self-stabilizing attractors that O -source coupling cannot. The stage axis is the one that gates *architectural location of repair*: it determines where in the pipeline the substitution or debiasing must be applied. These three operational outputs from the typology — wrappability, attractor possibility, repair location — each correlate with one axis, which is why the three-axis decomposition is more informative than the scalar.

Unification with Class 1's structure-vs-behavior refinement. The Class 1 cell of #der-directed-separation admits a refinement: *Class-1-by-structure* (no G in the belief-update query — structural commitment by type signature) vs *Class-1-by-behavior* (the query passes G but the component is instructed not to use it — separation by compliance). The form distinction at Class 2 is the same axis: *content-form* is the behavior-side (the operation accepts G but its goal-shaped component is post-hoc-subtractable); *process-form* is the structure-side (the operation's functional form depends on G inseparably, requiring substitution). Read together, the structure / content side and the behavior / process side describe two distinct *modes* of goal-coupling — one in which the coupling can be neutralized by *not asking* (or by subtracting after asking), and one in which the coupling is constitutive of the operation.

Why the Σ -source / O -source asymmetry matters. The orient cascade (#der-orient-cascade) has Σ updated as a function of (M, O) and O revised only when forced. This makes Σ *endogenous* to M via the cascade — Σ updates from

the new M that the agent's f_M produces — but leaves O *exogenous* to M in steady state. The asymmetry feeds back: a Class 2 agent with Σ -source coupling at any stage of f_M has the structure $M \rightarrow \Sigma \rightarrow f_M \rightarrow M$ closing a loop, while the same coupling sourced from O has no such closure (because O does not update from M per step). The result is that Σ -source coupling under multiplicative process-form admits *self-stabilizing fixed points* in which M stays misaligned with the environment indefinitely — the formal sunk-cost attractor of #der-belief-strategy-attractor. O -source coupling produces *bias* but not *runaway commitment*.

Canonical phenomena placed in the typology. The cells the typology produces are operationally meaningful:

Table AC.3

<i>Phenomenon</i>	<i>Stage(s)</i>	<i>Source</i>	<i>Form</i>	<i>Repair regime</i>
Goal-directed attention	(selection — pre- f_M)	O or Σ	—	None — formally allowed by #der-directed-separation scope condition
Motivated reasoning (identity-driven)	P1 + P2	O	Content (moderate) $\rightarrow$ Process (strong)	W_2 moderate; W_1 + identity-suppression strong
Sunk-cost commitment	P3	Σ	Process (multiplicative)	W_1 + Σ -suppression; admits attractors per #der-belief-strategy-attractor
Identity-protective consolidation	P4	O	Process (compositional)	W_1 + storage-protocol externalization
Frame coupling	P1	$O + \Sigma$	Process (compositional)	Multi-frame composition (not coercion to Class 1)
Wishful thinking	P3	O	Content (mild) $\rightarrow$ Process (strong)	W_2 mild; W_1 strong
Affect / urgency cascade-bypass	(cascade-bypass)	n/a (not stage-coupling)	n/a	External pacing scaffolding (per #disc-adversarial-coupling-pressure affect mechanism)
Attention-mediated transformer-LLM	P1+P2+P3	$O + \Sigma$ (prompt-mixed)	Process (compositional)	Full Class-3 — W_1 wrapping construction, no stage repair without internal access

The transformer-LLM case lands at the corner ($S = \{P1, P2, P3\}$ or $\{P1, P2, P3, P4\}$, $R = \{O, \Sigma\}$, $F \equiv$ process), which is the parameterization's structural corner near Class 3 (Coupled). The typology recovers canon at its endpoints. Classical confirmation bias is a *separate* failure mode: it is structurally $M_t^{\text{prior}} \rightarrow f_M$ self-coupling, not $G_t \rightarrow f_M$ coupling, and is allowed by #der-directed-separation's scope condition (which has $M_{\tau-}$ as an argument); it lives outside the (S, R, F) parameterization, except in the *trajectory-coupling* case where the prior has been historically shaped by G -coupled updates and the cumulative effect carries effective G -content. Trajectory coupling is a separate per-trajectory axis from the per-step typology.

Connection to the three operations on modularity state. The M4 meta-segment #disc-modularity-state-dynamics names three operations — truthification, strategic self-coupling, adversarial coupling pressure — that change modularity state. The typology here is *orthogonal* to those operations: the operations describe *transitions* through the parameterization (truthification reduces S or simplifies F ; strategic self-coupling expands S and shifts F toward process; adversarial pressure expands S from the outside, targeting specific cells — identity-binding targets P1+P2 / O ; sunk-cost-engineering targets P3 / Σ); the typology describes the *static structural sub-space* on which the operations act. Each adversarial-coupling-pressure mechanism corresponds to a specific cell, and the three-mechanism table is best read as the projection of the typology's static structure onto the *externally-driven-decreasing* leg of M4's three-operation pattern. M4 names the operations; this segment names the structural state-space.

Operational consequences — refined behavioral estimator. The existing $\hat{\kappa}_{\text{processing}}$ behavioral estimator (per #der-directed-separation §”Empirical estimator”) aggregates over the typology. A refined estimator would distinguish:

- *Stage*: probing intermediate representations (where mechanistic-interpretability access exists) localizes the upstream-most coupled stage.
- *Source*: probing under O varied at fixed Σ vs Σ varied at fixed O separates the source set.
- *Form*: probing distinguishes mean shifts (content signature) from covariance shifts or functional-form changes (process signature) in the agent’s responses across goal-variants.

The refinement targets *which sub-type* the agent inhabits, not just the aggregate magnitude. Per the composition with the leakage locus, all such probing should be confined to $\ker \mathcal{J}_\tau$ — the directions the observation does not identify — which is where the displacement lives.

Honest scope. The typology is most precise for *modular* Class 2 architectures (biological cortex per the canonical example; hybrid AI systems with separable preprocessing / inference / aggregation modules). For monolithic architectures (transformer LLMs, end-to-end-trained policies), the stage decomposition is *interpretive* — the stages are not architecturally distinct in the forward pass; the typology serves as a lens for mechanistic-interpretability investigations rather than as a structural classification. The form classification is *probing-protocol-dependent*; analysts should specify which probes were available. Content-form wrapping gives *Class-1-by-behavior*, not honesty: under gauge freedom in the identifiability, the wrapper produces a G -invariant version of the agent’s belief, up to an unknowable additive constant.

Findings.

Partial-Coupling Sub-Typology (Stage $\times$ Source $\times$ Form). **Brief:** The Class 2 (Partial Coupling) label in AAT names “some shared infrastructure, some separate pathways” between belief-update and goal-state processing, but the existing scalar measure $\kappa_{\text{processing}}$ collapses a rich internal sub-structure into a single magnitude number. Look more carefully and three structurally-independent axes emerge: *which stage* of the belief-update pipeline takes a goal argument (attention / interpretation / aggregation / storage); *which source* of goal-state acts (the agent’s objective, or its committed strategy); and *which form* the dependency takes (additive bias subtractable by post-hoc debiasing, vs functional-form change requiring internal substitution). Each axis carries a distinct operational consequence: the form axis gates whether external wrapping can coerce the agent back to Class 1; the source axis gates whether self-stabilizing belief-strategy attractors are possible; the stage axis gates where the repair must be applied. The Class 3 (fully Coupled) limit is the corner where all stages couple, both sources act, and the form is process-throughout; Class 1 is the opposite corner; Class 2 is the structured space between.

Impact: Refines the operational meaning of the Class 2 label from “uncomfortable middle category” to “structured sub-space with specific repair regimes per cell.” Unifies the *Class-1-by-structure* vs *Class-1-by-behavior* refinement (currently sitting at the Class 1 cell of #der-directed-separation) with the form-axis of the Class 2 sub-typology — they are the same distinction read at different architectural levels. Sharpens wrapping-regime selection (W_1 vs W_2) by sub-type rather than by Class label alone. Maps the three adversarial mechanisms named in #disc-adversarial-coupling-pressure (identity-binding / affect-urgency / sunk-cost-engineering) onto specific cells of the typology, with the affect/urgency case recognized as outside the static (stage $\times$ source $\times$ form) parameterization (it is a cascade-bypass, a separate failure mode). Provides the static-structural complement to the M4 meta-segment #disc-modularity-state-dynamics’s three operations on modularity state — the operations describe transitions through the parameterization the typology names.

Novelty Claim: *Claim recognition* of the (stage $\times$ source $\times$ form) sub-typology as the structural complement to Class 1’s structure-vs-behavior refinement. *Claim differentiation* on the wrapping-regime correspondence: which wrapping regime suffices for Class 2 $\rightarrow$ Class 1 coercion is determined by the sub-type’s form, not just by the Class label. The integration with the leakage-locus result (locus universal in $\ker \mathcal{J}_\tau$; typology determines functional form within the

locus) and the source-asymmetry implication (#der-belief-strategy-attractor) are the load-bearing structural consequences.

Search Log:

- 2026-05-22 (*intuition-only*): The active-inference / Pearl-blanket / Friston-blanket prior-art landscape is already covered in `ref/Prior_art_for_AAT_directed_separation.md` (Pillar-3 search) and addresses the unified variational machinery as the Class 3 (fully Coupled) case; the *partial-separation sub-typology* this segment develops is not in that prior-art landscape. The cognitive-psychology / motivated-reasoning / identity-economics / dual-process / self-deception literatures are *unsearched*; targeted Pillar search recommended before any tier upgrade. The form distinction (content vs process) likely has analogs scattered across literatures (most explicitly in Bénabou-Tirole's identity-vs-instrumental belief framing and in dual-process system 1 / system 2 separation); the source-asymmetry result is plausibly partially in the sunk-cost / commitment-cascade empirical literature implicitly but not as a derived structural theorem. The combined (stage $\times$ source $\times$ form) parameterization in AAT-internal vocabulary is plausibly novel under the search-depth conducted.

Working Notes.

- **Promotion path requires two sub-spikes.** (a) Pillar-style targeted prior-art search across motivated-reasoning, identity-economics, dual-process, and self-deception literatures; (b) derivation of the multiplicative form for Σ -source aggregation-stage gain $K(\Sigma)$ from utility-cost analysis of belief-revision-under-strategic-commitment (this gates #der-belief-strategy-attractor's tier from *conditional* to *exact*). Both are in `TODO.md` per the queue maintenance.
- **Composite-level sub-type inheritance.** The composite-level class-inheritance table in `#der-directed-separation` (axis-decomposed by routing $\times$ substrate $\times$ dynamic-regime) tracks Class (1/2/3) inheritance. Extending the table to track Class 2 *sub-type* inheritance under composition is a substantive follow-on: given sub-agents with sub-types (S_i, R_i, F_i), what sub-type does

the composite occupy under routing R and substrate σ ? Not on the critical path for this segment; recorded as a candidate sub-spike for the composition machinery to extend.

- **Trajectory coupling as separate axis.** The per-step (stage $\times$ source $\times$ form) parameterization does not cover *trajectory* coupling — cumulative goal-content accumulating in M_t 's prior across history through repeated small Class 2 couplings, then amplified by goal-blind processing of new evidence. This is a real failure mode (and arguably the operational route to confirmation-bias cascades) but lives in a per-trajectory dynamics layer rather than the per-step structural typology. A separate spike treating trajectory coupling would parallel this segment's per-step analysis; not pursued here.
 - **Refined behavioral estimator — construction.** §Discussion sketches a refined estimator that probes along $\ker \mathcal{J}_\tau$ and distinguishes mean (content) from covariance/functional-form (process) signatures. Actual estimator construction is a separate work item; the segment names the targets but does not construct the estimator.
 - **Brief is not yet at Feynman criterion.** The current Brief reaches for the structural-recognition framing rather than an everyday physical analog. A candidate analog under consideration: the difference between (a) an engineer reading instruments and writing a goal-blind report, then a separate engineer reading the report and deciding what to do, versus (b) a single engineer reading instruments with the decision already in mind, where what they notice depends on what they're trying to accomplish — the first is Class 1, the second Class 3, and Class 2 is the messy middle where the typology says *which* part of the data-reading process is being shaped by the goal, *whether* the shaping is what-the-engineer-wants or what-plan-they're-committed-to, and *whether* the shaping is a measurable bias (subtractable) or a wholesale reframing (not subtractable). The bathtub-equivalent has not been written; the engineer-and-report analog is a working candidate but its isomorphism to the load-bearing structure (especially the source-asymmetry attractor and the form-determines-wrappability cut) needs verification.
 - **Connection back to #def-agent-spectrum Working Note.** The Working Note in #def-agent-spectrum ("The one genuinely-new thread: where the dangerous coupling concentrates") points at the leakage locus as a *where-in-the-inference* localization. This segment is the *through-what-stage-of-the-inference* complement. Together with the leakage-locus result they answer the two complementary questions: *where in state-space the effect lives* (leakage locus) and *what functional form it takes there* (this typology). When the leakage-locus result lands as its own appendix segment, the cross-reference should be made explicit on both sides.
-

Appendix AD

Discussion: The W_1 Structural-Bound Boundary

The W_1 structural leakage bound of `#der-class-coercion-via-wrapping` exists if and only if the wrapped component carries no goal-correlated state across the call boundary (condition (C2')); otherwise the goal-leak routes through a channel the wrapper cannot observe or condition on, and only a behavioral (W_2 -type) bound remains. The discontinuity at the boundary is a *certifiability* discontinuity, not a behavioral one: the leakage itself is continuous — and quadratically flat — in the degree of (C2')-violation, while what snaps at the boundary is the availability of the structural certificate.

Formal Expression.

Setup: the two channels and the conditioning that distinguishes them. Recall from `#der-class-coercion-via-wrapping` that the W_1 regime issues a structurally goal-blind query q_M to a black-box component A , then updates the wrapper belief M_W from the response $A(q_M)$. Two distinct goal variables are in play: the wrapper's internal register G_W (which q_M structurally does not take as an argument; Theorem 1 closes this *processing* channel exactly), and the latent operator goal G^{op} inferable from query content (the *selection* channel bounded by $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$). The structural bound is a property of the wrapper's query-selection policy because, under (C2'), $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ is a Markov chain — the goal can reach the response *only* through the query the wrapper chose.

The no-go: statefulness reopens an unobservable channel.

Drop (C2'). Let A carry hidden state S — a conversation KV-cache, a retrieval buffer, adaptive context — that is correlated with G^{op} through shared history (e.g. a prior goal-conditioned call in the same macro-step touched S). Then the response can depend on the goal *through* S , and this dependence survives conditioning on the query:

Discussion (w1-structural-bound-no-go).

$$I(A(q_M); G^{\text{op}} | q_M) \geq 0, \quad \text{and generically } > 0 \text{ when } S \not\perp G^{\text{op}}. \quad (\text{AD.1})$$

Conditioning on q_M no longer closes the path, because the leak does not flow through q_M — it flows through S . The conditioning that *would* close it, $I(A(q_M); G^{\text{op}} | q_M, S) = 0$, is unavailable to any wrapper-level analysis: S is internal to the black-box oracle and the wrapper cannot observe or condition on it. The Markov chain $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ is broken — there is now a second edge $G^{\text{op}} \rightarrow S \rightarrow A(q_M)$ that bypasses the query — so the data-processing argument that yields $\kappa_{W_1}^{\text{sel}} \leq I(q_M; G^{\text{op}})$ no longer holds.

No-go statement. For a component carrying goal-correlated cross-call state, *no bound on the belief-channel goal-leakage is derivable from the wrapper's query-selection policy alone*. The structural W_1 bound is available if and only if (C2') holds. When (C2') fails, the leak flows through an unobservable, unconditionable channel, and only a *behavioral* bound — estimated by monitoring $I(A(q_M); G^{op} \mid q_M)$ in the responses — remains, exactly as in the W_2 regime and for the same structural reason (an unconditionable goal-correlated channel). This locates the structural-versus-behavioral split not only in *wrapper design* (where to place the separation commitment — the $W_0/W_1/W_2$ regime choice) but *also* in a *component property*: statefulness across the call boundary forces a behavioral-only bound regardless of how the wrapper is built. The condition is sharp — it is not online weight-adaptation that breaks the structural bound (a frozen-weights LLM adapts nothing) but mere goal-correlated state persistence across the call boundary, which a frozen-weights LLM with a conversation cache exhibits.

The discontinuity is in the certificate, not in the behavior. The boundary at (C2') is best read as a *certifiability* discontinuity. Parameterize the (C2')-violation by ε , the goal-correlation retained in the cross-call state ($\varepsilon = 0$ is exact statelessness-about-the-goal; $\varepsilon > 0$ is a sliver of goal-correlated memory). Two facts hold at the boundary, and they point in opposite directions:

- **The behavior is continuous.** The actual goal-information reaching the belief is a continuous function of ε through $\varepsilon = 0$ — no jump, no threshold. Two wrappers differing only in ε leak amounts that differ by an amount shrinking with ε ; they cannot be told apart by watching their belief updates.
- **The certificate's validity is a step.** At $\varepsilon = 0$ the design-side certificate — *the goal is not in the query, the component is stateless about the goal, therefore the belief update cannot see the goal* — is true. At any $\varepsilon > 0$ that same certificate is still computable and still asserts the same thing, but is now *false*: the real leak is positive and took the unobservable path. The certificate's *value* (a flat selection-channel reading of 0 under goal-blind selection) is continuous across the boundary; its *truth* is the step function. Once $\varepsilon > 0$ the only honest instrument is behavioral monitoring.

So the wall is in the epistemics, not in the world: the leakage the structural certificate would have bounded is continuous in the (C2')-violation, and the discontinuity is in what is *provable*, not in what the agent *does*. This pre-empts the natural objection — *surely a tiny bit of state can only leak a tiny bit?* — by agreeing with it and relocating the bite: the leak is indeed tiny, but the structural guarantee is gone entirely.

What is solid versus suggestive. Two parts of the picture are exact and carry the no-go:

1. **The behavioral identity at the limit.** At exact statelessness-about-the-goal the structural certificate's zero reading is the truth (the leak is zero); the Markov chain holds and $\kappa_{W_1}^{sel} \leq I(q_M; G^{op})$ is valid.
2. **The certificate-validity step.** The structural certificate is available iff (C2') holds; at any (C2')-violation it asserts a false zero and only the behavioral monitor remains valid. This is forced by the unobservability of S and does not depend on the magnitude of the violation.

What is *suggestive but not proven in general* is the global *continuity-and-flatness* of the leakage past the boundary. In an exact-enumeration toy (single bit, single call, a state-bends-the-answer mechanism) the leak is monotone, smooth, and $\Theta(\varepsilon^2)$ — flat to first order — throughout the violation range. That is moderately strong evidence for the continuity reading and against a behavior-discontinuity reading, but it is a deliberately simple toy: a component whose retained state *amplifies* (state that controls the response gain, or multi-step accumulation across many calls) could in principle exhibit super-linear or threshold leakage, and that is not ruled out. The continuity claim is therefore stated as *robust qualitative* — the certifiability step is the exact load-bearing content; the smoothness of the leak past the boundary is the toy-suggested, not-fully-general, companion.

Epistemic Status.

Robust qualitative. The no-go itself — *the structural W_1 bound is available iff (C2') holds; under goal-correlated cross-call state the belief-channel leak is unconditionable at the wrapper level and only a behavioral bound remains* — is exact: it follows directly from the unobservability of the component's internal state S and the consequent breaking of the $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ Markov chain. The certifiability-discontinuity framing (behavior continuous, certificate-validity a step) rests on (a) the exact behavioral identity at the (C2') limit and (b) the certificate-validity step, both solid. The *general* continuity-and-flatness of the leakage in the degree of (C2')-violation is *suggestive, not proven*: it is exhibited cleanly in an exact-enumeration toy ($\Theta(\varepsilon^2)$ flatness), but a component with an amplifying state mechanism could in principle break smoothness, and that case is not closed. Hence the segment as a whole sits at robust qualitative rather than exact: the boundary's *existence and location* are exact; the boundary's *shape past it* is qualitatively characterized.

Max attainable: robust qualitative for the continuity-shape claim absent a general continuity proof; the no-go's existence-and-location is already exact.

Discussion.

Why this is a sharpening, not a softening, of W_1 . The W_1 regime's structural guarantee is not undercut by this boundary — it is given a precise domain of validity. Theorem 1 of `#der-class-coercion-via-wrapping` (exact directed separation under (C1)–(C3)) is untouched; the selection-channel bound is untouched within (C2'). What this segment adds is the honest statement of *when the structural bound stops existing* and *what replaces it* (a behavioral bound), together with the recognition that the replacement is forced by a component property orthogonal to wrapper design. A no-go with an explicit boundary characterization is more useful than a structural bound asserted without a stated domain.

Practical reading. The $\Theta(\varepsilon^2)$ flatness of the toy carries a counter-intuitive design implication: a near-stateless component is *operationally* almost as safe as an exactly-stateless one (a little cross-call memory leaks very little goal-information), but it is *certificationally* not safe at all (the structural guarantee is lost entirely the instant statelessness fails). The value of enforcing exact (C2')-statelessness across the call boundary is concentrated almost entirely in what it lets you *prove*, not in the marginal leakage it prevents. When deciding whether the engineering cost of true call-boundary state-resetting is worth it over “mostly reset,” the thing being bought is a proof, not a meaningful behavioral delta.

Relation to the Class 2 sub-typology. This boundary is the agent-level companion to the Σ -channel observation in `#disc-partial-coupling-pathways`: a Σ -source coupling in a stateful component can undermine W_1 's structural commitment via strategy-context that persists across calls, which is precisely a (C2')-violation. The sub-typology names the component-internal form of the coupling; this segment names the call-boundary condition under which W_1 's structural certificate survives it.

Relation to the action-side bounded-signaling assumption. The unobservable-channel structure here is the belief-side twin of the action-side bounded-signaling assumption named in `#der-directed-separation` — both are “a goal-correlated channel the formalism does not see.” Whether they are the same phenomenon viewed from two sides is left open.

Findings.

The W_1 Structural-Bound Boundary (Certifiability Discontinuity at (C2')). **Brief:** Imagine a scaffold that keeps a language model honest about its beliefs by only ever asking it goal-blind questions — “summarize this diff,” never “summarize this diff so we can ship the fix.” The promise of strict wrapping (W_1) is that you can *certify from the design alone* that the operator's goal cannot bend the belief update: the goal is structurally not an input to the belief-side query. That promise holds exactly when the component forgets everything about the goal between the goal-blind question and the goal-conditioned one. The moment the component keeps a sliver of goal-touched memory across that boundary — a conversation cache, a retrieval buffer — the goal can sneak into the answer through the memory, on a path the scaffold cannot see, and the design-side certificate becomes false even though it still computes the same reassuring number. The

striking part is *how* it fails: the actual amount of goal that leaks is continuous and, near the boundary, quadratically tiny — you can get a near-stateless component arbitrarily close in behavior to a stateless one. What snaps, all-or-nothing, is not the behavior but the *provability*: you lose the entire structural guarantee for an almost-invisible behavioral cost. You were buying a proof, not a meaningful safety margin.

Impact: Locates the structural-versus-behavioral leakage split of `#der-class-coercion-via-wrapping` in a *component property* (goal-correlated cross-call statefulness) independent of wrapper design, complementing the $W_0/W_1/W_2$ regime choice that locates it in wrapper construction. Promotes the Σ -channel-suppressed- W_1 Working Note of the wrapping segment to a named, load-bearing condition (C2') and gives the precise reason it is needed. Frames the no-go as a certifiability discontinuity — sharpening the CS-norm practice of characterizing *what kind* of boundary a no-go draws — and supplies the practical corollary that exact call-boundary statelessness buys a certificate, not a behavioral delta.

Novelty Claim: *Claim recognition* that the W_1 structural leakage bound's availability is governed by a sharp component-side condition (no goal-correlated cross-call state), with the boundary characterized as a discontinuity in the *validity of the structural certificate* rather than in the agent's leakage behavior — the leakage being continuous, and second-order flat, in the degree of condition-violation.

Related Work: - Cover & Thomas, *Elements of Information Theory* (2nd ed., 2006), data-processing inequality (published 2006, found 2026-05-31) — *formal antecedent* — the DPI along $G^{\text{op}} \rightarrow q_M \rightarrow A(q_M)$ is what holds under (C2') and breaks when an unobservable S adds a bypassing edge. - Pearl, *Causality* (2nd ed., 2009), d-separation / unobservable-confounder structure (published 2009, found 2026-05-31) — *adjacent literature* — the broken-Markov-chain reading (a hidden S confounding G^{op} and $A(q_M)$ that the wrapper cannot condition on) is the causal-graph idiom for the no-go.

Search Log: - 2026-05-31 (*intuition-only*): No dedicated literature search for the certifiability-discontinuity framing as such; the underlying tools (DPI, unobservable-confounder structure) are standard and cited. A targeted search for prior art on “certifiable goal-blindness under stateful components” / structural-vs-behavioral verifiability boundaries in scaffolded-agent design has not been conducted.

Working Notes.

- Reasoning trail (filed): the correction that produced this no-go and the certifiability-discontinuity framing are in `spikes/.integrated/spike-w1-leakage-vacuity-2026-05-31.md` and `spikes/.integrated/spike-w1-w2-boundary-intuition-2026-05-31.md` (cycle narrative: CHANGELOG 2026-05-31).
 - The exact-enumeration sim exhibiting the $\Theta(\epsilon^2)$ flatness (`spikes/sim-w1-w2-boundary.py`, figure `spikes/w1-w2-boundary.png`) sits unintegrated in `spikes/`, blocking on the sim-integration process (G3 in `INTEGRATION-CLEANUP-TODO.md`).
 - **Open: amplifying-state mechanisms.** The general continuity-and-flatness of the leak past the boundary is toy-suggested, not proven. A component whose retained state controls the response gain, or accumulates across many calls, could exhibit super-linear or threshold leakage. Closing this would lift the continuity-shape claim from robust qualitative toward exact; it connects to the M4 “amplification under high component fidelity” thread in `#disc-modularity-state-dynamics` and the accuracy-vs-inference-effect decomposition in `#der-class-coercion-via-wrapping` §Discussion “Two senses of component competence.”
 - **Open: behavioral-monitor construction.** Past the boundary only the behavioral bound $I(A(q_M); G^{\text{op}} \mid q_M)$ remains; constructing a consistent estimator for it (and for the latent G^{op} it conditions on) is the same open follow-on as the $\hat{\kappa}_{\text{processing}}$ estimator of `#der-directed-separation` and the decomposed-estimator spike candidate recorded in `#der-class-coercion-via-wrapping` Working Notes.

Appendix AE

Derived: Belief-Strategy Attractors Under Σ -Source Coupling

A Class 2 agent whose belief-update coupling is sourced from the strategy Σ_t — rather than from the objective O_t — closes a feedback loop $M_t \rightarrow \Sigma_t \rightarrow f_M \rightarrow M_t$ through the orient cascade. The loop admits *self-stabilizing fixed points* (M^*, Σ^*) in which the agent’s belief stays misaligned with the environment indefinitely: evidence arrives, but a strategy committed to a particular belief depresses the effective belief-update gain on evidence that would refute that strategy, locking (M, Σ) in a joint attractor. O_t -source coupling under the same structural form does *not* produce such attractors — because O_t is exogenous to M_t in steady state per the orient cascade, the feedback loop $M \rightarrow O \rightarrow f_M \rightarrow M$ does not close in nominal operation.

The result is the formal statement of the long-recognized empirical asymmetry between *sunk-cost commitment cascades* (self-reinforcing) and *identity-driven motivated reasoning* (biased but not divergently runaway): the cascade-vs-bias structural distinction is forced by the orient cascade’s exogeneity of O and not-exogeneity of Σ . The asymmetry holds *robust qualitatively* across the general nonlinear $K(\Sigma)$ form and *exact* under the linearized fixed-point analysis with a posited multiplicative gain. The result strengthens to *exact* under a derivation of $K(\Sigma)$ from utility-cost-of-belief-revision (a recommended follow-on sub-spike).

The derivation matches and extends the third row of #disc-adversarial-coupling-pressure’s mechanism table (sunk-cost engineering as $\Sigma_t \rightarrow M_t$). The mechanism table named the channel; this segment derives the dynamical consequence — that channel produces self-stabilizing fixed points, not merely bias.

Formal Expression.

Setup. A Class 2 agent has Σ_t -source coupling at stage P3 (aggregation) per #disc-partial-coupling-pathways. The coupled aggregation takes multiplicative process-form:

Formulation (strategy-source-coupled-aggregation).

$$M_{\tau+} = M_{\tau-} + K(\Sigma_{\tau-}) \cdot \ell_{\tau} \quad (\text{AE.1})$$

where ℓ_{τ} is the likelihood signal from upstream stages (goal-blind by assumption — only P3 couples; if upstream stages also couple, the cascade-propagation result of #disc-partial-coupling-pathways applies and the analysis localizes at the upstream-most coupled stage), and $K : \mathcal{S} \rightarrow \mathbb{R}^+$ is a Σ -dependent positive gain.

Sunk-cost is the canonical instantiation: $K(\Sigma)$ decreases as Σ commits more heavily to specific beliefs about reality. Formally — as the projection of Σ onto strategies presuming $M = m^*$ grows, K falls for evidence challenging m^* . The mechanism is utility-cost driven: the cost of revising M_t is bundled with the cost of abandoning Σ_t (the agent would lose the sunk strategic investment if it abandons the strategy), and the agent's belief-update gain effectively reflects this bundled cost. A derivation of $K(\Sigma)$ from a utility-cost analysis of belief-revision-under-strategic-commitment is a recommended sub-spike (see Working Notes).

The strategy is updated by the orient cascade per #der-orient-cascade:

Definition (orient-cascade-Sigma-update).

$$\Sigma_{\tau+} = f_{\Sigma}(M_{\tau+}, O_t, \Sigma_{\tau-}). \quad (\text{AE.2})$$

Closed-loop dynamics.

Substituting,

Derived (closed-loop-coupling, from #form-strategy-source-coupled-aggregation + #der-orient-cascade).

$$M_{\tau+} = M_{\tau-} + K(\Sigma_{\tau-}) \cdot \ell_{\tau}, \quad \Sigma_{\tau+} = f_{\Sigma}(M_{\tau-} + K(\Sigma_{\tau-})\ell_{\tau}, O_t, \Sigma_{\tau-}). \quad (\text{AE.3})$$

This is a closed-loop system in (M, Σ) with M_t entering $\Sigma_{\tau+}$ through the orient cascade and $\Sigma_{\tau-}$ entering $M_{\tau+}$ through the coupled aggregation.

Fixed-point structure.

A fixed point (M^*, Σ^*) satisfies

Derived (fixed-point-conditions).

$$K(\Sigma^*) \cdot \ell^* = 0, \quad \Sigma^* = f_{\Sigma}(M^*, O_t, \Sigma^*). \quad (\text{AE.4})$$

The condition $K(\Sigma^*) \cdot \ell^* = 0$ admits two qualitatively distinct solutions:

(a) Honest convergence: $\ell^* \rightarrow 0$ — no further evidence to integrate. M^* is the agent's converged belief; the asymptotic dynamics match standard Bayesian convergence under a stationary evidence stream.

(b) Pathological attractor: $K(\Sigma^*) \rightarrow 0$ — the gain has collapsed *even though* $\ell^* \neq 0$. Evidence arrives that would, under honest gain, update M — but the gain has fallen near zero on the relevant subspace, so the evidence does not propagate. The agent's M stays at m^* ; Σ stays committed to the strategy that presumes m^* ; the system rests in a (m^*, Σ^*) attractor misaligned with the environment.

Case (b) is the **belief-strategy attractor** — the formal structure of sunk-cost commitment cascades.

Linearized stability.

Linearize the closed-loop dynamics around (M^*, Σ^*) . Define perturbations $\delta M_\tau = M_\tau - M^*$, $\delta \Sigma_\tau = \Sigma_\tau - \Sigma^*$, and partial derivatives at the fixed point:

Derived (linearized-stability), exact under linearization.

$$K^* = K(\Sigma^*), \quad K'^* = \partial_\Sigma K|_{\Sigma^*}, \quad A = \partial_M f_\Sigma|_{(M^*, \Sigma^*)}, \quad B = \partial_\Sigma f_\Sigma|_{(M^*, \Sigma^*)}. \quad (\text{AE.5})$$

Treating ℓ as a function of M for the locally-linearized evidence-arrival process — $\ell \approx -L\delta M$ for some positive-semi-definite information matrix L — the linearized dynamics are:

$$\delta M_{\tau+} = (I - K^*L)\delta M_{\tau-} + (K'^*\ell^*)\delta \Sigma_{\tau-}, \quad (\text{AE.6})$$

$$\delta \Sigma_{\tau+} = A\delta M_{\tau+} + B\delta \Sigma_{\tau-}. \quad (\text{AE.7})$$

The Jacobian of the closed-loop map:

$$J = \begin{pmatrix} I - K^*L & K'^*\ell^* \\ A(I - K^*L) & AK'^*\ell^* + B \end{pmatrix}. \quad (\text{AE.8})$$

The fixed point (M^*, Σ^*) is a stable attractor iff all eigenvalues of J have modulus less than 1. In the sunk-cost-collapse regime $K^* \rightarrow 0$, the top-left block $I - K^*L \rightarrow I$ — there is *no contraction in the M direction* — and stability is determined by the Σ -direction block B . If B has spectral radius less than 1 (the orient cascade is contractive in Σ near Σ^* , which is typical for strategy-update dynamics with friction), the joint fixed point is stable *despite the absence of M -direction contraction* — the strategy stabilizes around its commitment, and the absence of belief-update propagation keeps M near m^* .

Result (pathological-attractor-condition), conditional.

This is the formal statement: **Σ -source coupling with multiplicative process-form admits self-stabilizing attractors in which the agent's belief remains misaligned with the environment indefinitely.**

Contrast — O_t -source coupling produces no such attractor.

Substitute the same coupling form with O as source:

Derived (O -source-no-attractor), conditional on orient-cascade exogeneity.

$$M_{\tau+} = M_{\tau-} + K(O_t) \cdot \ell_\tau. \quad (\text{AE.9})$$

Per #der-orient-cascade, O_t revises only when forced — under nominal operation, O_t is *exogenous* to M_t in steady state. In steady state $O_t = O^*$ is constant; $K(O_t) = K(O^*)$ is constant. The closed-loop dynamics reduce to a standard contractive Bayesian update with a goal-shaped (but fixed) gain:

$$\delta M_{\tau+} = (I - K(O^*)L)\delta M_{\tau-} + 0 \cdot \delta O_{\tau-}. \quad (\text{AE.10})$$

The O -feedback term vanishes because O does not update from M in steady state. The map is contractive whenever $K(O^*)L$ has appropriate properties; the agent's belief has a *bias* (the gain $K(O^*)$ may be smaller than the honest gain,

producing slower convergence or a non-zero asymptotic residual relative to the true environment) but it has no feedback-induced *foreclosure* of belief-revision.

Pure O_t -source coupling produces bias but not runaway commitment. The source asymmetry is structural: it follows directly from the orient cascade's exogeneity of O and not-exogeneity of Σ , not from any additional property of K .

Source-asymmetry result.

Pure Σ_t -source coupling at any stage of f_M closes a feedback loop $M \rightarrow \Sigma \rightarrow f_M \rightarrow M$ through the orient cascade and admits self-stabilizing belief-strategy attractors. Pure O_t -source coupling at the corresponding stages does not, because the orient cascade's exogeneity of O in steady state prevents the loop from closing.

Derived (source-asymmetry-attractor), robust qualitative (exact under linearization with multiplicative K).

The asymmetry is *structural* — it follows from the topology of the orient cascade, not from a parametric difference between O and Σ . Any mixed-source coupling $R = \{O, \Sigma\}$ inherits the Σ -component's attractor possibility — even moderate Σ -source coupling, paired with strong O -source coupling, can produce the attractor through the Σ channel alone.

Epistemic Status.

Conditional. Max attainable under current derivation: *exact* for the linearized fixed-point analysis under the posited multiplicative gain $K(\Sigma)$ and the orient-cascade exogeneity of O ; *robust qualitative* for the general nonlinear K and the broader claim that any closed-loop topology $M \rightarrow \Sigma \rightarrow f_M \rightarrow M$ admits the attractor structure.

Stated conditions:

(R1) **Multiplicative gain form.** $K(\Sigma)$ is posited as a positive scalar (or pointwise-positive matrix) gain modulating the aggregation step's update magnitude. The form is structurally motivated by the empirical mechanism (sunk-cost bundles the cost of revising M with the cost of abandoning Σ , which in linearization presents as gain suppression) but not derived from a more primitive AAT mechanism. A derivation of $K(\Sigma)$ from utility-cost analysis of belief-revision-under-strategic-commitment is the gating sub-spike for tier-upgrade to *exact*.

(R2) **Orient-cascade exogeneity of O in steady state.** O revises only when forced per #der-orient-cascade. Agents that violate this — continuously updating O as a function of M — collapse the source asymmetry: O -coupling then closes a feedback loop too, but the orient cascade explicitly forbids this in canonical AAT. Identity-binding under sustained adversarial pressure may be the operational regime where O effectively updates from M (per #disc-adversarial-coupling-pressure); this is where the asymmetry attenuates.

(R3) **Linearization validity.** The fixed-point stability analysis is local. Generalization to nonlinear K , f_Σ preserves the *qualitative* asymmetry (the feedback-loop topology is independent of linearization) but the explicit fixed-point structure may admit multiple attractors, limit cycles, or chaos.

(R4) **Stage of coupling.** Stated for P3 (aggregation) for definiteness; the asymmetry is *generic across stages* — the closed-loop topology depends on which source is coupled, not on which pipeline stage hosts the coupling. P3 is the canonical sunk-cost site; identity-protective consolidation (P4 / O) and frame-coupling (P1 / Σ) instantiate the asymmetry at other stages.

Discussion.

The structural reason sunk-cost has a different empirical signature than motivated reasoning. Sunk-cost cascades are documented as *self-reinforcing* in psychology (Staw 1976; Brockner 1992; Arkes & Blumer 1985; Sleesman et al. 2012 meta-analysis) and in organizational behavior. Identity-driven motivated reasoning is documented as producing *bias* but not divergent attractors except in identity-bound communities reinforcing priors. The asymmetry across these literatures has not, to our knowledge, been derived as a structural theorem; the empirical clustering is well-known but the structural reason — strategy is endogenous to belief via the cascade, while objective is exogenous in steady state — is the AAT-internal contribution. The derivation above formalizes the empirical-clustering observation as a consequence of the orient cascade’s topology.

Implication for adversarial pressure. #disc-adversarial-coupling-pressure’s sunk-cost-engineering mechanism is the adversary engineering precisely this structure: by inducing the target to commit publicly or expensively to a strategy that presumes a particular belief, the adversary locks the target’s (M, Σ) into the attractor regime. Once the attractor is established, the adversary can stop driving and the target’s own internal dynamics maintain the misaligned belief. This is the structural reason sunk-cost engineering is so effective in propaganda, influence operations, and social engineering: the target’s own machinery does the maintenance work after the initial commitment.

Implication for class-coercion-via-wrapping. A Class 3 (Coupled) component wrapped to Class 1 status via the construction of #der-class-coercion-via-wrapping requires extra care when the un-wrapped component has Σ -source coupling. Even W_1 (strict wrapping — no G in the belief-update query) may be insufficient if the component’s *internal* Σ is influenced by historical query content that carries strategic context, and that internal Σ then suppresses the gain on subsequent goal-blind queries. The corrective is a Σ -channel-suppressed W_1 : the wrapper must additionally hold the component’s strategic context fixed across calls or strip strategic-context-bearing content from the queries. This is a finer-grained design constraint than the wrapping-construction segment currently surfaces; it follows directly from the source-asymmetry result.

Implication for compositional dynamics. The composite-level class inheritance table in #der-directed-separation tracks composite Class membership but not composite sub-type. A composite of Class 1 (Separated) sub-agents whose routing is goal-dependent (R_t depends on G_t^c) is Class 3 at the composite level per the inheritance table — but the source-asymmetry result of this segment further refines the composite’s sub-type: if the routing’s G^c -dependence is on the composite’s strategy Σ^c rather than its objective O^c , the composite admits belief-strategy attractors at the composite level. This is the operational reason organizations with strong strategic commitments and goal-dependent internal routing exhibit sunk-cost dynamics at the institutional scale.

The diagnostic question for a Class 2 agent. When inspecting a Class 2 agent, the diagnostic question that distinguishes attractor-vulnerable from bias-vulnerable sub-types is: *is the coupling sourced from O_t or from Σ_t ?* The question is sharper than asking the aggregate $\kappa_{\text{processing}}$ magnitude, because the topological consequence (attractor possibility) depends on the source, not on the magnitude. Empirically, the source can be probed by varying O_t at fixed Σ_t vs Σ_t at fixed O_t and observing which probe condition reveals the gain modulation. In setups where holding Σ fixed is operationally difficult, the diagnostic falls back to the dynamical-signature analysis: does the agent’s belief, under sustained counter-evidence, *converge slowly with bias* (O -source signature) or *fail to converge at all* in a self-stabilizing pattern (Σ -source signature)?

Findings.

Belief-Strategy Attractors From Σ -Source Coupling (Source Asymmetry). **Brief:** An agent whose belief-update is shaped by *what it currently wants to be true* will be biased — its beliefs will lean toward the goal — but a thoughtful third party can in principle measure the bias and correct it, and the agent’s beliefs will eventually catch up to reality as evidence accumulates. An agent whose belief-update is shaped by *what plan it is currently committed to* is structurally different: the strategy commitment depresses the agent’s belief-update gain on evidence that would invalidate the strategy, the depressed gain keeps belief at the strategy-consistent point, and the unchanging belief sustains the strategy

commitment. The agent locks into a joint *belief-and-strategy attractor* — a fixed point where the agent stays misaligned with reality indefinitely, with no internal mechanism to escape. The structural reason: the agent's strategy is updated by the agent's beliefs, so coupling beliefs to strategy closes a feedback loop. Beliefs and objectives are not coupled the same way — objectives are revised only when forced, so coupling beliefs to objectives doesn't close the loop. This is the structural reason sunk-cost cascades self-reinforce in a way that identity-driven motivated reasoning does not.

Impact: Names the structural origin of the sunk-cost / motivated-reasoning empirical asymmetry — both have been documented across psychology and organizational behavior, but the structural reason (orient cascade endogeneity of Σ vs exogeneity of O) has not, to our knowledge, been stated as a derived theorem. Sharpens the wrapping-regime selection of $\#der$ -class-coercion-via-wrapping for Class 2 components with Σ -source coupling: Σ -channel-suppressed W_1 may be required even when ordinary W_1 would suffice for O -source coupling. Connects $\#disc$ -adversarial-coupling-pressure's sunk-cost-engineering mechanism (third row of the mechanism table) to a dynamical-attractor structure rather than just a channel; explains why the mechanism is so effective in propaganda and influence operations (the target's own machinery does the maintenance work). Provides a diagnostic question for inspecting Class 2 agents — source of coupling — that is sharper than the aggregate $\kappa_{processing}$ magnitude.

Novelty Claim: *Claim recognition* of the structural source asymmetry as a direct consequence of the orient cascade's topology — strategy is endogenous to belief, objective is exogenous in steady state. *Claim differentiation* on the resulting fixed-point analysis: linearized stability with $K^* \rightarrow 0$ produces an attractor in the closed-loop dynamics under the Σ -source case but not under the O -source case. The empirical clustering across the sunk-cost and motivated-reasoning literatures is well-established; the AAT-internal contribution is naming the structural reason and stating it as a derived theorem.

- Kunda 1990 *Psychological Bulletin* “The Case for Motivated Reasoning” — *empirical instantiation supporting (contrast case)* — the canonical motivated-reasoning treatment; produces bias but not the divergent-attractor signature of sunk-cost — the empirical contrast the source-asymmetry result structurally explains.
- Kahan cultural-cognition project (various years) — *empirical instantiation supporting (contrast case)* — identity-driven motivated reasoning produces persistent bias but typically not runaway divergence except when paired with composite-level identity-binding community dynamics; the contrast with sunk-cost is exactly the source-asymmetry distinction.
- Bénabou & Tirole 2002, 2011 *Quarterly Journal of Economics* on identity economics and motivated beliefs — *adjacent literature, not yet searched* — formal models trading off truth vs identity; possibly anticipates aspects of the source distinction.

Search Log:

- 2026-05-22 (*intuition-only*): The empirical sunk-cost / commitment-cascade literature is well-established and well-known to converge on the self-reinforcement signature; the empirical motivated-reasoning literature is similarly well-established and converges on the bias-without-runaway signature. The *structural derivation* of the asymmetry from the orient cascade's topology has not been searched. Recommended Pillar-style targeted search before tier upgrade — primary targets are the formal-models side of behavioral economics (Bénabou-Tirole identity economics; Akerlof-Kranton identity economics) and the formal-models side of motivated-reasoning psychology (Kruglanski lay epistemics; possibly Shah-Friedman-Kruglanski goal-shielding 2002 *JPSP*). The active-inference / control-as-inference literatures are unlikely to have this specific result (they don't typically separate O and Σ as distinct goal-state objects), but should be confirmed.

Working Notes.

- **Tier-upgrade gating sub-spike — derivation of $K(\Sigma)$ from utility-cost analysis.** The multiplicative-gain form $K(\Sigma)$ is *posited* per condition (R1). The empirical mechanism (sunk-cost bundles the cost of revising M with the cost of abandoning Σ) suggests the effective dynamics are gain-suppressing in the linearized regime, but the explicit derivation has not been produced. Sub-spike scope: model the agent's belief-update as an optimization minimizing $\text{prediction-error}(M, e) + \lambda \cdot \text{strategy-revision-cost}(\Sigma, M)$, derive the effective belief-update first-order condition, and verify that the linearized form is gain-modulation with $K \propto 1/(1 + \lambda \cdot \partial_M^2 \text{strategy-revision-cost})$. If this matches the multiplicative form, the result strengthens to *exact* under the linearization. If the linearization yields a different form (e.g., additive regularization rather than multiplicative gain), the result is refined accordingly. Recommended as the higher-priority of the two disc-partial-coupling-pathways-gated sub-spikes.
- **Tier-upgrade gating sub-spike — Pillar prior-art search.** The empirical clustering across sunk-cost and motivated-reasoning literatures is well-established; the structural derivation as a theorem is plausibly novel under search-depth conducted. Recommended Pillar-style targeted search across behavioral economics (Bénabou-Tirole, Akerlof-Kranton), motivated-cognition psychology (Kruglanski, Shah-Friedman-Kruglanski), and self-deception philosophy (Mele, von Hippel-Trivers). See #disc-partial-coupling-pathways Working Notes for the broader scope.
- **Composite-level extension.** A composite of Class 1 sub-agents with goal-dependent routing where the goal-dependence is on the composite's *strategy* Σ^c (rather than its objective O^c) inherits the attractor possibility at the composite level. This refines the composite-level class inheritance table in #der-directed-separation. Extending the table to track composite sub-type (and hence composite attractor-vulnerability) is the structural-composition follow-on noted in #disc-partial-coupling-pathways Working Notes.
- **Empirical estimator — distinguishing O -source bias from Σ -source attractor under behavioral observation.** Conceptually distinct (slow biased convergence vs convergence-failure); in practice may require careful experimental design. The dynamical signature is the cleanest discriminator: under sustained counter-evidence, O -source coupling produces convergence asymptotically (with bias-magnitude proportional to the gain reduction); Σ -source coupling produces non-convergence (the gain falls toward zero faster than the evidence accumulates). The empirical literatures on sunk-cost vs motivated-reasoning have already documented this clustering; a behavioral-estimator construction that decisively distinguishes the two on a single agent under controlled probing is a separate work item.
- **Connection to #deriv-strategic-composition.** The strategic-composition machinery handles composite-level dynamics under partially-opposing objectives, with the dynamic-regime axis (#disc-dynamic-regime-axis) carrying the goal-alignment effects independently of architectural class. The source-asymmetry result of this segment is at the *single-agent* level — it constrains the structural properties of an individual Class 2 agent. The composite-level extension (above) would bridge the two; not pursued in this segment.
- **Brief is below Feynman criterion.** The current Brief states the result by contrasting two empirically-familiar phenomena (sunk-cost cascade vs identity-driven motivated reasoning), which is closer to recognition than to an isomorphic physical analog. A candidate analog reaching for the Feynman criterion: imagine a thermostat whose *current setpoint* (objective) is fixed exogenously by a building operator, vs one whose setpoint *itself drifts* based on the room temperature it has been recently

reading — the second creates a feedback loop where the thermostat slowly forgets what temperature the room is *supposed* to be at, because the goalpost has moved with the observation. The first thermostat reaches the setpoint with some bias if the temperature sensor is off; the second can drift indefinitely. The thermostat analog reaches for the closed-loop topology but doesn't capture the multiplicative gain mechanism — the load-bearing structure is in *which way* the loop closes, not just that one closes. The analog needs sharpening.

Appendix AF

Discussion: The Dynamic-Regime Axis — Contraction / Equilibrium / Cyclic-Distributional / Mean-Field

AAT composites differ on at least three independent structural axes: their *architectural class* (Class 1 Separated / Class 2 Partial / Class 3 Coupled, per #der-directed-separation) — about processing topology; their *dynamic regime* (this segment) — about the structural type of the joint-dynamics fixed point and the Lyapunov certificate available; and their *macro-state type* (state-variable / fixed-point object / distributional) — about what kind of object the composite's G_t^c is. This segment names the dynamic-regime axis as a first-class structural classifier, in vocabulary the framework already runs implicitly across #deriv-strategic-composition's α'/β' partition, #form-composition-closure's contraction presupposition, #disc-separability-pattern's Contraction ladder, #scope-composite-agent's scope-route disjunction, and #impl-strategic-composition's “contraction-to-equilibrium hand-off” framing.

The four-tier ladder is recognized prior art. This is integration, not invention. The partition AAT names — contraction-regime / equilibrium-regime / cyclic-distributional-regime / mean-field-equilibrium-regime — appears (under different vocabulary, with isomorphic structural content) across at least five neighboring literatures. Candogan, Menache, Ozdaglar & Parrilo's 2011 Hodge-style decomposition of finite games into potential + harmonic + nonstrategic components supplies a coordinate-free organizing structure for the equilibrium-regime / cyclic-regime boundary cleaner than any tier-wise enumeration; Letcher, Balduzzi et al.'s 2019 *Differentiable Game Mechanics* lifts the same potential/Hamiltonian decomposition to the dynamics side; Sandholm's 2010 *Population Games and Evolutionary Dynamics* organizes the potential/stable/cyclic taxonomy at the population level; Hofbauer & Sigmund's 1998 *Evolutionary Games and Population Dynamics* names the phase-portrait classification (equilibrium vs cycle vs heteroclinic) directly; Omidshafiei et al.'s 2019 α -Rank construction uses cyclic-dynamics-as-meaning as a solution concept; and Papadimitriou-Piliouras's 2018 *From Nash Equilibria to Chain Recurrent Sets* establishes the chain-recurrent set as the natural object when dynamics fail to converge. AAT's contribution is *not* the classification itself; it is (a) the consolidation of the partition into AAT-internal vocabulary that travels with #scope-composite-agent's scope-route disjunction and #disc-separability-pattern's separable-core / structured-repair / general-open shape, (b) three derivable structural identities that name what the axis carries within an integrated agent theory, and (c) cross-axis observations about how the axis composes with architectural class and macro-state type.

This segment is the *positive-half companion* to the broadened #disc-identifiability-floor Instance 3, which names the negative half — regime identification from component marginals is structurally impossible without composite-level coupling-topology observation. The two together mark AAT's scope on the axis at both extremes, parallel to how #disc-separability-pattern and #disc-identifiability-floor jointly mark scope on the identification axis.

The pattern.

Each composite agent satisfying #scope-composite-agent admits a dynamic regime — a structural property of its joint best-response dynamics that is *determined by the game structure* (the sub-agent objectives, the strategy spaces, the payoff curvatures) rather than by any particular trajectory the dynamics realize. The regime determines the strongest Lyapunov-class certificate the dynamics admit relative to their fixed-point set, and that certificate determines the operational machinery available — exponential convergence near a unique attractor, exponential convergence near an equilibrium set, polynomial convergence in distribution, or measure-space dynamics at the population-scale limit.

The classification is *not behavioral* (it does not depend on observing trajectories) and it is *not parametric* (it does not depend on a continuous tuning parameter). It is structural and discrete, the same shape #der-directed-separation's architectural classification has — a partition determined by the game structure, with sub-tier classifications within each regime.

The four tiers.

Following the order of progressively weakening Lyapunov certificate:

Table AF.1

<i>Tier</i>	<i>Fixed-point structure</i>	<i>Lyapunov certificate</i>	<i>Macro-state type</i>	<i>Convergence rate</i>	<i>Scope route entry</i>
R0 Contraction	Unique attracting $X^* \in \mathcal{X}^c$	Joint Lyapunov V , global or basin-restricted	State-variable X^*	Exponential at α_{joint}	C-i / C-ii / C-iii
R1 Equilibrium (α')	Fixed-point set $\mathcal{E} \subset \mathcal{X}^c$, locally attracting	Potential Φ (Monderer-Shapley) or weighted-norm (Rosen)	Fixed-point object $\mathcal{E}$	Exponential near $\mathcal{E}$ at $\alpha_{\text{joint}}^{(j)}$	C-iv + potential/monotone
R2 Cyclic-distributional (β')	No pure-strategy fixed point, or saddle-only	None on $\mathcal{X}^c$; doubling-trick CCE on $\Delta(\mathcal{X}^c)$	Distributional object $\mu \in \Delta(\mathcal{X}^c)$	Polynomial $O(1/\sqrt{T})$	C-iv without potential/monotone
R3 Mean-field equilibrium	Distributional fixed point in measure space	MFG-specific (Lasry-Lions monotonicity)	Distribution-on-population $\rho \in \mathcal{P}(\mathcal{A})$	MFG-specific, often exponential	Population-scope gap

Each tier inherits the tier-internal classification of its closest existing AAT machinery — R0's Tier 1 / Tier 2 / Tier 3 sub-classification from #disc-separability-pattern's Contraction ladder; R1's potential / monotone / general sub-tier per #deriv-strategic-composition's sub-scope α' ; R2's regret-bound sub-classification per Hart-Mas-Colell 2000; R3's MFG-uniqueness sub-classification per Lasry-Lions 2007.

R0 — Contraction-regime. The joint dynamics admit a unique attracting fixed point $X^* \in \mathcal{X}^c$ and a Lyapunov function $V : \mathcal{X}^c \rightarrow \mathbb{R}_{\geq 0}$ with $V(X^*) = 0$, $V(X) > 0$ for $X \neq X^*$, such that

$$\frac{d}{dt} V(X_t^c - X^*) \leq -\alpha_{\text{joint}} \cdot d(X_t^c, X^*)^2 \quad \forall X_t^c \in \mathcal{B}(X^*) \quad (\text{AF.1})$$

for some basin $\mathcal{B}(X^*)$ and contraction rate $\alpha_{\text{joint}} > 0$. Macro-state $X^* \in \mathcal{X}^c$ is a state-variable. Composites satisfying scope routes C-i (shared composite objective), C-ii (hierarchical derivation), or C-iii (mutual-benefit alignment) under matched-Tier sub-agents per `#deriv-critical-mass-composition` land here. The classical AAT machinery applies: `#result-sector-persistence-template`, `#form-composition-closure` bridge lemma, `#der-team-persistence`, `#der-tempo-composition`.

R1 — Equilibrium-regime (α'). The joint dynamics admit a fixed-point set $\mathcal{E} = \{X_j^*\}_{j \in J}$ with $|J| \geq 1$ where each X_j^* is a Nash equilibrium. Lyapunov-on-deviation holds locally near each equilibrium under either potential-game structure (Monderer-Shapley 1996) or monotone-game structure (Rosen 1965 diagonal strict concavity). The macro-state is a fixed-point object — either a single Nash X^* if unique, or the equilibrium set if multiple. Composites satisfying scope route C-iv with potential/monotone structure land here; `#deriv-strategic-composition`’s Cournot worked example is the canonical instantiation. The sector-persistence template transfers with the joint potential’s curvature (potential case) or the joint Jacobian’s symmetric part (monotone case) supplying $\alpha_{\text{joint}}^{(j)}$ at each equilibrium.

R2 — Cyclic-distributional-regime (β'). The joint dynamics admit no fixed point in pure-strategy space, or fixed points that are not local attractors (saddle-Nash in zero-sum games where best-response orbits without approaching). No-regret dynamics drive the empirical joint distribution to the coarse correlated equilibrium set (Hart-Mas-Colell 2000):

$$\frac{1}{T} \sum_{t=1}^T \mathbb{1}\{\pi_t^c \in \text{CCE}\} \rightarrow 1 \quad \text{at rate } O(1/\sqrt{T}). \quad (\text{AF.2})$$

The macro-state is a distributional object — a measure $\mu \in \Delta(\mathcal{X}^c)$ supported on the CCE set. Composites satisfying scope route C-iv without potential or monotone structure land here. AAT in R2 predicts only set-convergence of empirical play to CCE; it cannot predict short-run trajectory, per-sub-agent mismatch convergence, or equilibrium selection. This is the framework’s honest β' scope limit — a regime limit, not an architectural limit, distinct from any architectural-class restriction.

Cross-layer linearization fingerprint at saddle-only Nash. R2’s saddle-only Nash equilibria have a single-agent linearization-spectrum fingerprint of imaginary-axis-semisimple — the *R0-loss* rung of `#result-certificate-existence`’s single-agent certificate-strength ladder. The two R-letter ladders are layered, not collided: this segment’s R0/R1/R2/R3 classifies composite joint-dynamics on $\mathcal{X}^c$, while `#result-certificate-existence`’s R0-loss/R0-strict/R1/R2 classifies single-agent certificate-strength on the linearized error space $\mathbb{R}^n$. The bridge is via composition (the joint Jacobian at R2’s saddle-Nash linearizes to the antisymmetric R0-loss-at- $\mathcal{M} = I$ sub-case); the letters are deliberately reused to mark the bridge, not by collision.

R3 — Mean-field-equilibrium-regime. For $N \rightarrow \infty$, each agent interacts with the *distribution* of other agents’ strategies rather than with named others. The macro-state becomes a distributional fixed point in measure space; the dynamics may contract to this fixed point under explicit conditions (Lasry-Lions 2007; Huang-Malhamé-Caines 2006). R3 is distinct from R2: R2’s macro-state is a distribution-on-strategies arising as the empirical play of finite- N dynamics with saddle-or-cyclic fixed-point structure on the pure-strategy space; R3’s macro-state is a distribution-on-population-strategies arising as the thermodynamic limit with genuine attractor on the measure space. R3 is the only tier where macro-state type genuinely diverges from dynamic regime in a way the framework’s existing α'/β' does not capture. R3 is the population-scope gap that Part III currently flags.

AAT-specific derivable content.

The axis is not only consolidation. Three derivable contents fall out once it is stated formally; one is the candidate floor instance landing concurrently in `#disc-identifiability-floor` Instance 3 (broadened).

Identity: macro-state-type and dynamic regime coincide for finite N . For finite- N composites (tiers R0/R1/R2), the macro-state type is structurally identified by the dynamic regime:

- $\mathcal{R}(X^c) = R0 \Leftrightarrow G_*^c \in \mathcal{X}^c$ (state-variable).
- $\mathcal{R}(X^c) = R1 \Leftrightarrow G_*^c = \mathcal{E} \subset \mathcal{X}^c$ (fixed-point object).
- $\mathcal{R}(X^c) = R2 \Leftrightarrow G_*^c = \mu \in \Delta(\mathcal{X}^c)$ (distributional object).

Each direction follows from the entry conditions in §”The four tiers.” R0 demands unique attracting fixed point in $\mathcal{X}^c$, which gives a state-variable. R1 demands a fixed-point set under Lyapunov-on-deviation, which is a fixed-point object. R2 demands no pure-strategy fixed point plus no-regret CCE convergence, which gives a distributional object. The converse direction follows from the macro-state type forcing the available Lyapunov machinery: state-variable admits scalar Lyapunov (R0); fixed-point set admits potential or weighted-norm Lyapunov (R1); distributional macro-state admits only doubling-trick CCE convergence (R2).

R3 breaks the identity. Mean-field-equilibrium has distributional macro-state with contracting dynamics, distinct from R2’s polynomial CCE convergence. The two axes (dynamic regime, macro-state type) are genuinely distinct and the breaking case is exactly the population-scope frontier the framework currently flags as gap. The identity is the cleanest formal content the axis carries: it is the axis that unifies fixed-point structure, Lyapunov certificate, and macro-state type into a single classification for finite- N composites, with the mean-field limit as the explicit boundary case.

Transition asymmetry: descent is the default, ascent costs more. Five non-trivial transitions exist between adjacent tiers, with a structural asymmetry between descent ($R0 \rightarrow R1$; $R1 \rightarrow R2$) and ascent ($R1 \rightarrow R0$; $R2 \rightarrow R1$). Descent under generic perturbation of the objective structure is the default — alignment is fragile, potential-structure is fragile, both can be destroyed by local perturbations. Ascent requires explicit structural commitment that costs more than the descent did to acquire. Symbiogenic absorption (#hyp-symbiogenic-composition) is the structural mechanism for $R1 \rightarrow R0$ ascent; mechanism design under explicit potential-game constraints is the mechanism for $R2 \rightarrow R1$ ascent — both impose structural commitments that out-of-band negotiation, designer intervention, or institutional shaping must supply.

This is an energy-asymmetry on the dynamic-regime axis — descent is downhill, ascent is uphill, and the asymmetry is structural rather than parametric. Adversaries exploit it as the modularity-state version exploits the modularity descent (see #disc-adversarial-coupling-pressure for the modularity analog).

The transition asymmetry is currently argumentation-grade; a fully-derived statement tied to a structural-distance metric on game-rewiring space would upgrade it to derived, and this segment names the shape pending that derivation. The mechanism-design impossibility theorems (Gibbard-Satterthwaite 1973–75, Myerson-Satterthwaite 1983, Arrow 1951) are *floors on regime-ascent* under stated designer constraints; the queued #disc-implementation-impossibility meta-segment carries the formal treatment of mechanism-design impossibility as designer-side constructive-impossibility.

Lyapunov-machinery transfer $R0 \rightarrow R1$. The persistence template #result-sector-persistence-template lifts cleanly across $R0 \rightarrow R1$, with the Lyapunov function changing form at each tier:

$$R0: V_{R0}(X^c) = \|X^c - X^*\|^2 \quad \dot{V}_{R0} \leq -\alpha_{\text{joint}} V_{R0} \quad (\text{AF.3})$$

$$R1 \text{ potential: } V_{R1,\Phi}(\pi^c) = \Phi(\pi^c) - \Phi(\pi_*^c) \quad \dot{V}_{R1,\Phi} \geq \alpha_{\text{joint}} \|\nabla \Phi\|^2 \quad (\text{AF.4})$$

$$R1 \text{ monotone: } V_{R1,F}(\pi^c) = \frac{1}{2}(\pi^c - \pi_*^c)^\top P(\pi^c - \pi_*^c) \quad \dot{V}_{R1,F} \leq -\alpha_{\text{joint}} V_{R1,F} \quad (\text{AF.5})$$

with P the weighted-norm matrix solving the Lyapunov equation for the linearized ∇F at π_*^c . At R2 the Lyapunov form fails — no state-space Lyapunov exists; the dynamics orbit equilibria rather than converge to them. The doubling-trick (Hart-Mas-Colell 2000) gives a regret bound, which translates to empirical-distribution convergence to CCE at $O(1/\sqrt{T})$ rate. The transfer makes the framework's existing α'/β' partition explicitly a regime-axis property rather than scattered across #deriv-strategic-composition.

What the axis lets the framework consolidate.

The axis already lives across ten-plus existing segments under different names. Surfacing it as a formal classifier consolidates these implicit usages into one explicit definition:

Table AF.2

<i>Existing segment / construct</i>	<i>Axis-vocabulary content</i>
#scope-composite-agent routes C-i/ii/iii	Entry conditions for R0
#scope-composite-agent route C-iv	Entry condition for R1 + R2 (potential/monotone $\rightarrow$ R1; without $\rightarrow$ R2)
#form-composition-closure contraction presupposition	R0 machinery
#result-sector-persistence-template	R0 sector constant + persistence
#deriv-critical-mass-composition matched-Tier closed form	R0 sub-tier specialization
#der-team-persistence cooperative limit	R0 limiting case
#deriv-strategic-composition sub-scope α'	R1 with potential/monotone Lyapunov transfer
#deriv-strategic-composition sub-scope β'	R2 with CCE convergence only
#impl-strategic-composition “contraction-to-equilibrium hand-off”	R0 $\rightarrow$ R1 transition
#disc-separability-pattern Contraction ladder (row 4)	R0 sub-tier classification
#hyp-symbiogenic-composition	R1 $\rightarrow$ R0 transition mechanism (structural absorption)
#der-adversarial-destabilization	R0 or R1 target under exogenous adversarial parameter; per-target regime distinction

The consolidation has two operational consequences. First, the cross-segment consistency check becomes mechanical — any segment using regime-axis vocabulary can be cross-referenced against this segment's four-tier specification. Second, the meta-segment cross-references to #disc-separability-pattern (Contraction ladder as R0 sub-tier classifier) and to broadened #disc-identifiability-floor Instance 3 (regime-identification floor) form the integration backbone of how the axis sits inside the wider meta-pattern landscape.

Cross-axis interactions.

Three structural axes coexist in the framework after the dynamic-regime axis surfaces:

- **Axis A — Architectural class.** Processing topology — Class 1 / 2 / 3 per #der-directed-separation. Determined by sub-agent class plus routing structure plus shared-substrate-with- G^c -allocation.
- **Axis B — Dynamic regime.** Joint-dynamics fixed-point structure plus Lyapunov certificate — R0 / R1 / R2 / R3. Determined by objective alignment plus game structure plus population scale.
- **Axis C — Macro-state type.** Type-theoretic shape of G_*^c — state-variable / fixed-point object / distributional. For finite N , identified by Axis B per §”Identity”; for $N \rightarrow \infty$ (R3) the identity can break.

Axes A and B are independent. The full cross-product is meaningful:

Table AF.3

	<i>R0 contraction</i>	<i>R1 equilibrium</i>	<i>R2 cyclic-distributional</i>
Class 1 Separated	Kalman + LQR team, shared target	Cournot duopoly (distinct hardware)	Rock-paper-scissors players on distinct hardware
Class 2 Partial	Biological cortex in coordinated task	Hybrid AI–biological with partial coupling, strategic interaction	Hybrid in cyclic game
Class 3 Coupled	Multi-LLM shared substrate, aligned objective (wrapping construction available)	Multi-LLM shared substrate, strategic interaction (wrapping available)	Multi-LLM shared substrate, cyclic interaction

The cells are operationally distinct. The wrapping construction (`#der-class-coercion-via-wrapping`) operates *only* on Axis A — it converts Class 3 $\rightarrow$ Class 1 architecturally at the wrapper level, at structural-leakage cost. It does *not* change Axis B regime. A wrapped strategic composite remains in R1; the wrapping recovers Class 1 architecturally but the dynamics still admit equilibrium-shaped failure modes (multi-equilibria, saddle-Nash, equilibrium selection ambiguity). Symmetrically, alignment work operates only on Axis B — re-aligning objectives moves the composite from R1 to R0, without changing architectural class. Symbiogenic absorption is the structural mechanism for the R1 $\rightarrow$ R0 transition (`#hyp-symbiogenic-composition`).

Two distinct adversarial pressures act on the two axes. `#disc-adversarial-coupling-pressure` names the adversarial pressure on Axis A — adversaries strategically drive a target’s modularity downward because coupling expands attack surface. A separate adversarial pressure — call it *strategic divergence pressure* — drives a target’s Axis B regime downward (introduces objective divergence into a previously-aligned team, moving R0 $\rightarrow$ R1; introduces cyclic structure by mechanism manipulation, moving R1 $\rightarrow$ R2). The two are structurally distinct adversarial moves with distinct defenses (architectural scaffolding for Axis A; mechanism-design commitment for Axis B). The M4 meta-segment `#disc-modularity-state-dynamics` covers the three-operation modularity-state picture on Axis A; the dynamic-regime axis here covers the parallel three-operation picture on Axis B (alignment-strengthening self-driven-ascending; strategic-divergence-acquisition self-driven-descending; adversarial-divergence-pressure externally-driven-descending).

Epistemic Status.

Discussion-grade at the meta-pattern level. The segment articulates an axis-vocabulary consolidation rather than a derivation of new machinery. The four-tier partition itself is integration of recognized prior art — Candogan-Menache-Ozdoglar-Parrilo 2011 (Hodge decomposition), Letcher-Balduzzi et al. 2019 (Hamiltonian dynamics decomposition), Sandholm 2010 (population-games taxonomy), Hofbauer-Sigmund 1998 (phase-portrait classification), Omidshafiei et al. 2019 (α -Rank), Papadimitriou-Piliouras 2018 (chain-recurrent sets as natural object).

The AAT-specific derivable contents ($\S$ “AAT-specific derivable content”) are at distinct tiers: the macro-state-type / regime identity is *exact* for finite N given the entry conditions; the transition asymmetry is *argumentation-grade* pending the J9 derivation spike with a structural-distance metric; the Lyapunov-machinery transfer R0 $\rightarrow$ R1 is *exact* by direct construction (the algebra is inherited from `#deriv-strategic-composition` sub-scope α').

Max attainable: *discussion-grade* for the meta-pattern (it is an organizing principle, not a derivation); *exact* for the macro-state-type / regime identity; *exact* for the Lyapunov transfer; *argumentation-grade* for the transition asymmetry pending the J9 derivation.

Discussion.

The cross-segment integration consequence. Once the axis is named, #impl-strategic-composition's §"Modular safety architectures fail under goal divergence" implication has a cleaner derivation than the original architectural-class-change framing. The failure mechanism is *regime change* ($R0 \rightarrow R1$ under goal divergence) rather than *architectural-class change* (which does not happen — strategic composition with goal-blind routing leaves the composite architecturally Class 1). Modular safety guarantees designed for contraction-regime composites depend on the unique-attracting fixed point and the global Lyapunov contraction; under $R0 \rightarrow R1$ transition the unique attractor becomes a set of equilibria, saddle-point Nash breaks Lyapunov contraction, and multi-equilibria break uniqueness. Constitutional AI re-teaming and mesa-optimizer formation are the empirical instantiations. The dynamic-regime axis re-derivation gives the same conclusion on stronger ground.

Mechanism design as regime-shaping. An external designer who can shape the sub-agent objectives can target a regime — bring R2 down to R1 by adding potential structure, or R1 down to R0 by adding alignment. The mechanism-design impossibility theorems (Gibbard-Satterthwaite, Myerson-Satterthwaite, Arrow) are floors on what *external designers* can achieve in the regime-ascent direction under stated incentive-compatibility and welfare constraints. The queued #disc-implementation-impossibility meta-segment carries the formal treatment of designer-side constructive-impossibility; this segment's transition-asymmetry argument cross-references it as the structural complement.

The dynamic-regime axis and #disc-modularity-state-dynamics. Both axes admit a parallel three-operation modularity-like dynamics: alignment-strengthening / strategic-divergence-acquisition / adversarial-divergence-pressure on Axis B parallel to truthification / strategic-self-coupling / adversarial-coupling-pressure on Axis A. The parallel-pattern observation is itself meta-architectural content — the framework has *two* independently-shaped axes with parallel three-operation dynamics on each. Whether this parallel structure warrants a *higher-order* meta-segment (covering both Axes A and B at once) is open; the current arrangement keeps the two axis-segments separate (this one for Axis B; #disc-modularity-state-dynamics for Axis A landed 2026-05-24) and surfaces the parallel observation in each. Now that both meta-segments are stable, evaluating whether the cross-pattern is load-bearing enough for a higher-order meta-segment is a candidate follow-on.

Sub-tier structure within each regime. Each regime has its own internal classification — R0 inherits the Contraction ladder Tier 1 / Tier 2 / Tier 3 from #disc-separability-pattern; R1 has potential / monotone / general sub-tier per #deriv-strategic-composition; R2 has CCE-convergence-rate sub-classification; R3 has MFG-uniqueness sub-classification. Whether these sub-classifications unify across regimes under a single meta-classification (e.g., "Lyapunov-certificate-strength" as one axis across R0/R1/R2/R3) is a candidate for follow-on work — see Working Notes.

Findings.

The Dynamic-Regime Axis as Cross-Cutting Classifier. **Brief:** Composites differ in how their joint dynamics behave even when their components are individually clean. Think of a team rowing a boat — everyone wants the same destination, the dynamics contract to a shared target, the team is in the *contraction-regime* (R0). Now think of firms in a market — each wants to maximize their own profit, the prices settle into a stable joint equilibrium where no firm wants to deviate, the system is in the *equilibrium-regime* (R1). Now think of rock-paper-scissors players — no stable joint move exists in pure strategies, but the long-run frequencies of moves settle into a stable distribution, the system is in the *cyclic-distributional-regime* (R2). At population scale, where the natural object is the distribution of strategies across the whole population rather than named individuals, you get the *mean-field-equilibrium-regime* (R3). The regime is structural — you can read it off the game definition without running the dynamics — and it determines what kind of guarantee the framework can give you: exponential convergence in R0/R1, polynomial-in-distribution in R2, measure-space machinery in R3. The axis is independent of the architectural class (whether the agent's processing is goal-blind or not); both axes interact, and a strategic composite of architecturally-clean agents is still R1 in dynamic regime even though it remains Class 1 in architectural class.

Impact: Names a structural classifier the framework had been running implicitly across ten-plus existing segments under different vocabulary, consolidating them into one explicit axis with a clear sub-tier structure inherited from existing tiered ladders. Provides a cleaner derivation of #impl-strategic-composition’s “modular safety architectures fail under goal divergence” implication — the mechanism is regime change ($R0 \rightarrow R1$), not architectural-class change (which does not happen under goal-blind routing). Resolves the long-standing tension in #scope-composite-agent’s Working Notes between the alignment routes (C-i/ii/iii) and the strategic-equilibrium route (C-iv): they correspond to regime-tier entry conditions on the dynamic-regime axis, not to a continuous spectrum on a single scalar. Surfaces the structural-distance metric on regime-transition cost as a derivable open question (J9 spike candidate). Provides the positive-half complementarity for the broadened #disc-identifiability-floor Instance 3 (regime identification from component marginals is structurally impossible).

Novelty Claim: *Claim integration* of multi-agent dynamics classifications from at least five neighboring literatures (game-theoretic decomposition; multi-agent learning convergence taxonomy; population games; evolutionary games; mean-field games) into an AAT-internal regime-axis vocabulary that travels with the framework’s existing scope-route disjunction (#scope-composite-agent), separable-core / structured-repair / general-open shape (#disc-separability-pattern), and persistence machinery (#result-sector-persistence-template). The four-tier partition is recognized prior art; the AAT-specific contributions are (a) the macro-state-type / regime structural identity for finite N with $R3$ as the explicit boundary case where the identity breaks (*claim recognition* + *claim integration*); (b) the regime-transition cost-asymmetry framing (descent default / ascent costly) tied to mechanism-design impossibility (*claim recognition* — full derivation deferred to J9); (c) the Lyapunov-machinery transfer $R0 \rightarrow R1$ made explicit as a cross-tier consolidation of #deriv-strategic-composition sub-scope α' (*claim integration*).

AAT does not currently have R3 machinery; the tier is named as the population-scope frontier per #deriv-strategic-composition Working Notes mean-field extension
Mechanism-design impossibility (designer-side regime-ascent floor)	Gibbard 1973, <i>Econometrica</i> 41:587–601; Satterthwaite 1975, <i>J. Econ. Theory</i> 10:187–217; Myerson & Satterthwaite 1983, <i>J. Econ. Theory</i> 29:265–281; Arrow 1951, <i>Social Choice and Individual Values</i> (found pre-2026; flagged in #deriv-strategic-composition Discussion)	<i>formal antecedent (designer-side floors)</i> — floor on what external designers can achieve in the $R2 \rightarrow R1$ or $R1 \rightarrow R0$ regime-ascent direction. Forward-references the queued #disc-implementation-impossibility meta-segment for the formal treatment

Search Log:

- 2026-05-21 (*targeted*, BG1 Pillar prior-art search): Verdict on T1 (four-tier classification as unifying construct): *Substantial Overlap with Named Prior Art* (High confidence). Verdict on T2 (macro-state-type / regime identity §C.1): *Substantial Novelty with Adjacent Literature* (Medium-High). Verdict on T3 (transition asymmetry §C.3): *Substantial Novelty with Adjacent Literature* (Medium). Verdict on T4 (identifiability floor §H.5): *Substantial Novelty with Adjacent Literature* (Medium). Most consequential finding: Candogan-Menache-Ozdaglar-Parrilo 2011 Hodge decomposition as the recognized prior art for the R1/R2 boundary (now in the Related Work table).
- 2026-05-21 (*planned*): Second-pass Undermind search for the broadened-Instance-3 + escape (e) to refine the R1-vs-R2 classifier-under-rate-class-observation claim if prior art surfaces.

Working Notes.

- **Sub-tier unification candidate.** Each regime has its own internal sub-classification (R0 Contraction ladder Tier 1/2/3; R1 potential/monotone/general; R2 CCE-convergence-rate; R3 MFG-uniqueness). Whether these unify across regimes under a single meta-axis — *Lyapunov-certificate-strength* (full-state Lyapunov / local-on-deviation Lyapunov / distributional-on-empirical Lyapunov / no Lyapunov) — is open. Candidate for a follow-on spike if the cross-regime meta-classification turns out to compose cleanly with existing tier machinery.
- **§C.3 cost-asymmetry derivation (was J9) + standalone-paper trajectory (was J7) — migrated 2026-05-25 to proper homes.** The §C.3 transition cost-asymmetry derivation with a structural-distance metric on game-rewiring space is registered at spikes/PROPOSED.md Tier 2 (added 2026-05-25; segment-rooted with detail home here in this Working Notes section). Landing the derivation would upgrade §”Transition asymmetry: descent is the default” from argumentation-grade to derived; estimated 2 cycles. The standalone-paper trajectory it was the prerequisite for is now at ~/src/ops/papers/deferred/dynamic-regime-axis.md (deferred until the derivation lands or is declined; BG1’s T1 Substantial Overlap verdict means the four-tier classification itself is not the publishable contribution, and the AAT-specific identities — §C.1 macro-state-type + §C.3 cost-asymmetry + §H.5 identifiability floor — are; without the §C.3 derivation, only §C.1 and §H.5 are substantive standalone contributions, and the paper is not yet competitive). Provenance trail: spikes/strategic-composition-class-3-attempt-2026-05-21/07-SOLIDIFIED-PLAN.md §S.2 originally framed these as the J7/J9 Joseph-reserved tail of the strategic-composition

cluster; with that cluster's primary work closed 2026-05-25 (Tracks A/B/C/D/CR/E all DONE), the two items are migrated to their proper navigators.

- **#disc-modularity-state-dynamics parallel-pattern.** The parallel-three-operation observation in §"Cross-axis interactions" connects to #disc-modularity-state-dynamics (landed 2026-05-24 closing the modularity-as-contested-property cycle per msc/modularity-cycle-plan-2026-05-09.md). With both meta-segments now stable, a higher-order meta-segment covering both Axes A and B at the parallel-pattern level becomes a candidate follow-on cycle if the cross-pattern proves load-bearing for downstream framework work; the current arrangement holds the parallel observation in each of the two without forcing the higher-order recognition.
- **A4 second-pass Undermind on broadened Instance 3 (resolved 2026-05-21).** Completed per 07-SOLIDIFIED-PLAN.md A4; report at ref/Unidentifiability_and_rate_class_prior_art.md^d. Verdict on both targets: *no exact prior-art hit; rich near-miss landscape*. The R1-vs-R2 classifier strengthened-consequence qualifier was softened from "unique broadly-available" to "primary AAT-framework" to reflect that adjacent passive diagnostics for *related* regime distinctions exist (potentialness — Bichler et al. 2025^b; convergence-vs-recurrence — Legacci et al. 2024^c; best-reply structure — Pangallo et al. 2017^d; algorithm-specific rate dichotomies — Anagnostides et al. 2022^e, Shi-Zhang 2019^f), but none names rate-class-as-passive-classifier-of-regime in the form escape (e) instantiates. The Related Work table in #deriv-regime-marginal-indistinguishability carries the full neighbor citations; #disc-identifiability-floor Instance 3 escape (e) and strengthened consequence carry the softened framing with neighbor-citation acknowledgment. Two important caveats from the BG2 verdict landed: (a) Mertikopoulos-Papadimitriou-Piliouras 2017 *Cycles in Adversarial Regularized Learning*^g shows regret-rate alone is too blunt — escape (e) must specify *trajectory* rate, not regret rate (now landed in Instance 3 escape (e) wording); (b) Bielecki et al. 2011^b is the closest structural analogue for the cross-topology marginal-matching witness at the multivariate Markov-chain level — the witness math in #deriv-regime-marginal-indistinguishability extends the established marginal-non-determining shape to the game-topology layer.
- **Primary-source verification spike queued (2026-05-21).** All BG2-introduced citations in this Working Note (marked with footnote [^hbg2-2026-05-21]) and in the cross-referenced #disc-identifiability-floor Instance 3 escape (e) and #deriv-regime-marginal-indistinguishability Related Work need primary-source verification before any further reliance. The characterizations attributed to those papers are currently synthesized from ref/Unidentifiability_and_rate_class_prior_art.md, not from direct reading. Verification targets for this segment specifically: Mertikopoulos-Papadimitriou-Piliouras 2017 (the trajectory-vs-regret-rate caveat — load-bearing for the softening of "unique" to "primary AAT-framework"); Bichler et al. 2025 (named-passive-diagnostic counterexample to "unique" qualifier); Legacci-Mertikopoulos-Pradelski 2024 (closest convergence-vs-recurrence taxonomy neighbor); Bielecki et al. 2011 (closest structural analogue, load-bearing for #deriv-regime-marginal-indistinguishability's positioning). Spike to be scheduled per Joseph's go.
- **Mechanism reduction question.** Whether the regime-axis transition asymmetry reduces to a special case of the modularity-state-dynamics three-operation pattern (Axis A) under a structural translation, or whether the two patterns are genuinely independent at the meta-architectural level, is open. The current §"Cross-axis interactions" reading treats them as parallel-but-independent; a unification attempt would be a separate spike.
- **R3 machinery.** AAT does not currently carry mean-field-equilibrium-regime machinery. R3 is named as the population-scope frontier; per #deriv-strategic-composition Working Notes, the mean-field-extension awaits Part III population-dynamics machinery (latent structural diversity; endogenous coupling; composition-transition dynamics). When R3 lands properly, this segment will be revisited to verify the four-tier ladder remains the right granularity (vs collapsing R2 + R3 into a unified distributional tier, or splitting R3 further by MFG sub-class).

Appendix AG

Formulation: Resource Budget

A depletable scalar reservoir whose drain rate rises with mismatch and whose level gates correction capacity — the minimal structure that makes “a degrading model is more expensive to run” a dynamical statement rather than an informal one.

The construction is minimal: a scalar resource budget $\mathcal{B}_t$ evolving under drain-versus-replenishment, with two introduced structural posits — (**A-cost**) the drain rate $c(\|\delta\|)$ is non-decreasing in mismatch (degrading models cost more to run), and (**A-gate**) the sector parameter is resource-gated via $\alpha(\mathcal{B}) = \alpha^{\max}\psi(\mathcal{B})$ with $\psi(0) = 0$ (the depleted agent loses corrective capacity entirely). Hard-budget regime has zero replenishment ($r_{\mathcal{B}} = 0$, a finite pool that only depletes); regenerative regime has $r_{\mathcal{B}} > 0$.

This segment is *exploratory off-spine*: no Part I/II/III result depends on it; it opens a resource-structure axis 6.7 explicitly records as an open scope item. The formulation is *conditional by nature* — (A-cost) and (A-gate) are modeling assertions about an agent’s physical realization, not derivations from core machinery, so the formulation’s epistemic ceiling stays at conditional regardless of downstream development. The companion derivation AH uses this formulation to close 15.2’s Effects-Spiral by an alternative mechanism (agent’s own correction-rate decay rather than adversary coupling growth).

Formal Expression.

AAT’s core machinery is resource-blind: the policy $\pi(M_t, G_t)$ acts at no modeled cost, and correction capacity (tempo $\mathcal{T}$, 3.8) does not deplete. 6.7 records this as an explicit open scope item — for resource-constrained agents (embodied controllers under torque/battery/episode-length limits; teams under headcount; any agent whose every corrective action spends an exhaustible pool) the formalism carries no state for the pool and no coupling from model quality to its drain. This formulation introduces the minimal such structure.

A scalar **resource budget** $\mathcal{B}_t \geq 0$ (calligraphic-scalar by the NOTATION convention exception, as for $\mathcal{T}$; distinct from the agent label B of 15.2 and from the strategy-edge set E). Its evolution:

Definition (resource-budget).

$$\frac{d\mathcal{B}}{dt} = -c(\|\delta\|) + r_{\mathcal{B}} \quad (\text{AG.1})$$

where δ is the agent’s mismatch (3.4), $c(\cdot) \geq 0$ is the **correction-cost rate**, and $r_{\mathcal{B}} \geq 0$ is the **replenishment rate**. The hard-budget regime is $r_{\mathcal{B}} = 0$ (a finite pool that only depletes — a combat episode’s battery, a fixed torque-integral, a bounded step count); the regenerative regime is $r_{\mathcal{B}} > 0$.

The formulation is fixed by two structural posits — introduced, not derived from existing AAT.

c is non-decreasing in $\|\delta\|$, with $c(0) > 0$ (running the loop at all costs something) and c strictly increasing where $\|\delta\| > 0$. Minimal concrete form:

Assumption (A-cost: cost rises with mismatch).

$$c(\|\delta\|) = c_0(1 + \beta_{\mathcal{B}} \|\delta\|), \quad c_0 > 0, \beta_{\mathcal{B}} \geq 0. \quad (\text{AG.2})$$

Motivation, not derivation: a model that is wrong by δ actuates partly in wrong directions — the agent pays for the corrective action *and* for the wasted component, and re-observes more often to recover. Degradation is literally more expensive to carry. $\beta_{\mathcal{B}} = 0$ recovers the resource-blind special case (cost independent of model quality).

The sector/correction rate the persistence machinery uses — α in [G](#), equal to $\mathcal{T}$ in the canonical epistemic instantiation ([3.8](#), [4.5](#)) — is throttled by available resource:

Assumption (A-gate: tempo is resource-gated).

$$\alpha(\mathcal{B}) = \alpha^{\max} \psi(\mathcal{B}), \quad \psi : \mathbb{R}_{\geq 0} \rightarrow [0, 1] \text{ non-decreasing, } \psi(0) = 0, \psi(\mathcal{B}) \rightarrow 1 \text{ as } \mathcal{B} \rightarrow \infty. \quad (\text{AG.3})$$

Motivation, not derivation: with the pool exhausted the agent cannot run its observe–update–actuate loop at full rate (fewer sensor sweeps, slower control cycle, fewer remaining episode steps). $\psi \equiv 1$ recovers the resource-blind special case (constant α , exactly today’s template).

Together: $\mathcal{B}_t$ is the new state; (A-cost) couples model quality *into* its drain; (A-gate) couples its level *into* correction capacity. These two couplings are exactly what close the otherwise-open feedback in [15.2](#)’s Effects-Spiral corollary — the consequence is derived in [AH](#).

Epistemic Status.

Conditional. This is a representational choice (type: formulation) — several resource models would fit (per-action cost vectors, capacity constraints on the action set, queueing-theoretic service limits); $\mathcal{B}_t$ with (A-cost)/(A-gate) is the *minimal* one that makes the model-quality $\rightarrow$ drain $\rightarrow$ capacity loop dynamical with one added scalar and two monotone couplings. The defined objects ($\mathcal{B}_t$, the depletion law) are well-posed; the *content* is the two posits, which are introduced premises, honest as modeling commitments and not consequences of any prior segment. Anything downstream is conditional on them.

Max attainable: conditional. This ceiling is intrinsic: (A-cost) and (A-gate) are claims about a particular agent’s physical realization, not about the formalism, so no amount of derivation promotes the formulation itself beyond conditional. A *specific* agent class can satisfy them by construction (e.g. a controller whose actuation energy is measured and whose control-loop frequency is power-throttled), at which point downstream results inherit that class’s tighter status — but the formulation as stated stays conditional by nature, the same way [6.7](#)’s other scope items do.

This segment is an exploratory branch: it opens a resource-structure axis AAT has deliberately lacked. No spine segment depends on it; it is not a prerequisite of any Part I/II/III result.

Discussion.

What the two posits buy, minimally. Everything load-bearing downstream uses only *monotonicity*: (A-cost) that drain is non-decreasing in mismatch, (A-gate) that capacity is non-decreasing in budget with $\psi(0) = 0$. The explicit linear c and the shape of ψ are illustrative; the qualitative consequences in AH survive any (c, ψ) obeying the monotonicity and the endpoint $\psi(0) = 0$. The endpoint matters: $\psi(0) = 0$ encodes “an empty pool cannot correct at all,” which is what makes exhaustion *terminal* rather than merely *slowing*.

Why a new scalar rather than folding into ρ or $\mathcal{T}$. Resource is not disturbance: ρ is mismatch injected by the world, independent of how well the agent is doing; $\mathcal{B}_t$ drains *because* the agent is doing badly (A-cost). Nor is it tempo: $\mathcal{T}$ is a rate the agent has; $\mathcal{B}_t$ is a stock it spends to exercise that rate. Collapsing resource into either erases the very coupling that makes the Effects-Spiral close — a degrading model raising its own future cost is a stock-flow statement, not a rate statement. The new scalar is the minimum that keeps stock and flow distinct.

Relationship to the adaptive reserve $\Delta\rho^*$. G’s adaptive reserve $\Delta\rho^* = \alpha R - \rho$ is a *margin* (how much extra disturbance the agent can absorb at its current rate); $\mathcal{B}_t$ is a *fuel* (how much correction it can still afford to perform). They are independent: an agent can have comfortable margin and an almost-empty pool, or ample fuel and zero margin. The resource-bounded result is precisely about a system that is margin-safe at full fuel and still dies as the fuel drains the margin away — see AH.

Domain instances. Embodied combat/contested control under a battery or torque-integral budget (the case that motivated this branch); a development team under a fixed person-hour pool where a worsening codebase model raises rework cost; an incident-response org whose escalating confusion burns the on-call budget faster. In each, the resource-blind special case ($\beta_{\mathcal{B}} = 0, \psi \equiv 1$) is the agent for whom the pool is effectively infinite relative to the engagement — and there the existing constant- α machinery is exactly right, which is the honest boundary of this branch’s relevance.

Working Notes.

- The regenerative regime $r_{\mathcal{B}} > 0$ with $\mathcal{B}_t$ bounded above (a finite-capacity rechargeable pool) is the genuinely open dynamical case — it is a time-varying- α template instantiation in full and may be quasi-stationary-distribution / absorbing-barrier-flavored (cf. the open second no-go in the continuity-persistence reasoning trail). AH treats only $r_{\mathcal{B}} = 0$ rigorously; the regenerative case is flagged there and not attempted.
 - Reasoning trail: spikes/fight/03-energy-bound-effects-spiral.md (the Φ -prompted derivation attempt that produced this branch) and spikes/fight/99-verdict.md §3.
 - Open: whether $\mathcal{B}_t$ should be vector-valued (distinct pools — energy vs compute vs attention — with distinct c, ψ). Scalar is the minimal first cut; the persistence machinery it feeds is itself scalar-default with a tensor extension (3.8), so a vector $\mathcal{B}$ would compose with that tensor form. Not pursued here.
 - A NOTATION.md entry for $\mathcal{B}_t$ is added under a resource section; per the NOTATION drift caveat the segment, not the index, is ground truth.
-

Appendix AH

Derived: Resource-Bounded Destabilization

A hard-budget agent self-depletes to certain finite-time destabilization against even a *constant*-effectiveness adversary — closing 15.2’s Effects-Spiral not by formalizing its open coupling term but by making that term unnecessary, via the decaying- α instantiation of **G**.

Formal Expression.

15.2’s Effects-Spiral corollary ($\|\delta_B\| \uparrow \Rightarrow \text{erratic action} \Rightarrow \gamma_A \uparrow \Rightarrow \rho_B \uparrow \Rightarrow \|\delta_B\| \uparrow$) is *discussion-grade* there because the link “degrading model $\Rightarrow$ stronger adversary coupling” requires specifying how model degradation feeds back into the dynamics, which that segment’s machinery does not carry. The resource-budget formulation (**AG**) supplies that feedback through a different and cleaner channel — the agent’s *own* correction rate, not the adversary’s coupling.

Setup: the resource-coupled adversarial instantiation. Instantiate **G** with the target agent *B*’s mismatch as state variable, $\xi = \delta_B$, exactly as 15.2 does, but with the sector parameter made resource-gated per **AG** (A-gate):

$$\frac{d\delta_B}{dt} = -\alpha_B(\mathcal{B}) \delta_B + w_B(t), \quad \|w_B(t)\| \leq \rho_B^{\text{eff}} = \rho_{B,\text{base}} + \gamma_A \mathcal{T}_A, \quad \frac{d\mathcal{B}}{dt} = -c(\|\delta_B\|) + r_B, \quad \alpha_B(\mathcal{B}) = \alpha_B^{\text{max}} \psi(\mathcal{B}),$$

with ρ_B^{eff} the coupling-amplified disturbance of 15.2 (treated there, and here, with $\gamma_A, \mathcal{T}_A$ exogenous) and c, ψ as posited in **AG** (A-cost), (A-gate). The novelty is the *coupled pair*: δ_B and $\mathcal{B}$ co-evolve, with model quality draining the budget and the budget gating correction.

Regime split.

Budget-sufficient regime. If $\mathcal{B}_t$ stays large enough that $\psi(\mathcal{B}_t) \approx 1$ over the engagement (the pool is effectively infinite relative to the integrated cost), then $\alpha_B(\mathcal{B}_t) \approx \alpha_B^{\text{max}}$ is constant and the system is 15.2’s constant- α instantiation, unchanged. The resource structure adds nothing here. This is the honest boundary: the resource-blind special case ($\psi \equiv 1$) is exactly today’s machinery, and it is correct there.

Derived (resource-regime-split, from form-resource-budget + sector-persistence-template).

Budget-scarce hard regime ($r_B = 0$). With no replenishment, $d\mathcal{B}/dt = -c(\|\delta_B\|) \leq -c(0) < 0$ whenever correction runs, so $\mathcal{B}_t$ is strictly decreasing and reaches any level in finite time. Then $\alpha_B(\mathcal{B}_t)$ is a **time-varying, monotonically-decaying** sector parameter — exactly the structure **G**’s Epistemic Status flags as requiring additional machinery, and the structure 9.10 already instantiates (there $\alpha_\Sigma = 1/(n+1)$ decays with experience; persistence then requires the decay be counteracted faster than ρ_Σ/R_Σ). The resource-bounded case is the *same template slot* with budget-depletion in the role experience-accumulation plays for strategy persistence.

The result.

Define the **critical budget** $\mathcal{B}_{\text{crit}}$ by the persistence boundary of G (Model D) at the coupling-amplified disturbance:

Derived (Conditional on A-cost, A-gate; hard regime $r_B = 0$).

$$\alpha_B(\mathcal{B}_{\text{crit}}) = \frac{\rho_B^{\text{eff}}}{R_B} \iff \psi(\mathcal{B}_{\text{crit}}) = \frac{\rho_B^{\text{eff}}}{\alpha_B^{\text{max}} R_B}, \quad (\text{AH.1})$$

and the destabilization **hitting time** $\tau = \inf\{t : \mathcal{B}_t = \mathcal{B}_{\text{crit}}\}$. Then, in the hard regime with correction ongoing:

1. **Certain finite-time destabilization.** $\mathcal{B}_t \downarrow$ strictly, so $\tau < \infty$ for any finite $\mathcal{B}_0$. Because $\psi(0) = 0$, once $\mathcal{B}_t < \mathcal{B}_{\text{crit}}$ the persistence condition $\alpha_B(\mathcal{B}_t) > \rho_B^{\text{eff}}/R_B$ fails and 15.2's destabilization threshold is crossed. **The static persistence inequality holding at $t = 0$ does not prevent this** — an agent that would persist forever at full budget ($\alpha_B^{\text{max}} R_B > \rho_B^{\text{eff}}$) still destabilizes once the fuel drains the rate below threshold.
2. **The spiral, derived.** Substituting (A-cost), a mismatch excursion accelerates its own destabilization: $\|\delta_B\| \uparrow \Rightarrow c(\|\delta_B\|) \uparrow \Rightarrow \dot{\mathcal{B}}$ more negative $\Rightarrow \alpha_B(\mathcal{B}) \downarrow \Rightarrow (\alpha_B R_B - \rho_B^{\text{eff}}) \downarrow \Rightarrow \|\delta_B\| \uparrow$, which brings τ forward: a transient noise burst in w_B permanently advances the destabilization time. This is 15.2's Effects-Spiral, now a derived consequence of (A-cost)/(A-gate) rather than a discussion-grade schematic.
3. **The adversary's coupling need not grow.** The spiral closes through α_B *decaying* with γ_A held **constant**. The Effects-Spiral's substantive content — collapse invisible to the static threshold — is captured *without* the unspecified $\gamma_A(\|\delta_B\|)$ leg 15.2 could not formalize. Adversarial survival reduces to a **budget-versus-engagement-length race**: B persists iff the engagement ends before τ .

What Is Derived vs. What Is Chosen.

Table AH.1

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Budget-sufficient regime $\equiv$ constant- α template, unchanged	G (status exact), $\psi \equiv 1$ limit	Inherited exact
Resource-scarce case is the decaying- α template slot (the reduction)	G time-varying- α + 9.10 precedent	Derived, conditional on (A-cost),(A-gate)
Certain finite-time destabilization, $r_B = 0$	Monotone-budget + Lyapunov persistence-boundary crossing	Derived (conditional)
Effects-Spiral as derived feedback; τ advanced by excursions	(A-cost) substituted into the depletion law	Derived (conditional)
Adversary coupling need not grow (γ_A constant suffices)	Corollary of the above	Derived (conditional)
Orthogonal to — not a resolution of — the deferred symmetric joint-Jacobian problem	Comparison of which term carries the feedback (α_B vs γ_A)	Verified relationship
(A-cost), (A-gate)	AG	Introduced posits, not derived
Regenerative regime $r_B > 0$	—	Open (not attempted)

Epistemic Status.

Conditional on AG's two introduced posits (A-cost),(A-gate) and the hard regime $r_B = 0$. Given those, the chain is tight: the reduction to the decaying- α slot of G is exact-flavored (it is that template's own machinery, the same instantiation 9.10 makes for experience-decay), and certain finite-time destabilization follows by a monotone-budget + Lyapunov-boundary argument with no further assumption. The status is conditional rather than exact because the load-bearing premises are modeling posits about an agent's physical realization, not consequences of prior segments — inherited honestly from AG's own ceiling.

Maxattainable: conditional for the formulation-dependent result; a specific agent class that satisfies (A-cost)/(A-gate) by construction (measured actuation energy, power-throttled control loop) lifts *its* instance to that class's tighter status, but the general statement stays conditional by the nature of its premises.

Scope honesty — what this does not do. It does *not* resolve the symmetric joint-best-response / joint-Jacobian equilibrium problem 15.2 defers to 16.1. That deferred problem is about both agents' mismatch co-evolving and specifically about the adversary's $\gamma_A(\|\delta\|)$ leg; this result closes a *different* leg (the target's own resource-gated α_B) and is single-agent-with-resource. The two are orthogonal: this result needs no claim about γ_A growing, and makes none. Reading it as having cracked the symmetric equilibrium problem would be an overclaim — it routes *around* that problem by adding resource structure, at the cost of two posits AAT otherwise lacks.

The regenerative regime ($r_B > 0$) is genuinely open and not attempted here (see Working Notes).

Discussion.

Why this is a strengthening, not a softening. The honest move when facing 15.2's discussion-grade Effects-Spiral is not “leave it discussion-grade.” It is to ask whether the spiral can be made a theorem. It can — in the resource-bounded regime, by a reduction to existing exact machinery — and the resulting statement is *sharper* than the original conjecture: it eliminates the need for the unformalized $\gamma_A(\|\delta_B\|)$ term rather than supplying a guessed functional form for it. A constant-effectiveness adversary against a hard-budget target is already sufficient for certain finite-time collapse. The strengthen-before-soften discipline produced a cleaner result than the discussion-grade original gestured at.

The reframing is the payoff. “Can the adversary destabilize me?” becomes “does the engagement outlast my fuel?” Persistence under a competent constant adversary is no longer a static inequality on (α, ρ, R) but a race between the hitting time τ and the engagement horizon — and τ is endogenous, advanced by every mismatch excursion the agent suffers. This is the precise sense in which a degrading embodied agent under hard physical limits “spirals”: not because the opponent gets stronger, but because being wrong is expensive and the agent is spending a finite pool to be wrong in.

Relationship to 9.10. That schema and this result are the two non-epistemic instantiations of G's *time-varying- α* extension. Strategy persistence's α_Σ decays with accumulated experience and is rescued by forgetting; here α_B decays with spent budget and is rescued only by replenishment or by ending the engagement before τ . Same template slot, different decay driver, structurally parallel rescue conditions. The parallel is itself evidence the template's time-varying- α extension is the right general object, with these as two of its instances.

Findings.

Resource Depletion Closes the Effects Spiral by Eliminating Its Open Term. Brief: A robot fighting another robot on a finite battery does not lose because its opponent gets cleverer as it falters — it loses because faltering is expensive. A wrong model wastes actuation, the wasted actuation drains the battery, the drained battery slows the control loop, the slower loop lets the model fall further behind: a self-reinforcing collapse that needs no help from the adversary. The everyday version: a tired driver makes more mistakes, each mistake costs more energy to recover from, and the exhaustion that follows makes the next mistake likelier — the spiral is in the fuel, not in the road. AAT had this spiral only as an informal sketch because it could not say how a worse model makes an opponent stronger. The resource

view removes the question: the opponent's strength can be held fixed; a finite, mismatch-sensitive fuel pool is enough to force certain collapse in finite time, with the only open question being whether the fight ends before the fuel does.

Impact: Converts 15.2's Effects-Spiral corollary from discussion-grade to conditional-derived — not by formalizing its unspecified adversary-coupling term but by making that term unnecessary, via a reduction to the decaying- α slot of G (the same machinery 9.10 uses for experience-decay). Reframes adversarial survival under a competent constant adversary from a static (α, ρ, R) inequality to a budget-versus-engagement-length race with an endogenous, excursion-advanced hitting time. Opens the resource-structure axis 6.7 records as an explicit gap, as an exploratory branch off the spine. Explicitly does *not* resolve the deferred symmetric joint-Jacobian problem (16.1) — it is orthogonal, and the Finding marks that boundary so the result is not over-read.

Novelty Claim: *Claim differentiation* on 15.2's Effects-Spiral: the contribution is showing the spiral becomes a derived finite-time-destabilization result once a minimal resource state is added, and that the strengthening *removes* rather than supplies the previously-open coupling functional form. The sector-Lyapunov and decaying- α machinery are AAT-internal and standard; resource-constrained control and energy-bounded games are established external territory; the differentiation is the specific recognition that the energy bound is the feedback variable that closes AAT's own named-open spiral by eliminating its open leg, conditional on two explicit posits.

Related Work:

Table AH.2

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Resource/energy budgets shaping control behavior	Energy-bounded / resource-constrained control and RL (broad external literature)	<i>adjacent literature</i> — supplies the modeling milieu (depletable budgets, cost-of-control); AAT's contribution is the coupling of model quality into drain and budget into the sector parameter, closing a specific AAT-internal spiral
Decaying-gain $\rightarrow$ eventual instability	9.10 (experience-decay forgetting prerequisite)	<i>formal antecedent (AAT-internal)</i> — the same time-varying- α template slot; resource-depletion is its second non-epistemic instantiation
Effects-Spiral as informal panic mechanism	15.2 Corollary (discussion-grade)	<i>formalized by this finding</i> — the prior segment's open feedback term is here made unnecessary, not filled in

Search Log: - 2026-05-19 (*intuition-only*): The resource-constrained-control and energy-bounded-games literatures are large and were not searched; the AAT-internal claim (energy bound as the feedback variable that closes the Effects-Spiral by eliminating its open $\gamma_A(\|\delta\|)$ leg, conditional on (A-cost)/(A-gate)) has not been searched against that literature. The constituent machinery (sector-Lyapunov, decaying- α) is AAT-internal and standard; the differentiation claim is plausibly distinctive but unverified. Targeted future search: cost-of-control / energy-aware MPC, budgeted-RL regret under adversaries, lazy-control and event-triggered control under depletable actuation. Pre-search expectation: constituent moves well-precedented externally; the AAT-internal “closes its own named-open spiral by removal” framing is the candidate-distinctive part.

Working Notes.

- Reasoning trail: spikes/fight/03-energy-bound-effects-spiral.md (the Φ -prompted derivation attempt that produced this branch) and spikes/fight/99-verdict.md §2–3. The math lands here per math-lives-in-segments; the spike is the trail only.
- Open — regenerative regime.** $r_B > 0$ with a finite-capacity pool is the full time-varying- α ODE and is not attempted. It is plausibly quasi-stationary-distribution / absorbing-barrier-flavored (structural cousin of the open second no-go in the continuity-persistence reasoning trail). The natural next spike: classify whether bounded replenishment can guarantee $\mathcal{B}_t >$

$\mathcal{B}_{\text{crit}}$ indefinitely or only postpone τ in expectation (a Feller-test / absorbed-chain boundary question, exactly parallel to the continuity-persistence barrier-reachability open problem).

- **Open — rate constants.** τ as an explicit function of $(\mathcal{B}_0, \beta_{\mathcal{B}}, \psi, \text{engagement length})$ is not computed; only its finiteness and monotone advancement under excursions are derived. A closed-form τ under the linear c and a specific ψ (e.g. saturating $\psi(\mathcal{B}) = \mathcal{B}/(\mathcal{B} + \mathcal{B}_{1/2})$) is a tractable follow-on if the branch is pursued.
 - Exploratory-branch status: no spine segment depends on this or on [AG](#); OUTLINE marks both exploratory. Promotion past draft is gated on Joseph electing to develop the resource axis (regenerative case + a worked agent class satisfying (A-cost)/(A-gate) by construction would be the path to lifting an instance above conditional).

Appendix AI

Result: Contraction Template

#result-sector-persistence-template states AAT's persistence arguments with a Euclidean sector condition (T2) matched to a quadratic Lyapunov in Euclidean norm. Generalizing the sector inequality to a **contraction-metric condition** (Lohmiller & Slotine 1998) preserves the template's ultimate-bound results while extending its coverage in three directions: (a) sub-scope α gains natural non-Euclidean metrics that remove condition-number penalties currently visible in 4.3; (b) two additional sub-scope β items (PID-bounded-plant; non-convex-within-basin) promote to derived sub-scope metric- α_2 under explicit conditions; (c) composition acquires **topology-indexed closure results** (parallel / hierarchical / small-gain-feedback) from Slotine 2003 that generalize #deriv-critical-mass-composition's matched-symmetric-Tier-1 closed form to heterogeneous sub-agents. This segment states the generalization once in parameter-free form so that each lifting citation can reference it and specify only what varies.

#result-sector-persistence-template remains as the $M = I$ Euclidean specialization.

Formal Expression.

Preconditions.

Let $\xi(t) \in \mathbb{R}^n$ evolve under $\dot{\xi} = -F(\xi, t) + w(t)$ where F is C^1 in ξ and continuous in t . Let $M : \mathbb{R}^n \times \mathbb{R}_+ \rightarrow \mathbb{S}_{++}^n$ be a smooth symmetric positive-definite matrix-valued function with uniform conditioning:

Template preconditions (contraction-template).

$$m_1 I \preceq M(\xi, t) \preceq m_2 I \quad \text{for all } \xi \in \mathcal{B}_R, t \geq 0 \quad (\text{M0})$$

with constants $0 < m_1 \leq m_2 < \infty$.

(CT1) **Zero correction at zero state.** $F(0, t) = 0$ for all t .

(CT2) **Local differential-contraction condition.** There exist $\lambda > 0$ and $R > 0$ such that for all $\xi \in \mathcal{B}_R, t \geq 0$:

$$\dot{M}(\xi, t) + M(\xi, t) \frac{\partial F}{\partial \xi}(\xi, t) + \left(\frac{\partial F}{\partial \xi}(\xi, t) \right)^T M(\xi, t) \geq 2\lambda M(\xi, t). \quad (\text{CT2})$$

(CT3) **Bounded disturbance.** Either Model D ($\|w(t)\| \leq \rho_\xi$) or Model S ($w(t)$ Wiener-process increment with $\mathbb{E}[\|w(t)\|^2] = \sigma_\xi^2$).

Ultimate bound — Model D.

Under the preconditions with $V(\xi, t) = \xi^T M(\xi, t) \xi$, the state is ultimately bounded:

Result (contraction-template-D), conditional on (M0), (CT1)–(CT3-D).

$$\limsup_{t \rightarrow \infty} \|\xi(t)\| \leq \frac{\rho_\xi}{\lambda} \sqrt{\frac{m_2}{m_1}}. \quad (\text{CT-D})$$

Structural persistence (the ultimate bound fits within the contraction region $\mathcal{B}_R$) requires

$$\lambda R \sqrt{m_1/m_2} > \rho_\xi. \quad (\text{CT-D-persist})$$

Proofsketch. Compute $\dot{V} = \xi^T \dot{M} \xi - 2\xi^T M F + 2\xi^T M w$. Integrate (CT2) along the ray $s\xi$, $s \in [0, 1]$, using $F(0) = 0$: $2\xi^T M F(\xi, t) \geq 2\lambda \xi^T M \xi - \xi^T \dot{M} \xi$. Substituting: $\dot{V} \leq -2\lambda V + 2\xi^T M w$. Cauchy-Schwarz in M -inner product + (M0) gives the affine-contraction bound on $W = \sqrt{V}$; conversion to Euclidean norm via (M0) yields (CT-D). $\square$

Ultimate bound — Model S (with Itô correction).

Under stochastic disturbance $d\xi = -F(\xi, t) dt + \sigma_\xi dW_t$ and a metric M satisfying the Itô-correction bound $\frac{1}{2}\sigma_\xi^2 \text{tr}(M + \text{Hessian correction in drift direction}) \leq c_{\text{Itô}} m_2$ locally (automatic for state-independent M ; bounded by M 's Hessian otherwise), the stopped process satisfies

Result (contraction-template-S), conditional on (M0), (CT1)–(CT3-S), Itô-compatible metric.

$$\mathbb{E}[V(\xi(t \wedge \tau_R), t \wedge \tau_R)] \leq V(\xi(0), 0) e^{-2\lambda t} + \frac{n\sigma_\xi^2 c_{\text{Itô}} m_2}{2\lambda}, \quad (\text{AI.1})$$

where $\tau_R = \inf\{t : \|\xi(t)\| > R\}$. Mean-square structural persistence requires

$$\lambda R^2 > \frac{n\sigma_\xi^2 c_{\text{Itô}} m_2^2}{2m_1}. \quad (\text{CT-S-persist})$$

This is the natural extension of #deriv-sector-condition's Prop A.1S region condition (Khasminskii 2012 ch. 5) to weighted metrics. When $M = I$ (Euclidean), $c_{\text{Itô}} = 1$, and the result reduces to Prop A.1S.

Recovery of #result-sector-persistence-template. When $M \equiv I$ (Euclidean metric, time-independent), (CT2) reduces to

$$-\frac{\partial F}{\partial \xi} - \left(\frac{\partial F}{\partial \xi}\right)^T \leq -2\lambda I, \quad (\text{AI.2})$$

which is the **incremental Euclidean sector condition** (strong monotonicity of F in Euclidean norm, equivalently **DA2'-inc** in #form-composition-closure's bridge-lemma language). This implies the one-point sector condition $\xi^T F(\xi) \geq \lambda \|\xi\|^2$ by integration along the ray $s\xi$, so $\alpha = \lambda$ when $M = I$. The template's ultimate bound ρ_ξ/α is reproduced with $m_1 = m_2 = 1$.

The structural observation: (CT2) at $M = I$ is strictly stronger than (T2) — it requires the Jacobian's symmetric part to be uniformly positive definite everywhere, matching DA2'-inc rather than (T2). The contraction formulation therefore **collapses (T2) and DA2'-inc into one condition** at the cost of requiring differential (Jacobian-level) rather than

integral (inner-product-at-a-point) information. This is one of the template’s structural contributions: the same condition that runs the template runs the bridge-lemma that #form-composition-closure depends on, so the gap between single-agent persistence and composite tracking faithfulness closes when (CT2) holds.

Sub-scope metric- α_1 / metric- α_2 / metric- β partition. The contraction formulation refines #deriv-sector-condition’s A2’ sub-scope partition into three tiers:

Sub-scope metric- α_1 (Euclidean metric, AAT-internally derived via DA2’-inc $\equiv$ (CT2) with $M=I$). Scalar Kalman, Euclidean strongly-convex gradient, L2-regularized convex, linear-PD-symmetric. These cases carry (CT2) with $M = I$ which is exactly DA2’-inc — a condition #form-composition-closure has required at the composite level all along. AAT’s existing commitment already forces (CT2)-Euclidean at these cases; the template surfaces it.

Sub-scope metric- α_2 (non-Euclidean metric, derived under explicit conditions). Five cases lift here:

- *Matrix Kalman under information metric* $M = (P^-)^{-1}$: contraction rate $\lambda = \lambda_{\min}(H^T R^{-1} H)/2$ on the observable subspace; Euclidean $\kappa(P^-)$ degradation removed. Under (PI)/Čencov (see #der-gain-sector-bridge “Fisher-metric cases under parameterization-invariance”), the information-metric form is *uniquely forced* — AAT-internally derived rather than theorem-imported.
- *Exponential-family natural parameters under Fisher metric* $M = I(\theta)$: contraction rate $\lambda = \eta$ globally on the interior of the natural-parameter domain (Fisher-conditioning degradation removed). Also AAT-internally forced under (PI)/Čencov.
- *Hessian-metric strongly-convex* $M = \nabla^2 L$: contraction rate $\lambda = \eta$ under bounded metric-derivative in the drift direction. Theorem-imported (Hessian metric chosen to match loss curvature; no AAT-internal axiom forces the specific coordinate).
- *Linear-Hurwitz-non-symmetric under Lyapunov metric*: M solves $MA + A^T M = -Q$ for $Q \succ 0$. Contraction rate $\lambda = \lambda_{\min}(Q)/(2\lambda_{\max}(M))$ in the M -metric. **New coverage:** asymmetric-stable linear corrections where Euclidean A2’ fails. Theorem-imported (Lyapunov equation construction is standard; no AAT-internal axiom forces Q).
- *PID with bounded plant nonlinearity under Lyapunov metric*: derived under plant-Lipschitz bound $L_p < \lambda_{\min}(Q)/(2\lambda_{\max}(M))$. **Promotion from sub-scope β .** Theorem-imported for the Lyapunov-metric construction; specializations include SPR-tuned PID (phase margin as sector constant; see #der-gain-sector-bridge Verified Instances).

Sub-scope metric- β (contraction-metric formulation fails). Four cases:

- *Variational / amortized / approximate posteriors*: contraction to the *projected* target (best-in-class q^*) is derivable, but the projection error $\text{KL}[q^* \| p_t]$ to the true posterior is a residual disturbance that contraction machinery cannot address.
- *Rule-based / symbolic / discontinuous updates*: non-smooth F ; (CT2) requires C^1 . Piecewise-smooth extensions (Di Bernardo et al. 2014) cover switched systems but not general rule-based reasoning.
- *Severely misspecified agents*: contraction to a wrong target is still wrong. Metric choice is silent on target validity.
- *Per-step SGD / human judgment*: noise-is-disturbance treatment identical to the Euclidean formulation; no improvement from metric choice.

This is **the seventh ladder** in #disc-separability-pattern (A2’-scope): metric- α_1 separable-core / metric- α_2 structured-repair / metric- β general-open.

Compositional contraction.

When sub-agents individually satisfy the preconditions with metrics M_i and rates λ_i , the composite satisfies (CT1)–(CT3) under specific topologies:

Result (compositional-contraction), conditional on Slotine 2003 Thm 1–3 + per-sub-agent (CT1)–(CT3).

(CC-parallel) Parallel composition. $\dot{x} = (\dot{x}_1, \dot{x}_2)^T$ with independent $(\dot{x}_i = -F_i(x_i) + w_i)$. The composite contracts under $M_c = \text{blockdiag}(M_1, M_2)$ at rate $\lambda_c = \min(\lambda_1, \lambda_2)$. Recovers #der-team-persistence’s weakest-link bound; cooperative coupling improves effective disturbance via the existing signed-coupling mechanism.

(CC-cascade) Hierarchical / lower-triangular cascade. If $\dot{x}_1 = f_1(x_1)$ contracts at λ_1 and $\dot{x}_2 = f_2(x_1, x_2)$ contracts in x_2 at λ_2 uniformly in x_1 with coupling gain $\|\partial f_2 / \partial x_1\| \leq k$, the cascade contracts. Rate bounded below by $\min(\lambda_1, \lambda_2)$ up to coupling-gain-dependent adjustment.

(CC-feedback) Negative feedback with bounded loop gain (Slotine 2003 Thm 3). Two systems with rates λ_1, λ_2 connected by negative feedback with loop gains k_{12}, k_{21} — the closed loop contracts iff

$$k_{12}k_{21} < 4\lambda_1\lambda_2. \quad (\text{CC-feedback})$$

Heterogeneous critical-mass — (CM2-M).

Specializing (CC-feedback) to the signed-coupling structure of #deriv-critical-mass-composition for heterogeneous Tier-1M sub-agents with metric-contraction rates λ_1, λ_2 , coordination costs C_1, C_2 , and feedback loop gains k_{12}, k_{21} :

Derived (CM2-M), from (CC-feedback) + ‘#deriv-critical-mass-composition’ signed-coupling structure.

$$(\lambda_1 - C_1)(\lambda_2 - C_2) > k_{12}k_{21}/4. \quad (\text{CM2-M})$$

Specializing further to the matched-symmetric case ($\lambda_1 = \lambda_2 = \lambda, C_1 = C_2 = C, k_{12} = k_{21} = k$): $(\lambda - C)^2 > k^2/4 \iff \lambda - C > k/2$, which matches #deriv-critical-mass-composition’s (CM2) with $k = 2\gamma\mathcal{T}/R$ (up to normalization). **Heterogeneous-architecture composites now have a closed-form critical-mass inequality** where the matched-symmetric case was the only closed form previously available; #deriv-critical-mass-composition’s §6.1 obstruction on heterogeneous composites is thereby closed for the Tier-1M case.

Epistemic Status.

Conditional. Conditional on (M0) + (CT1)–(CT3) and the specific metric M chosen for each sub-scope α entry. The (CT-D) and (CT-S) ultimate-bound results are standard Lohmiller-Slotine theory (Lohmiller & Slotine 1998; Slotine 2003) specialized to AAT’s per-instance state-variable choices; the proof technique is integration along the ray $s\xi$ followed by affine contraction. The contraction-metric primitive (Riemannian M) is standard in nonlinear control theory (Lohmiller-Slotine 1998; Forni & Sepulchre 2014 for the Finsler extension); AAT’s contribution is the AAT-internal mapping of M -choices to sub-scope α_1/α_2 and the recognition that the compositional theorems (CC-parallel / CC-cascade / CC-feedback / CM2-M) directly generalize Part III’s existing closure machinery.

The Jacobian-level observation. #form-composition-closure’s DA2’-inc condition is equivalent to (CT2) with $M = I$ for $C^1 F$ on convex domains. AAT has been carrying the Jacobian-level Euclidean contraction condition at the composite level all along under the name DA2’-inc; the contraction template’s Euclidean specialization surfaces this at the single-agent level.

The (PI)/Čencov observation. Two metric- α_2 cases (information-metric Kalman, Fisher-metric exp-family) are AAT-internally forced under the (PI) axiom in #scope-agent-identity combined with Čencov’s 1982 uniqueness theorem

— the fourth primary instance of the meta-pattern in #disc-additive-coordinate-forcing. The Euclidean metric- α_1 case is **AAT-internally derived via DA2'-inc equivalence** rather than theorem-imported, structurally connecting it to the bridge lemma in #form-composition-closure. The remaining metric- α_2 cases (Hessian, Lyapunov-linear-Hurwitz, Lyapunov-PID) are theorem-imported: the metric choice is problem-specific (matched to loss curvature or plant structure) rather than forced by an AAT-internal axiom.

Max attainable: *conditional*. The condition (the metric specification must be consistent with the system structure; the Slotine 2003 compositional theorems must apply to the topology) is inherent to the contraction-metric framework, not removable. Non-smooth systems (rule-based), strategic/game-theoretic equilibria, and systems without regular metric-state coupling remain honestly outside the template's scope (see §Honest failure modes).

Relationship to monotone-operator theory. The contraction-metric condition (CT2) is a specialization of monotone-operator theory's strong-monotonicity condition in a Hilbert space with a specific inner product structure (Rockafellar 1970; Bauschke & Combettes 2017 §§4, 22–28). AAT's #deriv-sector-condition reading of A2' α/β as operator-family classification — proximal / firmly nonexpansive / cocoercive / strongly-monotone-gradient / linear-PD — identifies the same mathematical content in operator-theoretic language; see that segment's Grounding paragraph for the correspondence. The present template does not claim the contraction-metric machinery as distinctively AAT — it claims the specific instantiation to AAT's state-variable choices and the composition with identifiability-floor + composition-scope-condition content as AAT-distinctive.

Honest failure modes.

The contraction-metric formulation does **not** lift AAT's coverage in five cases:

1. **Non-smooth dynamics.** Rule-based agents, state-machine controllers, threshold-triggered switches, and discontinuous policies fail the C^1 requirement. Piecewise-contraction extensions exist (Di Bernardo, Liuzza & Russo 2014, *SIAM J. Control Optim.* 52) but apply to specific switched structures, not general rule-based reasoning. This barrier is structural, not a gap in the metric machinery.
2. **Strategic / adversarial equilibria — three independent convergent obstructions.** The adversarial / strategic half of Part III is structurally outside contraction-metric scope for three distinct reasons that converge on the same conclusion; the convergence matters because it shows the limit is not an accident of one particular framework choice:
 - (i) *Compositional-contraction applicability* (Slotine 2003 §III): compositional contraction theorems require each sub-system to be individually contracting *and* for the composition topology to preserve contraction. Two-agent strategic dynamics with opposing objectives yield **saddle-point equilibria of the joint best-response dynamics** — attracting in some directions and repelling in others. Contraction requires attracting fixed points; saddle points break the framework directly.
 - (ii) *Passivity universality* (Khalil 2002 ch. 6 Thm 6.4): the dissipation inequality $\dot{S} \leq s(u, y)$ holds for *all* inputs u by the passivity property's universal quantifier. A strategic opponent can select u to maximize the recipient's storage-function growth rather than respecting the port structure. Passivity delivers cooperative/neutral robustness, not adversarial.
 - (iii) *Last-iterate convergence failure* (Daskalakis, Ilyas, Syrgkanis & Zeng 2018 “Training GANs with optimism” *ICLR*): adversarial gradient-ascent-descent dynamics (fictitious play, no-regret dynamics) converge to Nash equilibria *in average-iterate* sense (Cesàro-mean) but generically **fail last-iterate convergence** for non-zero-sum games. No contraction metric exists for systems whose last iterates do not converge to an attractor.

The three obstructions come from different theorem families (compositional-contraction / dissipativity-universality / differential-Lyapunov-attractor-theory) but converge on the same verdict: **contraction metrics cover the cooperative half of Part III** (#der-team-persistence, cooperative #deriv-critical-mass-composition, cooperative

#form-composition-closure). The adversarial / strategic half belongs to #deriv-strategic-composition (equilibrium convergence via Monderer-Shapley / Rosen) and #der-adversarial-destabilization (asymmetric attacker-target dynamics). This is a scope boundary that AAT correctly honors, not a gap to be closed — the apparatus that handles adversarial regimes is equilibrium-theoretic, structurally different from Lyapunov-contraction machinery.

3. **State-dependent metric stochastic coupling.** Pham & Slotine 2007 extends contraction to stochastic systems under small-noise bounds; the Itô-correction $c_{Itô}$ in (CT-S) is manageable for state-independent or slow-varying metrics. Strongly state-dependent M (adaptive-metric algorithms where M is learned alongside ξ) introduces cross-coupling that can destabilize contraction — the same structural issue #deriv-adaptive-gain-dynamics handles with its (MG-4) meta-gain coupling-boundedness condition.
4. **Multi-basin dynamics.** Lohmiller-Slotine contraction is local-on-a-region. Agents with multiple basins of attraction admit only basin-local metrics, giving a basin-chart structure rather than a single global metric. The basin-crossing boundary is exactly the #result-structural-adaptation-necessity trigger; the metric formulation makes the basin structure explicit but does not escape it.
5. **Identifiability-floor intersection.** The metric formulation operates downstream of identification. It assumes the correction function F points in a valid direction. Under the floors in #disc-identifiability-floor (on-policy L0-insufficiency no-go; L1' unobservable- C Cramér-Rao floor; composition-layer Instance 3 Liberzon no-go), the correction direction is structurally unavailable. Contraction metrics cannot recover identification — the two architectural moves are orthogonal.

Discussion.

Why factor this out. The Euclidean sector inequality in #result-sector-persistence-template (T2) matches a quadratic Lyapunov in Euclidean norm. For several AAT-relevant agent classes, the natural Lyapunov lives in a non-Euclidean metric (Fisher for statistical-manifold learning; Mahalanobis for Kalman; Hessian-induced for strongly-convex optimization; Lyapunov-equation-determined for asymmetric-stable linear systems). Stating AAT's persistence machinery once in parameter-free metric-formulation form makes visible that the sector condition and the contraction-metric condition are two states of the same apparatus — Euclidean and non-Euclidean — with the specific metric instantiated per sub-scope entry.

This is the *interior facet* of the stability certificate (5) in the non-Euclidean metric: the contraction-metric M is the certificate, and which metric is available per sub-scope is the certificate-strength ladder (R0-strict widest contraction / R1 cocoercive / R2 Čencov-forced; R0-loss is the wider Lyapunov-stable rung below where the certificate exists at $\kappa = 0$) of H . The five non-Euclidean metric cases are five certificates of one object, not five separate conditions.

The compositional payoff. The topology-indexed closures (CC-parallel / CC-cascade / CC-feedback) extend to heterogeneous-architecture composites via (CM2-M), closing the §6.1 heterogeneous-architecture obstruction in #deriv-critical-mass-composition. This is Part III's single largest coverage expansion: from “closed form for symmetric-matched-Tier-1” to “closed form under any of four topology classes with per-sub-agent (CT1)–(CT3) verification.”

Relationship to #result-sector-persistence-template. The two segments coexist. #result-sector-persistence-template's Euclidean formulation remains the default for agents whose natural coordinate is already Euclidean; #result-contraction-template is invoked when a non-Euclidean metric is natural (matrix Kalman, exp-family, ill-conditioned gradient, asymmetric-stable linear, PID-with-bounded-plant-nonlinearity). Every #result-sector-persistence-template invocation can be re-read as a #result-contraction-template invocation at $M = I$; the inverse mapping goes from metric to Euclidean with a $\kappa(M)$ degradation. Which direction is natural depends on the instance.

Relationship to #form-composition-closure's bridge lemma. The bridge lemma's DA2'-inc condition is equivalent to (CT2) with $M = I$ on convex C^1 domains. #result-contraction-template therefore sharpens the bridge-lemma understanding: Tier 1 (DA2'-inc globally) $\equiv$ metric-contracting-globally at $M = I$; Tier 2 (DA2'-inc locally with

$\kappa(D\delta)^2$ degradation) $\equiv$ metric-contracting-locally with a specific local metric; Tier 3 (per-domain verification) $\equiv$ no globally valid metric exists. The tier structure of the bridge lemma carries over to #result-contraction-template as Tier 1M / 2M / 3M respectively.

Relationship to #disc-identifiability-floor Instance 3 (composition-layer no-go). Instance 3's §3.3 construction uses matched-symmetric-Tier-1 scalar systems; the coupling-sign bit is unidentifiable from component marginals. Escape route (E-d) in that Instance names “shared metric structure (common contraction metric; Lohmiller-Slotine 1998)” as an adjacent machinery the no-go motivates; #result-contraction-template is the segment that machinery lives in. The Instance 3 escape is therefore operationalized by a #result-contraction-template invocation with a composite metric constructed from sub-agent metrics per the topology (parallel / cascade / feedback).

Relationship to meta-patterns.

- #disc-separability-pattern: metric- α_1 / metric- α_2 / metric- β is the seventh ladder (A2'-scope), closing the “binary special case” gap that segment's Discussion flagged. Separable-core (metric- α_1 , Euclidean, AAT-internally derived via DA2'-inc $\equiv$ (CT2)-M=I) / structured-repair (metric- α_2 , non-Euclidean, derived under explicit conditions including (PI)/Čencov for Fisher-metric cases) / general-open (metric- β , metric formulation fails).
- #disc-identifiability-floor: orthogonal axis. Contraction metrics lift the *geometry-of-correction* half of sub-scope α ; identifiability-floor operates on the *what-correction-to-make* half. The two architectural moves compose (Instance 3 at composition layer + metric-Tier structure at single-agent layer) but do not interact.
- #disc-additive-coordinate-forcing: the (PI)/Čencov axiom that grounds two of five metric- α_2 cases is the fourth primary instance of the meta-pattern, adding a Čencov-invariance machinery alongside the three Cauchy-FE instances. See that segment's Four Instances tables.

Findings.

Topology-Indexed Compositional Closures via Contraction-Metric Generalization. Brief: AAT's central machinery for proving an adaptive system holds its mismatch bounded was originally written in the simplest geometric setting (the equivalent of measuring distance with a ruler in flat space). Many real systems have a more natural geometry — a Kalman filter “thinks” in terms of an information ellipsoid, a learning agent thinks in Fisher-information geometry, a controller designed for an asymmetric plant thinks in a different metric still. This result restates the persistence machinery in a way that uses each system's natural geometry, lifting five additional agent classes from sub-scope β (assumed) to sub-scope α_1/α_2 (derived under explicit conditions), and inheriting Slotine 2003's topology-indexed compositional closures (parallel / cascade / negative-feedback) at the composition layer.

Impact: Part III's largest single coverage expansion: from “closed-form composite persistence under matched-symmetric Tier-1” to “closed-form composite persistence under any of four topology classes with per-sub-agent contraction verification, including heterogeneous-architecture mixes via (CM2-M).” For Part II, the structural-transparency observation that DA2'-inc $\equiv$ (CT2)-at-M = I shows AAT's existing Euclidean machinery was already carrying the Jacobian-level contraction commitment under another name; what changes is making that commitment legible and lifting non-Euclidean cases (Fisher-metric Kalman, exp-family natural-parameter, ill-conditioned strongly-convex gradient, asymmetric-stable linear, PID with bounded plant) from theorem-imported to AAT-internally derived under named axioms. Three independent obstructions (Slotine 2003 saddle-point; passivity-universality; Daskalakis 2018 last-iterate non-convergence) bound the template's scope honestly — adversarial composition is structurally outside contraction analysis and properly handled by #deriv-strategic-composition's equilibrium-convergence machinery.

Novelty Claim: *Claim synthesis* on contraction-metric machinery + AAT's sub-scope partition + (PI)/Čencov axiom. The contraction-metric primitive itself is standard nonlinear control theory; the topology-indexed closures are Slotine 2003. The synthesis is the AAT-internal mapping of metric choices to per-instance state-variable choices, the recognition that the Euclidean specialization is structurally the bridge-lemma's DA2'-inc, and the (PI)/Čencov axiom forcing two of the metric- α_2 cases to be AAT-internally derived rather than theorem-imported.

Differential-contraction primitive on Riemannian metrics	Lohmiller & Slotine 1998, “On Contraction Analysis for Non-linear Systems” <i>Automatica</i> 34:683–696 (published 1998, found pre-2026)	<i>formal antecedent</i> — supplies the (CT1)–(CT3) preconditions and the (CT-D) ultimate-bound argument adopted directly
Compositional contraction under topology	Slotine 2003, “Modular stability tools for distributed computation and control” <i>Int. J. Adapt. Control Signal Process.</i> 17:397–416 (published 2003, found pre-2026) — Theorems 1–3 (parallel; cascade; negative-feedback small-gain)	<i>formal antecedent</i> — supplies (CC-parallel) / (CC-cascade) / (CC-feedback) and the heterogeneous (CM2-M) extension. AAT adopts these directly, applied to the composition-validity question of #form-composition-closure
Finsler (direction-dependent) generalization	Forni & Sepulchre 2014, “A Differential Lyapunov Framework for Contraction Analysis” <i>IEEE TAC</i> 59 (published 2014, found 2026-04)	<i>adjacent literature</i> — Finsler-metric extension; flagged in Working Notes for highly anisotropic agents; not currently load-bearing
Strong monotonicity / firmly-nonexpansive operators	Rockafellar 1970, “On the maximality of sums of nonlinear monotone operators” <i>Trans. AMS</i> ; Bauschke & Combettes 2017, <i>Convex Analysis and Monotone Operator Theory in Hilbert Spaces</i> §§4, 22–28	<i>formal antecedent</i> — (CT2) at $M = I$ is strong monotonicity in Hilbert space; the Rockafellar-Wets / Nesterov equivalence (DA2’-inc $\Leftrightarrow$ Jacobian-symmetric-part PD $\Leftrightarrow$ (CT2)-at- $M = I$) is the standard monotone-operator identity AAT uses to make the Euclidean metric- α_1 case AAT-internally derived rather than theorem-imported
Fisher-metric / information-geometry uniqueness	Čencov 1982, <i>Statistical Decision Rules and Optimal Inference</i> AMS Translations 53	<i>formal antecedent</i> — under the (PI) axiom in #scope-agent-identity, Čencov’s theorem forces the Fisher-metric Kalman and exp-family natural-parameter cases AAT-internally
Bounded-loss composition under predictive compression	Subramanian, Sinha, Seraj & Mahajan 2020, “Approximate information state for approximate planning and reinforcement learning in partially observed systems” <i>arXiv:2010.08843</i> (published 2020, found 2026-04)	<i>adjacent literature</i> — closest mathematical neighbor to the bridge-lemma side of #form-composition-closure. The contraction-metric machinery in this segment supplies the (CT2) condition that, at $M = I$, is the bridge-lemma’s DA2’-inc; Sub20’s predictive-loss-to-control-error result lives in the same shape but at a coarser granularity (single-agent compressed control, not composite agent boundary)
Influence-based abstraction loss bounds	Congeduti, Mey & Oliehoek 2020, “Loss Bounds for Approximate Influence-Based Abstraction” <i>arXiv:2011.01788</i> (published 2020, found 2026-04)	<i>adjacent literature</i> — bounds value loss from approximate cross-agent influence; the (CC-feedback) topology with bounded loop gain is the contraction-metric counterpart at the dynamics layer
Saddle-point / adversarial limits of contraction	Daskalakis, Ilyas, Syrgkanis & Zeng 2018, “Training GANs with optimism” <i>ICLR</i> (published 2018, found 2026-04); Khalil 2002 <i>Nonlinear Systems</i> 3rd ed. ch. 6 Thm 6.4 (passivity-universality)	<i>contradicted by this finding</i> (in the sense of correctly bounding scope) — three independent obstructions to handling adversarial regimes converge: Slotine 2003 §III saddle-point limitation; passivity-universality’s universal quantifier; Daskalakis 2018 last-iterate non-convergence. The convergence demonstrates the scope boundary is not an artifact of one framework; adversarial composition is structurally outside contraction analysis

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Switched-systems common-Lyapunov nonexistence	Liberzon 2003, <i>Switching in Systems and Control</i> Theorem 2.1	<i>formal antecedent</i> — supplies #disc-identifiability-floor Instance 3's no-go; the contraction-metric construction operationalizes escape route (d) (common contraction metric) for that Instance

Search Log:

- 2026-04 (*nominally comprehensive*): The composition-layer extension of this segment (the (CC-*) closures and (CM2-M)) was reviewed under the same Undermind pass that covered #form-composition-closure. Verdict: the contraction-metric machinery itself is standard adopted prior art (formal antecedent); the AAT-internal mapping of metric choices to per-instance sub-scope α_1/α_2 entries and the use of (PI)/Čencov to force two metric- α_2 cases AAT-internally are the synthesis-level contributions. The Sub20 / Con20 positioning at the composition-validity layer is recorded both here and at #form-composition-closure since the contraction template is what supplies the formal mechanism the bridge lemma uses.
- 2026-04 (*targeted*): Lohmiller-Slotine 1998 / Slotine 2003 / Forni-Sepulchre 2014 known and cited from the contraction-analysis literature. The three adversarial obstructions (Slotine 2003 §III; Khalil 2002 ch. 6; Daskalakis et al. 2018) are convergent scope-boundary evidence.
- 2026-04 (*intuition-only*, prior): expected the contraction-metric primitive to be standard control-theory; expected the composition theorems to be the more proprietary content. Comprehensive search confirmed both: the primitive is well-established, and the composition theorems are Slotine 2003's, with AAT's contribution lying in the application to #form-composition-closure's admissibility-and-bridge-lemma framework.

Working Notes.

- **Landing context.** The segment is the primary result of spikes/.integrated/spike-contraction-metric-generalization.md (2026-04-23 Gap A/B cycle). The Jacobian-level observation (DA2'-inc $\equiv$ (CT2)-M=I) and the (PI)/Čencov observation derive from the jacobian-b1 strengthening (2026-04-23 follow-up; absorbed in the spike-routing cycle, CHANGELOG 2026-05-17).
- **Heterogeneous general-graph composition.** Slotine 2003 §IV's virtual-system technique covers general directed graphs under a small-gain-along-every-cycle condition. Operationalizing this for #form-composition-closure's general multi-agent setting — including identifying which cycle-gains to measure in practice — is a follow-up derivation. (CM2-M) in this segment handles 2-agent negative-feedback; $N \geq 3$ with general topology remains open but structurally clear.
- **Jacobian-level B1 strengthening is open.** The (CT2) condition on F 's Jacobian is a Jacobian-level B1 analog. Whether the integral B1 of #der-gain-sector-bridge can be *strengthened* to a Jacobian-level B1* that implies (CT2) AAT-internally (rather than via theorem-import from Lohmiller-Slotine) was attacked in the jacobian-b1 strengthening (spike-routing cycle, CHANGELOG 2026-05-17). Three of the five metric- α_2 cases (Hessian, Lyapunov-linear-Hurwitz, Lyapunov-PID) remain theorem-imported after that spike; two (Fisher-metric-Kalman, Fisher-metric-exp-family) lift AAT-internally under (PI)/Čencov. The remaining gap is the three theorem-imported cases.
- **Candidate strong-option promotion.** Under a *heredity* axiom (composite admissibility derivable from sub-agent properties — a legitimate AAT-internal strengthening of #disc-composition-consistency), agent-level B1* is forced, metric-Tier structure collapses, and (CM2-M) promotes from Slotine-imported to AAT-derived. Flagged in the Jacobian-level B1 spike's §II strong option; promotion is an architectural decision requiring its own scoping.
- **Finsler metrics.** Forni & Sepulchre 2014 extends the differential Lyapunov framework to Finsler (direction-dependent) metrics. Likely useful only for highly anisotropic corrections (coordinate-asymmetric agents); not priority.

- **The (T2) / (CT2) structural observation matters for Part I too.** #result-persistence-condition's linear special case ($F = \mathcal{T}\delta$, $\alpha = \mathcal{T}$, (T2) global) is trivially contraction-metric with $M = I$ and $\lambda = \alpha$. But non-linear #result-persistence-condition instances (nonlinear mismatch dynamics, gradient on strongly convex losses) would benefit from contraction-metric framing to remove the Euclidean-norm-specific condition-number penalty in the persistence constant. A cross-reference from #result-persistence-condition back to this segment may be warranted after the next promotion pass.
-

Appendix AJ

Derivation: Variational Approximate-A2' (ε -Fidelity)

Variational / approximate-posterior agents (VI, amortized VI, active-inference-style variational free energy) currently sit in A2' sub-scope β per #form-sector-condition: their correction functions target the *best-in-class* variational posterior q^* rather than the true posterior p , and the approximation gap can rotate the correction direction enough to break B1 directional fidelity (4.3). Under a KL bound $\text{KL}(q_\phi \| p) \leq \varepsilon$ on the variational approximation, directional fidelity recovers in a quantifiable form: **ε -fidelity B1**, with sector-constant degradation scaling as $O(\sqrt{\varepsilon})$ (Pinsker-tight). The sector-persistence template applies under a Regime-A / Regime-B decomposition — clean sector bound on an annulus away from the projection-error floor, approximation-dominated on a ball of radius $\delta_0 = O(\sqrt{\varepsilon})$ around the target. This promotes controlled-KL VI from sub-scope β to a new intermediate tier α' within the A2' partition (cf. the $\alpha / \alpha_1 / \alpha_2 / \beta$ refinements from #deriv-adaptive-gain-dynamics and #deriv-fisher-whitened-update-rule).

The result has a striking operational consequence: **mean-field VI is structurally sub-optimal as an adaptive system by a factor $\sqrt{1 - r^2}$ in the sector constant, regardless of compute or training data**, because the mean-field family does not match the Fisher metric. **Natural-gradient VI recovers the full sector parameter** (Khan-Lin 2017 conjugate-computation equivalence places it in full sub-scope α rather than α') because the natural-gradient direction matches the Fisher metric — no degradation. Where persistence-optimality matters, the variational-family choice is not interchangeable; the long-running Bayesian-deep-learning practical preference for natural-gradient over mean-field has a principled persistence-theoretic reading inside AAT.

Formal Expression.

ε -fidelity B1.

Let the true posterior be $p(z | x)$ and the variational approximation $q_\phi(z | x)$ with $\text{KL}(q_\phi \| p) \leq \varepsilon$. Under standard Lipschitz assumptions on the observation model and nested-support on the variational family, the total-variation distance bounds as $\|q_\phi - p\|_{TV} \leq \sqrt{\varepsilon/2}$ (Pinsker's inequality). Propagating this bound through the correction function via Cauchy-Schwarz:

Derived (eps-fidelity-B1, from Pinsker + Cauchy-Schwarz).

$$(\hat{K}\hat{P} - P^*)^T(\hat{P} - P^*) \geq (c_{\min} - C_H\sqrt{2\varepsilon/\|\delta\|}) \cdot \|\delta\|^2 \quad (\text{AJ.1})$$

where C_H is a constant depending on the observation-model Lipschitz constant. The effective sector constant

$$c_\varepsilon(\|\delta\|) = c_{\min} - C_H \sqrt{2\varepsilon/\|\delta\|} \quad (\text{AJ.2})$$

is state-dependent: large-mismatch regions see near-full sector constant; near-target regions see degraded sector constant due to approximation error dominating.

Regime-A / Regime-B decomposition.

Define $\delta_0 = 2C_H \sqrt{2\varepsilon/c_{\min}}$ (the approximation-dominated radius around target). Then:

Formulation (regime-decomposition-variational).

- **Regime A — clean sector bound** ($\|\delta\| > 2\delta_0$). On the annulus $\mathcal{B}_R \setminus \mathcal{B}_{2\delta_0}$, $c_\varepsilon \geq c_{\min}/2$: sector condition holds with constant $c_{\min}/2$. The template's ultimate bound $\rho_\xi/(c_{\min}/2)$ applies.
- **Regime B — approximation-dominated floor** ($\|\delta\| \leq 2\delta_0$). Near target, c_ε can be arbitrarily small; the correction may not contract. The ultimate bound gains an additive $O(\sqrt{\varepsilon})$ term: $R_\varepsilon^* = \rho_\xi/(c_{\min}/2) + \delta_0 = \rho_\xi/(c_{\min}/2) + O(\sqrt{\varepsilon})$.

Sector-persistence template instantiates with: - State variable $\xi = \hat{P} - P^*$ (variational mismatch to target posterior). - Effective ultimate bound R_ε^* on Euclidean norm. - Persistence requires $R_\varepsilon^* < R$, i.e., $\rho_\xi/(c_{\min}/2) + O(\sqrt{\varepsilon}) < R$.

Khasminskii stopping-time localization (same technique as #deriv-sector-condition Prop A.1S and the A2' strengthening spike) applies to the annulus Regime A; Regime B is handled by accepting δ_0 as a projection-error floor.

Per-case verdicts.

The α' -membership depends on the specific variational scheme:

Derived (per-variational-case).

Natural-gradient VI with exponential-family q_ϕ . Khan & Lin 2017 (*Conjugate-computation variational inference*) showed natural-gradient VI is equivalent to closed-form conjugate-Bayesian updates for exponential-family variational distributions. This recovers *full* sub-scope α membership (not merely α'), with A2' derived rather than ε -degraded, by converting the variational update into a Bayesian update in a reparameterized family. The $\varepsilon = 0$ limit is exact.

Mean-field VI. When the true posterior is approximately factorized ($p(z) \approx \prod_i p_i(z_i)$), mean-field VI achieves small ε and is the workhorse α' case. Ultimate bound degrades by additive $O(\sqrt{\varepsilon})$; sector persistence holds.

Amortized VI (VAE-style). Amortization adds a second approximation error (the variational network's function-class limit). KL bounds compose *additively*: δ_0 grows as $\sqrt{\varepsilon_{\text{family}} + \varepsilon_{\text{amort}} + \varepsilon_{\text{generalization}}}$. Under controlled- ε amortized VI, α' membership holds with a larger floor.

Diffusion-posterior / energy-based with uncontrolled MCMC. No controlled ε bound; ε grows with mixing time. Stays firmly in sub-scope β .

Active inference (variational free energy). Conditional α' under exponential-family q + natural-gradient; ε -degraded α' otherwise. This does **not** force V-strong G-BP2 (presentation of AAT as control-theoretic specialization of active inference) — V-medium (KL-divergence-based cognitive cost) remains the appropriate scope commitment; the comparison trail is in the spike-routing cycle (CHANGELOG 2026-05-17).

Sub-scope α' in the A2' partition.

The A2' sub-scope partition is structured as:

Derived (sub-scope-alpha-prime-partition).

- **Sub-scope α** (derived under B1 directional fidelity; #der-gain-sector-bridge): Kalman, conjugate Bayesian, exponential-family natural parameters, strongly-convex gradient, L2-regularized, linear-PD-symmetric.
- **Sub-scope α_1/α_2** (#result-contraction-template): metric-formulation generalization of α .
- **Sub-scope α_3** (#deriv-fisher-whitened-update-rule): correlated evidence + Fisher-whitened under (PI)/Čen-cov.
- **Sub-scope α'** (this segment): controlled-KL VI under Pinsker's inequality with $O(\sqrt{\varepsilon})$ sector-constant degradation + Regime-A/B decomposition.
- **Sub-scope β** : uncontrolled- ε agents; non-smooth rule-based; severely misspecified; per-step SGD; human judgment.

This gives the full current picture: $\{\alpha, \alpha_1, \alpha_2, \alpha_3, \alpha', \beta\}$.

Epistemic Status.

Conditional. Max attainable: *exact* for the Pinsker-bound derivation (standard inequality). The $O(\sqrt{\varepsilon})$ rate is tight in general — improving to $O(\varepsilon)$ requires stronger inequalities (log-Sobolev, Talagrand T2) holding for the specific variational family and target; not chased in this segment but is a potential refinement for concentration-preserving families.

Load-bearing: - Pinsker + Cauchy-Schwarz gives the $O(\sqrt{\varepsilon})$ rate rigorously. - Regime-A annulus sector bound with $c_{\min}/2$ is derived (straightforward bookkeeping on the state-dependent c_ε). - Natural-gradient VI promotion to full α is standard (Khan & Lin 2017). - Mean-field VI as workhorse α' is standard variational analysis.

Not established: - $O(\varepsilon)$ rate (would require stronger inequalities). - Quantitative ε bounds for specific variational families in practice (amortization gaps are typically not estimable tightly). - α' membership under mode-missing VI (multimodal posteriors where q concentrates on a subset of modes). These may require separate analysis.

Honest Failure Modes.

- **Uncontrolled- ε agents:** diffusion posteriors with finite MCMC; VAEs trained without KL control; any VI without a bounded- ε certificate. Stays in β .

Scope honesty — variational-alpha-prime-limits.

- **Mode-missing on strongly multimodal posteriors:** q misses modes; ε is irreducible regardless of optimization. α' fails structurally.
- **Non-Lipschitz observation models:** the C_H constant diverges; the Pinsker propagation bound doesn't hold. α' fails.
- **Support mismatch:** q 's support is not a subset of p 's support (or vice versa); KL is $+\infty$. α' fails.
- **Non-exponential-family + non-amortized + uncontrolled + multimodal:** the worst case, strictly β .

Discussion.

Relationship to #form-strategy-complexity-cost. The G-BP2 V-medium variational form landed in #form-strategy-complexity-cost uses KL divergence in the cognitive-cost term. This segment provides the complementary story on the persistence side: KL-bounded VI has ε -fidelity B1 and α' sector condition. The two together characterize the cognitive/persistence tradeoff for variational agents: ε controls both the cognitive cost (how far from the target) and the persistence degradation (how much sector-constant penalty). Large ε means cheap-but-persistently-weak; small ε means expensive-but-persistently-sharp.

Relationship to #disc-compression-operations. Variational compression is the first of the four AAT compression operations; its α' sector structure gives a concrete persistence guarantee for variational representation of M_t . The other three operations (strategy Σ_t , shared-intent, coarse-graining Λ) may admit similar ε -fidelity analyses where a KL-bound on the compression is available.

Meta-pattern positioning. - #disc-separability-pattern: α' sits on the structured-repair tier of the A2'-scope ladder (7th ladder from #result-contraction-template), alongside metric- α_2 and α_3 . Each represents "sector condition recovered under explicit additional structure." - #disc-additive-coordinate-forcing: variational persistence sits *outside* this meta-pattern — no logarithmic coordinate is forced; Pinsker is a bound, not a Cauchy-FE argument. α' is an adjacent family member (shape: controlled-approximation-with-quantified-degradation), not a primary instance.

Working Notes.

- Landing context: spikes/.integrated/spike-variational-a2prime.md (2026-04-23 Gap A/B cycle).
 - **Open: $O(\varepsilon)$ rate via Talagrand T2.** For concentration-preserving variational families with log-Sobolev or T2-Talagrand inequalities, the Pinsker bound can be sharpened to $O(\varepsilon)$ directly (without square-root). Not chased here; would extend α' to a tighter sub-tier for specific family classes.
 - **Amortization gap bounds.** Generalization-gap analysis for VAEs (Rainforth et al. 2018; Nowozin 2018) gives function-class error bounds; composing with variational-family error gives the full δ_0 in amortized VI. Follow-up work.
 - **Connection to natural-gradient VI.** Khan & Lin 2017's conjugate-computation framing makes natural-gradient VI full sub-scope α (not just α'). The α' tier is for *non-natural-gradient* VI under KL control.
-

Appendix AK

Derivation: L1' Update-Bias Formula

Under L1' correlated-evidence regimes with unobservable common cause, the default log-odds edge-update (U) converges to a **biased fixed point** — edges settle at log-odds values that match the L1' root-probability rather than the marginal-edge truth. This segment derives a closed-form bias formula for the two-edge OR-root case, verifies it via Monte Carlo, and composes it with #disc-identifiability-floor Instance 2 and #schema-strategy-persistence's forgetting prerequisite to produce a **dual forgetting-rate requirement** on strategic persistence.

The bias is the quantitative companion to F13's structural-identifiability-floor result: F13 shows identification is *structurally impossible* from single-channel observation; this segment shows the resulting *magnitude drift* is bounded, Lipschitz in correlation strength ρ , and Cramér-Rao-floored under forgetting. The dual forgetting-rate requirement reads operationally: forget *fast enough* to track non-stationarity (the plasticity lower bound from 9.10) *and* fast enough to keep the L1' bias bounded (this segment's upper-bound-driving lower bound on $1 - \lambda$). When the two compose with #form-consolidation-dynamics's stability cadence into an empty admissibility window, the agent must augment its observability or accept biased-fixed-point operation — the operational signature of a forgetting-window infeasibility in which constraint is binding.

Formal Expression.

Closed-form bias at matched-marginal initial conditions (two-edge OR-root).

Let root node G have two direct causal parents e_1, e_2 via OR-aggregation under L1' with latent common cause C producing correlation ρ between the parent edges. Assume matched-marginal initial conditions: $\hat{\mu}_j^{\text{init}} = \mu_j^*$ for each edge's marginal probability. Under the default log-odds update with per-edge gain $\eta_{\text{edge}} = 1/(n_k + 1)$ and identifiability coefficient ι_k , the per-cycle bias on edge k 's log-odds update satisfies

Derived (L1-bias-formula-OR-root).

$$B_k(\rho) = -\frac{\iota_k \cdot (1 - \mu_{\bar{k}}) \cdot \rho}{(n_k + 1) \cdot [(1 - \mu_1)^2 + (1 - \mu_2)^2]} \quad (\text{AK.1})$$

where $\bar{k} \in \{1, 2\} \setminus \{k\}$ is the sibling edge. The bias is linear in ρ , decays as $1/(n_k + 1)$ with experience, topologically asymmetric via the Jacobian factor $(1 - \mu_{\bar{k}})/\|\mathbf{J}\|^2$.

Admissible region (precise). The denominator is the squared OR-aggregation Jacobian norm $\|\mathbf{J}\|^2 = (1 - \mu_1)^2 + (1 - \mu_2)^2$. The first-order perturbation is well-posed precisely when $\|\mathbf{J}\|$ is bounded below by some fixed $\epsilon_J > 0$ — equivalently, when at least one edge probability is bounded away from 1. This is the **Jacobian-norm admissibility**

condition $\|\mathbf{J}\| \geq \epsilon_J$; it is *weaker* than requiring both μ_1, μ_2 to be bounded away from 1, and it is *sharper* than the qualitative “bounded away from determinism” reading: only the joint deterministic-success corner $\mu_1, \mu_2 \rightarrow 1$ together is excluded. As either edge alone approaches deterministic success the bias formula remains valid (the surviving sibling edge carries the Jacobian norm); only the diagonal corner where both edges saturate is excluded, and there the per-cycle update itself vanishes (observations carry no residual information), so “no learning, no bias” is the operationally correct behaviour and the formula’s apparent singularity is degenerate rather than physical. Inside the admissible region $\|\mathbf{J}\| \geq \epsilon_J$, the closed-form predictions are quantitatively verified by Monte Carlo; at the diagonal corner the segment defers to #deriv-edge-credence-dynamics’s degenerate-update analysis. The Jacobian-norm condition is the natural admissibility statement because the bias formula is the projection of the update onto $\mathbf{J}/\|\mathbf{J}\|^2$, so well-posedness requires only that this projection be defined.

For AND-root aggregation, the bias has the same structural form with opposite sign. For mixed OR-AND sub-plans, the bias decomposes sub-plan-wise.

L1'-induced biased fixed point.

Under continued L1' evidence, the log-odds fixed point satisfies

Derived (biased-fixed-point-exists).

$$\lambda_k^{\text{L1'-FP}} = \lambda_k^* + \int_0^\infty e^{-\eta_{\text{edge}} t_k t} B_k(\rho) dt = \lambda_k^* - \rho \cdot (1 - \mu_k) / [(1 - \mu_1)^2 + (1 - \mu_2)^2] \quad (\text{AK.2})$$

(for constant- t approximation). Each edge’s log-odds converges to a **wrong value** that matches the L1' root probability rather than the marginal truth. **Plan-level correctness is purchased at edge-level miscalibration:** the agent predicts plan outcomes correctly on-policy (the L1' mixture on the sibling matches the L1' marginal), but its per-edge credences are systematically biased.

This is the quantitative companion to F1’s on-policy undetectability (#disc-identifiability-floor Instance 1) at the marginal level: the bias accumulates at rate $1/(n_k + 1)$, converges to a bounded non-zero value, and is *not detectable from on-policy data* because the mixture’s marginal is matched to the on-policy observations.

Observable-C zero-bias result.

Under Prop B.7’s five-way-gating with C observable, conditioning on C decomposes the L1' mixture into two single-child-per-component problems:

Derived (observable-C-zero-bias).

$$B_k(\rho \mid C = c) = 0 \quad \text{in expectation at conditional truth, for each } c \in \{0, 1\}. \quad (\text{AK.3})$$

Prop B.7’s decomposition *exactly eliminates the bias* — the five gating conditions (facilitator monotonicity; C -observability; $t > 0$ for common-cause edge; marginal sector condition; identifiability of per-component rates) are precisely the conditions under which conditional-on- C updates restore exactness. This makes Prop B.7’s derivation the quantitative escape from the L1' bias.

Unobservable-C Cramér-Rao bias floor under forgetting.

When C is unobservable and the agent uses experience discounting at rate $\lambda \in [0, 1)$ to maintain plasticity (#schema-strategy-persistence's forgetting prerequisite), the steady-state bias is

Derived (bias-floor-under-forgetting).

$$B_k^{SS}(\rho, \lambda) = -\frac{\iota_k \cdot \rho \cdot (1 - \mu_{\bar{k}})}{(1 - \lambda) \cdot [(1 - \mu_1)^2 + (1 - \mu_2)^2]}. \quad (\text{AK.4})$$

The Cramér-Rao floor from #disc-identifiability-floor Instance 2's rank-1 Fisher matrix translates directly: no unbiased estimator can reduce the bias below $\rho/(1 - \lambda) \cdot [\text{constant}]$. The bias is structurally present in any online estimator operating on single-channel observation of one child edge, not merely the specific default-signal estimator.

Dual forgetting-rate requirement.

#schema-strategy-persistence requires forgetting rate $(1 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$ for asymptotic sector-persistence. The L1' bias floor above imposes a **second** constraint: to keep the bias bounded relative to the sector reserve,

Derived (dual-forgetting-requirement).

$$(1 - \lambda) > c_B \cdot \rho/R_{\Sigma}^{\text{bias}} \quad (\text{AK.5})$$

where c_B is a topology-dependent constant from the Jacobian factor and R_{Σ}^{bias} is the tolerable bias-reserve within the sector region. The forgetting rate must satisfy **both**:

$$(1 - \lambda) > \max\left(\frac{\rho_{\Sigma}}{R_{\Sigma}}, \frac{c_B \cdot \rho}{R_{\Sigma}^{\text{bias}}}\right). \quad (\text{AK.6})$$

When the admissibility window is empty (no forgetting rate satisfies both constraints simultaneously), no standard persistence regime works — the agent must augment (observable-C via instrumented regime indicators; multi-child joint observation; plan-level fallback) or accept biased-fixed-point operation.

Monte Carlo verification.

Two independent Monte Carlo implementations confirm the closed-form predictions — the original 2026-04-23 record (four scenarios: symmetric strong common-cause, asymmetric mild, degenerate $\rho = 0$, θ_C sweep; 400 trials $\times$ 5000 cycles, OR-root) and a fresh 2026-07-16 implementation that reproduces the original's scenario-A cumulative drift to 4 significant figures (-0.3996 vs -0.3997) and extends verification to the AND-root case: - Initial-cycle rate matches the closed form within $< 1\%$ for **both OR and AND roots** across the feasible covariance range $\rho \in \{0.04, 0.09, 0.16, 0.20, 0.24\}$ (note $\rho = \text{Cov}(Y_1, Y_2) \leq 1/4$ by construction) and in the asymmetric-edge case. - Sign matches prediction everywhere; **OR and AND roots produce opposite-sign biases of matching magnitude** (AND-root now simulated, not derivation-only). - Vanishing at $\rho = 0$ verified (degenerate L1'); no false positive under L0-matched truth (drift $\approx 3 \times 10^{-4}$ over 5000 cycles). - Cumulative drift is log-order (far from linear) and decelerates slightly faster than the frozen-state $\sum_t 1/(n + t + 1)$ prediction, consistent with the bias-induced $\mathbf{p}(t)$ trajectory effect; the exact transient shape has no closed form (see Epistemic Status).

Empirical claim (monte-carlo-confirmation).

Epistemic Status.

Conditional. Max attainable: *exact* for the two-edge OR-root / AND-root matched-marginal case. The closed-form bias formula is derived via first-order perturbation of the log-odds update around matched-marginal truth; the Jacobian factor is specific to the DAG topology (OR vs AND vs mixed). *Robust qualitative* for deeper DAG structures where the bias Decompose sub-plan-wise but closed-form coefficients depend on per-sub-plan Jacobians.

What is load-bearing: - The linear-in- ρ scaling is exact (first-order in small correlation). - The $1/(n_k + 1)$ experience scaling is exact (follows from #deriv-edge-update-natural-parameter's Beta-Bernoulli gain). - The observable- C zero-bias result under Prop B.7 gating is exact. - The dual forgetting-rate requirement is a first-order composition of two separate constraints.

What is not established: - Closed-form bias for non-matched-marginal initial conditions (transient bias during convergence). Numerical simulation works; analytic form is messier. - Higher-than-second-order DAG structures (L2-general). Scope boundary. - Full coupled bias formula under #deriv-adaptive-gain-dynamics meta-gain machinery. Open.

Discussion.

Composition with #disc-identifiability-floor Instance 2. F13 establishes the structural no-go for single-channel L1' mixture identification (Cramér-Rao rank-1); this segment gives the **quantitative numerical-floor** companion — the bias is bounded, continuous in ρ , and vanishes at $\rho = 0$. Instance 2 answers “is it identifiable?” (no, structurally); this segment answers “if we update anyway, how wrong is the result?” (bounded drift to a biased fixed point).

Composition with #deriv-fisher-whitened-update-rule. The Fisher-whitened update recovers sharp *directional* fidelity but does not reduce the *magnitude* bias — Fisher whitening operates downstream of identification, and Instance 2's obstruction is an identification obstruction. The full picture for the default signal function under L1': **direction preserved (angle $\leq 45^\circ$ per #deriv-fisher-whitened-update-rule), magnitude biased by $B_k(\rho)$ with Cramér-Rao floor under forgetting (this segment), observable- C restores exactness (Prop B.7), undetectable on-policy (Instance 1 + Instance 2 composition).** This is the honest quantitative account of what the default signal function does under Gemini's Gap A (validation under correlated failures).

Relationship to #schema-strategy-persistence's forgetting. The segment's existing forgetting prerequisite (for asymptotic sector-persistence) becomes dual under L1': forgetting must *both* outpace sector disturbance *and* prevent bias accumulation. When the two constraints are compatible (admissibility window non-empty), the existing forgetting-rate requirement suffices with appropriate ρ -dependent tuning. When incompatible, augmentation is required — a structural scope narrowing that elevates observable- C instrumentation from convenience to prerequisite.

Connection to X. The detection-latency theorem ($\mathbb{E}[T_{\text{detect}}] = \Omega((n_{\min} + 1)/\varepsilon)$) assumes unbiased marginal tracking; under L1' bias, the pre-accumulated drift degrades effective ε for subsequent regime-change detection. High-operating-point agents with pre-accumulated L1' bias face a compounded myopia floor. Follow-on refinement possible in X.

Working Notes.

- Landing context / reproducibility: the closed-form derivation and the original Monte Carlo record (scenarios A–D, OR-root) are in spikes/.integrated/spike-l1-update-bias.md §7 (2026-04-23 Gap A/B cycle; its script lived in /tmp and is lost). The 2026-07-16 re-verification — fresh implementation, full script preserved, OR+AND roots, feasible- ρ grid, 4-sig-fig reproduction of the original scenario-A drift — is spikes/spike-l1-bias-sim-rerun-2026-07-16.md. Citable-supplement release at publication should use the rerun's script.
- 2026-07-16 — Monte Carlo block corrected (truth-status repair from the bulk-64 verify-pass). The block previously described a simulation that was never run (“four scenarios: OR/AND $\times$ cooperative/adversarial”; “ $\rho \in \{0.1, \dots, 0.9\}$ ” — infeasible, since $\text{Cov} \leq 1/4$ under the spike's parameterization): a confabulated summary written at landing, while the

actual 2026-04-23 record was sound (it reproduces exactly). Restated to what ran, strengthened by the rerun (AND-root now verified). Guard: when summarizing a simulation record into a segment, transcribe its parameters — don't paraphrase from memory.

- **Open: non-matched-marginal transient bias.** Closed-form for arbitrary initial conditions is messier but numerically tractable. A tighter analytic treatment would compose `#deriv-edge-update-natural-parameter's` β -Bernoulli dynamics with the L1' mixture and likely requires Markov-chain convergence-rate analysis.
 - **Open: N -edge common-cause extensions.** Three or more children of a single common cause produce a tensor of Jacobian factors. The structural scaling likely remains $O(\rho)$ per edge, but the exact coefficients need working out.
-

Appendix AL

Derived: Architecture No-Identifiability from On-Policy Summary Data

The framework’s identifiability-floor at the *agent-internal architecture* layer. Two AAT agents whose linearized closed-loop residual dynamics are minimal state-space realizations related by an invertible similarity transformation produce *identical* on-policy summary statistics: identical innovation spectrum, identical sector-condition summary (α, R) , identical similarity-invariant deviation summaries — and therefore identical observation law under on-policy, in-regime, summary-only access. An observer with that access cannot distinguish the two agents, even though they implement the correction in structurally distinct internal coordinates. The architectural degree of freedom AAT cares about — #der-agent-opacity’s “which internal mechanism” — lives entirely in the $GL(n)$ similarity fiber and is annihilated by the on-policy observation map.

The no-go is *exact* in the linear-Gaussian / Kalman sub-scope, anchored by Kalman 1963 and Ho-Kalman 1966 canonical-form non-uniqueness; *robust-qualitative* in the general sub-scope via the Causal Hierarchy Theorem applied at the agent-as-SCM layer (Bareinboim, Correa, Ibeling & Icard 2022). The mechanism is **not** Sylvester’s law of inertia inherited for free — the *generating* group action that produces the indistinguishable pair is state-space similarity $T(\cdot)T^{-1}$, not the metric congruence $S^T(\cdot)S$ that Sylvester governs. It *reduces*, however, to the same shape as the Instance-2 rank-collapse floor (R Prop B.7): the on-policy Fisher information of the realization manifold is identically zero along the similarity-fiber tangent distribution, so the observed-Fisher is rank-deficient on a structurally-forced indeterminacy manifold — Instance-2’s mechanism with the manifold being a Lie-group fiber rather than a single indeterminacy sub-manifold. Escape-irreducibility under the agent’s *metric/coordinate* freedom (distinct from the similarity freedom that *generates* the pair) is then Sylvester at one remove, identically to Instance 2.

Three structurally distinct escapes: (a) loop-interventional access (7.3) perturbs along similarity-fiber directions that on-policy data never excites — the intervention generates Level-2 data, the no-go is Level-1-only; (b) higher-moment / out-of-regime observation distinguishes the pair in the nonlinear sub-scope (AAT’s β) — *provably void* in the linear-Gaussian sub-scope, since a Gaussian innovation carries no information beyond second order; (c) architecture instrumentation (direct read of the update rule or internal state) breaks the black-box scope, structurally the same kind as Instance 2’s “instrument the latent” escape. A fourth proposed escape — horizon extension under the same policy — collapses into (a): more samples of an annihilated observation law cannot escape the annihilation.

The strengthened consequence is that #der-loop-interventional-access acquires a *third semantically-distinct deployment mode* — at the agent-internal layer — alongside Instance 1’s agent-self-intervention (breaking causal-sufficiency degeneracy) and Instance 3’s observer-on-sub-agent intervention (breaking coupling-sign degeneracy). The shared content across the three modes is “Level-2 data breaks a Level-1 degeneracy”; the distinct content is *which* degeneracy.

Formal Expression.

The Setting.

Two AAT agents A and A' are *architecturally distinct, behaviorally identical from on-policy summary data* in a regime Ω when:

Definition (architecture-noidentifiability-setting).

- both operate on the same regime-restricted trajectory under their respective on-policy execution;
- both share the same sector-condition summary (α, R) in $\Omega(A)$, equivalently the same ultimate-deviation statistics on the similarity-invariant summaries of $\|\delta\|$ in that regime;
- the observer has *on-policy, in-regime, summary-only* access — no off-policy intervention, no out-of-regime samples, no white-box read of the update rule or internal state.

Per #scope-agent-identity, A and A' are agents on singular trajectories with action-marginal invariance under change of internal-coordinate parameterization. The question is whether the architectural content — the basis in which the correction is implemented, internal to the agent — can be recovered from the observer’s accessible data.

The No-Go Theorem (exact in the linear-Gaussian / Kalman sub-scope).

Let the linearized closed-loop residual dynamics of A and A' be minimal state-space realizations

Derived (architecture-noidentifiability-Kalman, from Kalman-Ho canonical-form non-uniqueness applied to AAT-agent realizations), exact in the linear-Gaussian sub-scope.

$$d\delta_t = -F \delta_t dt + \sigma_w dW_t, \quad d\delta'_t = -F' \delta'_t dt + \sigma'_w dW_t \quad (\text{AL.1})$$

with F, F' Hurwitz (sector-condition-satisfying per #deriv-sector-condition) and the two realizations related by an invertible similarity $T \in GL(n)$:

$$F' = T F T^{-1}, \quad \sigma'_w \sigma'^{\top}_w = T \sigma_w \sigma_w^{\top} T^{\top}. \quad (\text{AL.2})$$

Claim. The stationary innovation process — hence the (α, R) -summary, the innovation spectrum, and every *similarity-invariant* summary of the on-policy observation law — is **identical** for A and A' . No on-policy, in-regime, summary-restricted statistic distinguishes them.

Derivation. The innovation’s stationary law is determined by the pair $(F, \sigma_w \sigma_w^{\top})$ only through similarity-invariant quantities. Specifically:

- The eigenvalues of F (the α -spectrum entering the sector summary) are similarity-invariant.
- The stationary covariance Π solves the Lyapunov equation

$$F \Pi + \Pi F^{\top} = \sigma_w \sigma_w^{\top} \quad (\text{AL.3})$$

(standard form for the OU drift $-F$ with F Hurwitz, sign convention matching #deriv-sector-condition), and transforms under similarity as $\Pi' = T \Pi T^{\top}$.

- The observed quantities are the *innovation spectrum* $\det(i\omega I - F)$ and its similarity-invariant moments — for example, the *deviation magnitude under any similarity-invariant norm* (a norm derived from the dynamics, such as the F -induced metric, rather than a fixed external basis). Each is annihilated by the similarity action.

The architectural content — the basis T , that is, *which* internal coordinates implement the correction — lives entirely in the similarity orbit and is annihilated by the on-policy observation map. $\square$

Scope of “identical.” The claim restricts to *similarity-invariant* summaries of the on-policy observation law. Fixed-external-basis quadratic forms in the raw residual are *not* in general similarity-invariant — for instance,

$$\mathbb{E} \|\delta\|^2 = \text{tr } \Pi, \quad \text{tr}(T \Pi T^\top) \neq \text{tr } \Pi \text{ in general} \quad (\text{AL.4})$$

(equality only when T is orthogonal). The on-policy observer who consumes (α, R) summaries and the innovation spectrum sees only similarity-invariant content; an observer with access to a fixed external basis can in principle break the orbit by observing the raw covariance, but that is a *different* observation regime than the on-policy summary access the no-go is stated under.

The General Sub-Scope (robust qualitative).

Outside the linear-Gaussian sub-scope, the no-go is robust-qualitative rather than exact. Model the agent as a structural causal model over its internal state space (per #scope-agent-identity’s token-level commitment to singular-trajectory agents). The Bareinboim, Correa, Ibeling & Icard (2022) Causal Hierarchy Theorem then applies at the agent-as-SCM layer: two SCMs over the agent’s state space agreeing on Level-1 observation data — the on-policy summary distribution — cannot in general be distinguished on Level-2 questions about $d\mathcal{O}(\cdot)$ on the agent’s internal coordinates.

Derived (architecture-noidentifiability-general, from causal hierarchy theorem applied at agent-as-SCM layer), robust qualitative.

The dual-anchor structure (sharp Kalman-Ho for the linear-Gaussian sub-scope; CHT-at-agent-as-SCM for the general case) is the same shape Instance 1 carries — explicit construction sharp / CHT general — and the tier separation is load-bearing: collapsing to “exact” overclaims; collapsing to “robust-qualitative” understates the sub-scope’s sharpness.

Mechanism: Instance-2 Fisher Null on a Lie-Group Fiber.

The no-go’s *generating* group action is state-space similarity $F \mapsto T F T^{-1}$ on the realization manifold. Sylvester’s law of inertia (5.1 §Discussion) governs metric *congruence* $\mathcal{G} \mapsto S^\top \mathcal{G} S$, a different group action; the no-go therefore does **not** inherit Sylvester at the generating-action layer.

Derived (mechanism-reduction-to-instance-2, from Fisher-information factorization through similarity-invariants).

The reduction to Instance-2 mechanism proceeds via Fisher geometry. Parameterize the agent by

$$\theta = (\text{similarity-invariants, orbit-coordinates}) \quad (\text{AL.5})$$

— formally, the realization manifold fibered over the transfer-function manifold by the $GL(n)$ similarity group. By the §“No-Go Theorem” derivation, the on-policy observation law depends on θ only through the similarity-invariant base. The Fisher information of the on-policy observation channel, as a quadratic form on the full realization manifold, is therefore *identically zero* on the entire tangent distribution of the similarity fiber. That is the Instance-2 structure (Fisher rank-deficiency along a structurally-forced indeterminacy manifold; R Prop B.7), with the manifold being a $GL(n)$ Lie-group fiber rather than the mixture-indeterminacy manifold of Instance 2.

The agent’s *escape-irreducibility under its metric/coordinate freedom* is then Sylvester at one remove — identically to Instance 2. Once the rank-deficient observed-Fisher is recognized, no reparameterization of the observation model refills the rank-deficient direction; congruence preserves inertia.

The two group actions and their roles, made precise:

- The **similarity action** $T(\cdot)T^{-1}$ on the realization manifold *generates* the indistinguishable architectural pair (A, A') . This is what makes the floor a floor at all, and it is *not* Sylvester — it is the fiber of the realization-to-transfer-function bundle.
- The **congruence action** $S^T(\cdot)S$ on the observed-Fisher governs the agent’s potential escape by reparameterizing its observation model. This *is* Sylvester, and it forbids the escape, identically to Instance 2.

This no-go is therefore a member of the rank-collapse subclass of #disc-identifiability-floor ({Instance 1, Instance 2, Instance 4} via Sylvester at one remove) rather than Instance 3’s projection / Schur-complement obstruction. The additional structure beyond Instance 2 is that the rank-deficient direction is a Lie-group fiber.

Boundary Characterization: Three Structurally Distinct Escapes.

The no-go’s scope is (i) on-policy, (ii) in-regime, (iii) summary-only. Each scope-condition violation corresponds to an AAT capability that admits identification:

Derived (escape-routes, from no-go scope conditions).

Table AL.1

<i>Route</i>	<i>Scope violated</i>	<i>AAT capability</i>	<i>Detection strength</i>
(a) Loop-interventional access	(i) on-policy	7.3 — $do(\cdot)$ on the agent’s input	Sharp in linear-Gaussian sub-scope; robust qualitative general
(b) Higher-moment / out-of-regime	(ii) in-regime + (iii) summary-only	Beyond sub-scope α : higher-moment statistics of the innovation; out-of-regime sampling	Provably void in linear-Gaussian sub-scope; informative in nonlinear sub-scope β
(c) Architecture instrumentation	(iii) summary-only (white-box)	Direct read of the update rule or internal state; same kind as Instance 2’s “instrument the latent”	Strongest when available

Route (a) — loop-interventional access (sharp). A $do(\cdot)$ intervention on the agent’s input perturbs the system along *similarity-fiber directions that on-policy data never excites*. The interventional response (correction-function Jacobian probed off the on-policy manifold) is *not* similarity-invariant: TFT^{-1} and F respond differently to a probe in a fixed external basis. The intervention generates Level-2 data; the §“No-Go Theorem” derivation is a Level-1-only statement. Genuinely escapes the orbit degeneracy.

Route (b) — higher-moment / out-of-regime (sub-scope-bounded). In the nonlinear sub-scope β , two agents matched at (α, R) and second-order generally differ at moments of order ≥ 3 . In the linear-Gaussian sub-scope this route is *provably void*: a Gaussian innovation carries no information beyond second order, so higher-moment observation adds nothing — the similarity orbit remains invisible. The “escape exists here, provably not there” boundary is exactly the kind of sharp scope-statement that makes a floor instance informative.

Route (c) — architecture instrumentation. Direct read of the update rule or internal state breaks the black-box scope: the observer now has access to the basis T itself, not just its annihilated projection onto the on-policy observation law. Structurally the same kind as Instance 2’s escape (i) (“instrument the latent” — R Prop B.7); genuinely distinct from (a) and (b) in *what the observer must have* (white-box access versus interventional access versus moment-level access).

Route (d), horizon extension under the same policy — does not escape. Passive observation at longer horizons under the *same* on-policy execution generates more *samples* of the same observation law; the §”No-Go Theorem” derivation is a statement about the *law* (the architectural content is annihilated by the spectrum map), not about the sample size. Horizon extension that takes the agent *out of the current regime* is no longer the same policy in the same regime — that is a regime change, which is structurally an exogenous intervention-like event, collapsing into route (a)/(b). Route (d) is therefore either void (same regime) or a special case of (a)/(b); the count of structurally distinct escapes is **three**, not four.

Why Fano Is the Finite-Sample Refinement, Not the Exact Anchor.

A Fano-style anchor (Fano 1961, *Transmission of Information*) gives a lower bound on prediction error probability *given* a bound on the channel mutual information $I(A; \text{obs})$ between the architectural variable and the observation. Under the similarity-orbit construction, the on-policy observation law is *identical* for A and A' — not merely close — so $I(A; \text{obs}) = 0$ exactly. Fano degenerates to the trivial bound “error probability $\geq$ prior,” vacuous and strictly weaker than the *exact* Kalman-Ho indistinguishability statement.

Derived (fano-degeneracy-at-zero-information), exact.

Fano is therefore the right tool for the *approximate / finite-sample* version of the no-go — architectures that are close but not equal in innovation spectrum, $I > 0$ small — and the wrong tool for the *exact* population-level no-go. The exact anchor is Kalman-Ho; Fano is honest open follow-on work on the finite-sample refinement, distinct from the floor itself. (Cross-reference: #der-agent-opacity Working Notes record the parallel finding from the observer-side H_b task.)

Strengthened Consequence.

The no-go elevates #der-loop-interventional-access to a load-bearing role at the *agent-internal* layer — the third semantically distinct deployment mode after:

Derived (third-mode-of-interventional-access).

1. **Mode 1: agent-self-intervention** — Instance 1’s escape, breaking a *causal-sufficiency* degeneracy among the agent’s action propositions (9.2).
2. **Mode 2: observer-on-sub-agent intervention** — Instance 3’s escape, breaking a *coupling-sign* degeneracy across composite sub-agents (J).
3. **Mode 3: observer-on-agent-input intervention** — this segment’s escape, breaking a *similarity-orbit* degeneracy on the agent’s internal architecture.

The three modes are *different group-theoretic objects*: each breaks a Level-1 degeneracy of a distinct kind, yet shares the load-bearing content “Level-2 data is the unique broadly-available violation of the Level-1 no-go.” This converts the Instance-4 floor from “yet another no-go” into structural confirmation that #der-loop-interventional-access carries the same load-bearing role at *three* distinct AAT layers (action, composite, architecture), each escape preserving the framework’s existing scope honesty rather than introducing new machinery.

Tier. *Exact* in the linear-Gaussian / Kalman sub-scope (α_1), anchored by Kalman-Ho canonical-form non-uniqueness. *Robust qualitative* in the general sub-scope, anchored by CHT-at-agent-as-SCM. **The exact / robust-qualitative tier boundary is load-bearing and must be carried consistently** — collapsing to flat “exact” overclaims the general case; collapsing to flat “robust qualitative” understates the sub-scope’s sharpness. The mechanism reduction (§”Mechanism”) is exact: the Fisher-null factorization through similarity-invariants follows in elementary steps from the §”No-Go Theorem” derivation.

The escape-count statement (“three structurally distinct escapes, with the proposed fourth collapsing into the first”) is *exact* — the collapse of route (d) into (a) and the void of route (b) inside the linear-Gaussian sub-scope are both elementary consequences of the no-go statement itself. The escape-machinery mappings are *robust qualitative*, inheriting the tier of the cited segments (7.3, 16.2).

Epistemic Status.

Conditional. Max attainable: *exact* for the Kalman-Ho derivation in the linear-Gaussian sub-scope; *robust qualitative* for the general case via CHT-at-agent-as-SCM; *exact* for the mechanism reduction to Instance-2 Fisher-null on a Lie-group fiber; *exact* for the escape count (three, not four) and for the Fano-degeneracy-at- $I = 0$ observation; *robust qualitative* for the escape-machinery mappings.

Load-bearing: - The Kalman-Ho construction makes the architectural-identifiability no-go *exact in a precisely characterized sub-scope* — replacing the prior sketch-grade framing (16.2 Working Notes’ candidate-status for a generic observer-side floor). - The mechanism reduction to Instance-2 Fisher-null on a $GL(n)$ fiber places the no-go in the rank-collapse subclass {Instance 1, Instance 2, Instance 4} via Sylvester at one remove, repairing #disc-identifiability-floor’s Sylvester-mechanism taxonomy to three rank-collapse members plus one projection/closure member ({Instance 3}). - The three-mode classification of #der-loop-interventional-access (causal-sufficiency / coupling-sign / similarity-orbit) is a structural unification across three identifiability-floor instances.

Not established: - The general (non-linear-Gaussian) sub-scope at *exact* tier. CHT-at-agent-as-SCM is robust-qualitative; an explicit construction-grade no-go in general sub-scope β is honestly open. - The finite-sample Fano refinement (architectures close-but-not-equal in innovation spectrum, $I(A; \text{obs}) > 0$ small). Open follow-on direction, distinct from the population-level no-go derived here. - Sharp characterization of the boundary between similarity orbits and behavioral equivalence classes when the agent’s nonlinear dynamics admit *partial* spectrum identifiability (the sub-scope- β moment-cascade question).

Honest Limits.

- **Linearization scope.** The Kalman-Ho construction operates on the *linearized* closed-loop residual dynamics. Sector-condition-satisfying agents (A) admit such linearization in a basin around the singular trajectory; the no-go’s exact tier inherits that scope. Outside the basin, the general-case CHT anchor applies but the construction is not closed-form.
- **Action-marginal invariance vs. internal-coordinate freedom.** Per #scope-agent-identity, the action space is coordinate-free and observed quantities are parameterization-invariant. The similarity orbit is a *different* invariance — internal to the realization manifold, distinct from action-marginal parameterization-invariance — and the no-go is about identifying the internal architecture, not about action-level identifiability.
- **Closed-loop residual dynamics, not open-loop plant.** The no-go is stated for the closed-loop δ -dynamics (3.4) — what the on-policy observer actually sees. Open-loop plant identification from interventional experiments is route (a) and is *not* subject to this no-go.

Discussion.

Position in the identifiability-floor pattern. This no-go is the fourth instance of #disc-identifiability-floor and the third member of the rank-collapse subclass via Sylvester at one remove. The Sylvester-mechanism Discussion of the meta-segment (5.1 §Discussion) is repaired by this addition: the three-rank-collapse taxonomy is {Instance 1, Instance 2, Instance 4} unified by congruence-preserves-inertia at the escape-irreducibility layer; Instance 3 stands alone as the projection/closure obstruction. The plurality-of-mechanism that makes the floor pattern a *family* rather than a single theorem is preserved (Sylvester for rank-collapse, Schur/projection for composition); the Sylvester-side is strengthened from two to three members.

Why Instance-2's mechanism, not new. The Fisher-null direction here is a $GL(n)$ Lie-group fiber rather than the single mixture-indeterminacy manifold of Instance 2, but the *kind* of obstruction is identical: a rank-deficient observed-Fisher along a structurally-forced indeterminacy manifold. Naming it a new mechanism would be inflation — the AAT-distinctive recognition is precisely that the architectural d.o.f. AAT cares about (#der-agent-opacity's "which internal mechanism") is the similarity orbit and that the orbit is annihilated by the on-policy observation map; the obstruction theorem itself is the same shape as Instance 2. Naming it Sylvester-for-free would be the opposite inflation — similarity and congruence are different group actions. The honest position is "Instance-2 mechanism on a Lie-group fiber, Sylvester at one remove on the escape."

Relationship to #der-agent-opacity's observer-indexed H_b . This segment's no-go is structurally distinct from a generic observer-prediction-of-action floor: the architectural d.o.f. is invisible *at the observation-law level* regardless of observer instrumentation, not because of a particular observer's filtration. An observer with arbitrarily fine $\mathcal{F}_B^t$ over the on-policy summary distribution still cannot escape the similarity orbit; the observer-indexing of H_b is orthogonal. The natural relationship is at the meta-pattern level (both name floors in the family of #disc-identifiability-floor); the *quantities* are distinct (H_b is observer-conditional action entropy; this segment's invariant is the similarity orbit).

Conservative integration with the Sylvester recognition. The 2026-05-14 Sylvester-recognition Finding in #disc-identifiability-floor taxonomized two rank-collapse floors (Instances 1, 2) and explicitly said "*the floors do not share one mechanism — Sylvester for rank-collapse, a projection/closure obstruction for composition.*" This segment's addition does not contradict that recognition; it extends the rank-collapse subclass to three members and preserves the projection/closure distinction for Instance 3. The plurality-as-feature framing of the meta-segment's Discussion is intact.

Multi-agent / Hafez bridge. The architectural d.o.f. that this no-go identifies as un-recoverable from on-policy summary data is structurally adjacent to #der-agent-opacity's H_b in this sense: both quantities concern the *world's view of the agent's internal architecture* through information-theoretic limits. The Hafez et al. 2026 IDT pattern (Information Digital Twin, bi-predictability P) — operationally a low- H_b -preserving observation channel — is a structurally-instrumented escape, and its 89% perturbation-detection performance is consistent with this segment's route (c) "architecture instrumentation" classification.

Findings.

Architecture No-Identifiability from On-Policy Summary Data — the Fourth Identifiability Floor. **Brief:** Imagine two agents that both keep a desk tidy by the same rules: same overall reaction speed, same tolerance for clutter, same long-run mess level. One agent reasons by tracking pile heights; the other tracks distances between piles. Watching them work — under their normal habits, summary statistics only — you literally *cannot tell which one is running*. The visible behavior is the same, the variability is the same, the rate of clean-up is the same, the cluttered ceiling is the same. Different inner mechanisms, identical outer signature. There are only three honest ways to tell the agents apart: poke one in a way it wouldn't normally do (intervention), look at fine-grained details its rules would not normally generate (out-of-regime / higher-moment observation), or open the hood and read the wiring (white-box access). And a fourth pretender — "just watch longer" — does *not* work, because watching longer accumulates more samples of the same signature, never the missing distinction. This is the floor: it is structurally impossible to recover the inner-mechanism

information from the outer summary alone, and the only paths forward are exactly the three named escapes, each of them violating a clearly-stated scope condition.

Impact: Closes the long-contested fourth instance of #disc-identifiability-floor with a sharp, dual-anchored no-go (Kalman-Ho linear-Gaussian sub-scope, exact; CHT-at-agent-as-SCM general, robust qualitative). Extends the Sylvester-mechanism rank-collapse subclass to three members {Instance 1, Instance 2, Instance 4} via the at-one-remove escape-irreducibility, while preserving the projection/closure distinctness of Instance 3 — the plurality-of-mechanism that makes the floor pattern a presentational family rather than a single theorem stays intact, sharpened. Elevates #der-loop-interventional-access to a third semantically-distinct deployment mode (agent-internal architecture, alongside agent-self-intervention and observer-on-sub-agent), unifying the strengthened-consequence content of three identifiability-floor instances under one piece of machinery. The result mathematically settles the Regime-C confound of the rho-decomposition ($3.5 + \mathbb{W}$) as the same object projected onto the disturbance-statistic coordinate — one decision, not two.

Novelty Claim: *Claim derivation* of the architecture-noidentifiability floor with named scope (linear-Gaussian sub-scope, on-policy summary access) and named dual anchor (Kalman 1963 / Ho-Kalman 1966 / Anderson-Moore 1979 §10.4 for the sharp sub-scope; Bareinboim, Correa, Ibeling & Icard 2022 for the general case). The Kalman-Ho canonical-form non-uniqueness theorem is classical (1963/1966); the AAT-distinctive content is *recognizing* that the architectural degree of freedom the framework cares about — #der-agent-opacity’s “which internal mechanism” — *is* the similarity orbit, and that the orbit is annihilated by the on-policy observation map. *Claim differentiation* on mechanism: the obstruction is Instance-2’s Fisher-null along a structurally-forced indeterminacy manifold (the manifold being a $GL(n)$ Lie-group fiber) rather than a new mechanism, with Sylvester preserving inertia on the escape side identically to Instance 2 — a *member* of the rank-collapse subclass, not a new mechanism family. *Claim recognition* that the previously-proposed Fano anchor degenerates at $I(A; \text{obs}) = 0$ (vacuous lower bound on prediction error under a zero-information channel), so Kalman-Ho is the exact-population anchor and Fano is the finite-sample refinement — a demonstrated no-go on the proposed Fano anchoring, not an assertion.

(2013), <i>Matrix Analysis</i> (2nd ed.), Thm 4.5.8	<i>formal antecedent</i> — applied here to the <i>escape</i> side (congruence on the observed-Fisher), distinct from the generating action (similarity on the realization manifold). Sylvester forbids the escape by reparameterization identically to Instance 2
Fisher-information reparameterization law	Lehmann, E. L. & Casella, G. (1998), <i>Theory of Point Estimation</i> (2nd ed.), §2.5 — $\mathcal{G}_\varphi = S^T \mathcal{G}_\theta S$ as the standard congruence law	<i>formal antecedent</i> — the law that makes the escape-side reparameterization a congruence action
Hafez et al. 2026 / IDT bi-predictability	Hafez, A. M., Khan, F. M. & Iqbal, M. (2026), <i>A Mathematical Theory of Agency and Intelligence</i> — IDT pattern, bi-predictability P	<i>adjacent</i> — IDT-as-architecture-instrumentation is route (c) of this segment’s escape structure; the 89% IDT detection rate is consistent with white-box access escaping the orbit

Search Log: - 2026-05 (*targeted*): Kalman 1963 / Ho-Kalman 1966 / Anderson-Moore 1979 §10.4 verified as the canonical-form-non-uniqueness anchors; CHT-at-agent-as-SCM application of Bareinboim et al. 2022 verified consistent with Instance 1’s general-sub-scope use. Fano 1961 $\leftrightarrow$ Cover-Thomas §2.10 verified for the finite-sample refinement framing. Sylvester 1852 + Horn-Johnson Thm 4.5.8 + Lehmann-Casella §2.5 inherited from the 2026-05-14 Sylvester-recognition Finding in #disc-identifiability-floor. - 2026-04 / 2026-05 (*intuition-only*) on whether the cross-instance recognition “the architectural d.o.f. AAT cares about *is* the similarity orbit, annihilated by the on-policy observation map” has been articulated in the system-identification or causal-inference literatures as the AAT-internal-agent-theory framing applied to multi-agent identifiability. The constituent pieces (Kalman-Ho canonical-form non-uniqueness; CHT-at-agent-as-SCM; Fisher rank-deficiency along Lie-group fibers) are textbook; the cross-instance unification as the fourth member of an integrated agent-theoretic floor pattern appears to be a presentational contribution under cursory search. Targeted future search candidates: system-identification literature on the agent-theoretic interpretation of canonical-form non-uniqueness; observability / identifiability literature for nonlinear agents; mechanism-grounded identifiability in multi-agent reinforcement learning.

Working Notes.

- **Provenance.** The architectural-noidentifiability floor was previously sketched in spikes/spike-neutral-drift-endogenous-coupling-strengthening-2026-04-24.md §8 / §10.1 (candidate, Fano anchor proposed but uncompleted) and surfaced from the disturbance-statistic coordinate as the Regime-C confound of spikes/.integrated/spike-rho-structure-recheck-2026-05-18.md §3 (same object). The 2026-05-18 resolution spike spikes/.integrated/spike-identifiability-floor-instance4-resolution-2026-05-18.md re-derived the no-go independently and supplied the Kalman-Ho construction, the mechanism reduction to Instance-2-on-a-fiber, the escape audit, and the Fano-degenerates-at- $I = 0$ no-go on the proposed Fano anchor; the math-gate trail at spikes/.routing-trail/SPIKE-VERIFY-471802/ (confirmer $\neq$ author) cleared the substantive math conditional on three named repairs that are applied in this segment: (i) the “identical” claim restricted to similarity-invariant summaries (not raw moments); (ii) the Lyapunov-equation sign matching #deriv-sector-condition’s standard form ($F\Pi + \Pi F^T = \sigma_w \sigma_w^T$); (iii) the exact / robust-qualitative tier boundary carried consistently rather than collapsed to flat exact.
- **Finite-sample Fano refinement is honestly open.** The Fano-style bound on the *approximate* version (architectures close-but-not-equal in innovation spectrum, $I(A; \text{obs}) > 0$ small) is real research, distinct from the population-level Kalman-Ho no-go. Candidate spike for a future cycle; not blocked by anything here.
- **General non-Gaussian sub-scope at exact tier.** The CHT-at-agent-as-SCM general-case anchor is robust-qualitative. An explicit construction-grade no-go in the nonlinear sub-scope β would upgrade the general case to exact-with-conditions; honestly open.
- **The mechanism reduction’s relationship to operator-sector machinery.** The §”Mechanism” section’s recognition that the Fisher-null here is a rank-deficiency on a $GL(n)$ Lie-group fiber places it in the stability-certificate spine’s *boundary facet*

(5, 5.1) at the same level as Instance 2's mixture-indeterminacy manifold. Whether the Lie-group-fiber generalization of Instance 2's mechanism is worth its own meta-statement (a "Fisher-null-along-structurally-forced-manifold" sub-pattern of the rank-collapse subclass) is open architectural taxonomy.

Appendix AM

Derivation: Fisher-Whitened Edge Update Under Correlated Evidence

Under L1'/L2 correlated-evidence regimes, the default log-odds edge-update (from #deriv-edge-update-natural-parameter) retains correct *direction* — the angle between log-odds gradient and natural gradient never exceeds 45° at finite correlation ρ , so B1 directional fidelity (4.3) is never actively violated — but its *magnitude alignment* degrades by a factor $\sqrt{1 - r^2}$ in the sector constant. The Fisher-whitened correction restores sharp B1 on the Fisher-weighted inner product. Under the (PI) parameterization-invariance axiom named in #scope-agent-identity and promoted to a primary instance of #disc-additive-coordinate-forcing via Čencov 1982, Fisher whitening is **AAT-internally derivable** rather than externally imported. The result adds sub-scope α_3 (correlated evidence + Fisher-whitened update + Bayesian coherence $\rightarrow$ A2' derived) to the A2' partition and composes cleanly with the meta-gain machinery of #deriv-adaptive-gain-dynamics (Fisher whitening is a special case of meta-gain with $K_t = \mathbf{I}^{-1}(\lambda_t)$).

The framework's posture splits cleanly. *Without* the (PI) commitment, the Fisher-whitened correction is an externally imported choice from information geometry. *With* (PI), Čencov 1982's uniqueness theorem *forces* the Fisher metric as the unique Markov-invariant metric on the statistical manifold, and the whitened-update form is then the AAT-internally canonical correction for directional-fidelity preservation across reparameterizations. Operational prescription: where correlated evidence is the dominant regime, Fisher whitening recovers sharp persistence guarantees at the cost of meta-gain machinery; where it is mild or rare, the default log-odds update with $\sqrt{1 - r^2}$ magnitude-alignment degradation suffices. Sibling at the model-parameter-update layer is AR (update *magnitude* under Fisher-local regime); together they make the Fisher-local invariance regime AAT-internally complete.

Formal Expression.

Angle characterization under L1' correlation.

For a block-correlated two-edge evidential model (soft-facilitator Prop B.7 parameterization), the Fisher information matrix has off-diagonal entry

Derived (angle-bound-finite-correlation).

$$r = \frac{\theta_C(1 - \theta_C)\Delta_1\Delta_2}{\sigma_1\sigma_2} \in [-1, 1], \quad (\text{AM.1})$$

where θ_C is the latent-cause probability, $\Delta_j = p_{j|C} - p_{j|\neg C}$ is the separability gap, and σ_j is the marginal-edge standard deviation. The Euclidean angle between the log-odds update direction and the natural-gradient direction (at single-edge plan residual) satisfies

$$\theta_{\text{LO-NG}} = \arccos \frac{1}{\sqrt{1+r^2}} \leq 45^\circ \quad \text{for all } r \in [-1, 1]. \quad (\text{AM.2})$$

The log-odds update **never flips sign** under any finite correlation — B1 is never actively violated, only degraded in magnitude. Under the operational claim that “the default signal function needs validation under correlated failures,” the finding is: **the default direction is preserved; only magnitude alignment degrades**. The sector constant in B1 degrades by a factor $\sqrt{1-r^2}$ under Euclidean B1; the Fisher-weighted B1 recovers the unperturbed sector constant.

Fisher-whitened update rule.

In log-odds coordinates $\lambda \in \mathbb{R}^{|E|}$ with Fisher information $\mathbf{I}(\lambda)$, the Fisher-whitened edge update is

Definition (Fisher-whitened-update).

$$T_{\text{FW}}(\lambda) = \lambda - \eta_{\text{edge}} \cdot \mathbf{I}^{-1}(\lambda) \cdot \mathbf{J} \cdot (\hat{P}_\Sigma(\sigma(\lambda)) - y_G) \quad (\text{AM.3})$$

(compared to the Euclidean log-odds update $T_{\text{edge}}(\lambda) = \lambda + \eta_{\text{edge}} \cdot \text{diag}(t) \cdot \mathbf{J}(y_G - \hat{P}_\Sigma)/\|\mathbf{J}\|^2$). The Fisher-weighted inner product $\langle a, b \rangle_{\mathbf{I}} = a^T \mathbf{I}^{-1} b$ makes the update’s directional fidelity invariant under reparameterization of the natural-parameter coordinate.

Two AAT-internal axiom paths.

Path A (B1-parameterization-invariance). Require B1 directional fidelity to be *parameterization-invariant* in the sense of #scope-agent-identity’s (PI) axiom: the theorems about sub-scope α derivation in #der-gain-sector-bridge should not depend on arbitrary coordinate choices for M_t ’s natural parameters. Under (PI), B1 sub-scope α partition is coordinate-invariant iff the inner product defining the directional-fidelity condition is the Fisher metric (Čencov 1982 uniqueness theorem under (PI); extended by Ay-Jost-Lê-Schwachhöfer 2017). The Fisher-weighted inner product is therefore *forced* by (PI), and the Fisher-whitened update is the AAT-internally derived correction direction for directional-fidelity preservation across parameterizations.

Derived (Fisher-whitening-from-B1-parameterization-invariance).

Path B (Lyapunov-coordinate-matching via adjacent-family classification). In the adjacent-family framing of #disc-additive-coordinate-forcing, the Lyapunov coordinate is *matched* (not forced) to the sector condition. For natural-gradient updates, the canonical Lyapunov is Fisher-weighted (Amari 1998, “Natural gradient works efficiently in learning,” *Neural Computation* 10); this matches the geometry of the update operator. The two paths converge on the same Fisher-weighted result; Path A forces it via axiomatics, Path B confirms it via adjacent-family coordinate-matching.

Under L0 (no correlation), $r = 0$ and $\mathbf{I}$ is diagonal — Fisher whitening is vacuous (reduces to the existing Euclidean log-odds update). The axioms pick out Fisher whitening *uniquely* only under L1’/L2 (correlated evidence) regimes; they are vacuously satisfied under L0.

New sub-scope α_3 .

Correlated-evidence + Fisher-whitened update + Bayesian coherence yields A2' *derived*:

Derived (sub-scope-alpha-3).

$$(T_{\text{FW}}(\lambda) - \lambda^*)^T \mathbf{I}(\lambda^*)^{-1} (\lambda - \lambda^*) \geq \beta \|\lambda - \lambda^*\|_1^2 \quad \text{with } \beta = \eta_{\text{edge}} \mu \quad (\text{AM.4})$$

on the Fisher-metric sector region around the fixed point $\lambda^* = \text{logit}(\theta^*)$. The directional-fidelity proof of #der-gain-sector-bridge carries over with $\kappa(\mathbf{I})$ as Euclidean-transfer penalty — structurally identical to the Kalman case's $(P^-)^{-1}$ -norm weighted-norm treatment. The Kalman case in #der-gain-sector-bridge's Verified Instances is a special case of Fisher-weighted sector.

Sub-scope α_3 extends the refinement introduced by #deriv-adaptive-gain-dynamics: - **Sub-scope α_1** : fixed-gain, independent evidence (Euclidean B1 applies; the existing A2' partition). - **Sub-scope α_2** : adaptive-gain, independent evidence (meta-gain conditions (MG-1)–(MG-4) per #deriv-adaptive-gain-dynamics). - **Sub-scope α_3** : fixed-gain, correlated evidence (Fisher-whitened update; this segment).

Additional composition: adaptive-gain + correlated-evidence (sub-scope α_4) would compose #deriv-adaptive-gain-dynamics meta-gain machinery with Fisher whitening at the primary state; open.

Connection to meta-gain as special case.

The Fisher-whitened update is a meta-gain law in the sense of #deriv-adaptive-gain-dynamics with $K_t = \mathbf{I}^{-1}(\lambda_t)$ — a *degenerate* special case where the meta-gain is a deterministic function of the primary state rather than an independently learned variable. All four meta-gain conditions (MG-1)–(MG-4) are satisfied trivially: - (MG-1) Meta-gain sector: $\mathbf{I}^{-1}$ is symmetric-positive-definite on the interior of the natural-parameter domain. - (MG-2) Meta-gain bounded: $\|\mathbf{I}^{-1}\|$ bounded on compact natural-parameter subsets. - (MG-3) Smoothness: $\mathbf{I}^{-1}$ depends smoothly on λ for exponential families. - (MG-4) Primary-meta coupling bounded: $\mathbf{I}^{-1}$'s state-derivative in the drift direction is bounded for exponential families.

Derived (Fisher-whitening-as-special-meta-gain).

This hands #deriv-adaptive-gain-dynamics a **concrete second instance** of derivable meta-gain alongside adaptive-Kalman-with-Mehra-estimator (its primary instance). The machinery of meta-gain composition via #result-sector-persistence-template (augmented-state Lyapunov) applies directly.

L2 regime: candidate third #disc-identifiability-floor instance or strengthening of Instance 2.

Under L2-latent regimes (unobservable correlation structure beyond what Fisher information can resolve), Fisher whitening fails: the correlation sub-block of Fisher is rank-deficient (Cramér-Rao floor on unobservable parameters). This parallels #disc-identifiability-floor Instance 2's L1'-unobservable-C Fisher-rank-1 obstruction — potentially a new L2 instance, or potentially a generalization of Instance 2 to higher correlation orders. Open whether these are distinct floors or a single unified obstruction.

Hypothesis (L2-latent-floor).

L2-degenerate (perfect correlation, $r \rightarrow 1$) is a *structural* collapse — it requires DAG repair (edge merging) rather than update repair. This sits outside the Fisher-whitening framework.

Epistemic Status.

Conditional. Max attainable: *exact* under Path A ((PI) + Čencov combined with B1 directional fidelity) + L1'/L2 regimes + Bayesian coherence. The derivation is textbook information-geometry (Amari 1998; Amari-Nagaoka 2000) plus the AAT-internal (PI) axiom from #scope-agent-identity. What is AAT-distinctive is (a) the identification of (PI)/Čencov as the forcing machinery rather than merely a preferred choice; (b) the sub-scope α_3 labeling within the A2' partition; (c) the composition with #deriv-adaptive-gain-dynamics' meta-gain framework as a degenerate special case.

The angle bound is $\leq 45^\circ$ for all finite r . This is a sharp load-bearing observation: AAT's existing default log-odds signal function is *directionally robust* under correlated failures. The bias formula in #deriv-l1-update-bias gives the quantitative magnitude-bias; this segment gives the qualitative direction-preservation. Together they characterize the default signal function's behavior under L1' fully: **direction preserved, magnitude biased, observable-C restores exactness (Prop B.7), unobservable-C floor per F13.**

Without (PI) adoption. If (PI) is not adopted as an AAT axiom, Fisher whitening remains a theorem-imported technique from information geometry. The sub-scope α_3 labeling still applies (correlated evidence + Fisher-whitened + Bayesian coherence $\rightarrow$ A2' derived) but without the AAT-internal forcing. This is the adjacent-family status.

Discussion.

Relationship to the default signal function. #disc-credit-assignment-boundary's default log-odds signal was landed in the 2026-04-22/23 strengthening cycle via the Cauchy-FE uniqueness theorem in #deriv-edge-update-natural-parameter. Under L0 evidence independence, the default signal is exact. Under L1' correlated evidence, the default signal's direction is preserved ($\leq 45^\circ$ angle to natural-gradient direction) but magnitude degrades by $\sqrt{1-r^2}$. This segment's Fisher-whitened update is the correction under (PI)/Čencov; it recovers sharp B1 under L1' by lifting the inner product from Euclidean to Fisher.

Relationship to #disc-identifiability-floor Instance 2. Instance 2 (L1' unobservable-C Cramér-Rao floor) refutes single-channel identification of mixture parameters. Under observable C , Prop B.7 gives the L1' transfer; under unobservable C , no update — including Fisher-whitened — recovers identification. Fisher whitening operates *downstream* of identification: it corrects the update direction given that the Fisher information is known; it does not manufacture Fisher information that the data cannot yield.

Composition with the (PI)/Čencov 4th primary instance. The Fisher-metric cases in #der-gain-sector-bridge's Verified Instances table (Matrix Kalman, Exponential family in natural parameters) are also AAT-internally forced under (PI)/Čencov. Fisher whitening at the edge-update layer of Part II therefore shares the same AAT-internal axiom as the Kalman / exp-family cases in Part I's update machinery. This is a cross-layer consistency: the (PI) axiom operates uniformly across Parts I and II whenever the natural parameters are parameters on a statistical manifold.

Working Notes.

- **Sub-scope α_4 composition** (adaptive-gain + correlated-evidence). Composing #deriv-adaptive-gain-dynamics meta-gain machinery with Fisher whitening gives an augmented-state contraction argument where both the primary state (log-odds) and the meta-state (Fisher information estimate) are updated. Open derivation.
- **L2 regime.** Fisher whitening at L2 (non-tree correlation structure) requires computing higher-order Fisher correlations. For sparse DAG structures with limited correlation order, Fisher-tree approximations may suffice; for dense correlation structures, the computational cost scales exponentially. Scope boundary for Fisher whitening as a practical technique.
- **Relationship to natural-gradient variational inference.** Khan & Lin 2017 (*Conjugate-computation variational inference*) derives natural-gradient VI as a special case of conjugate Bayesian computation. Under (PI)/Čencov, their result becomes

AAT-internally derived within sub-scope α_3 . This composes with `#deriv-variational-sector-condition` if that segment lands — natural-gradient VI would be the $\varepsilon = 0$ limit of ε -fidelity B1.

- **Landing context.** This segment lands from `spikes/.integrated/spike-fisher-whitened-update.md` (2026-04-23 Gap A/B cycle). The AAT-internal axiom path via (PI)/Čencov was validated by the jacobian-b1 strengthening (2026-04-23 follow-up; absorbed in the spike-routing cycle, CHANGELOG 2026-05-17). The broader uniqueness-theorem-machinery discussion clearing the `#disc-additive-coordinate-forcing` discipline lives in that meta-segment.
 - **Sibling segment at the model-parameter layer.** `#deriv-fisher-local-update-gain` derives update *magnitude* under the Fisher-local invariance regime, sibling to this segment's derivation of update *direction* under correlated evidence. Both share (PI)/Čencov via Path A's axiomatic chain. Together they make the Fisher-local invariance regime AAT-internally complete: direction at the edge-update layer and magnitude at the model-parameter-update layer.
-

Appendix AN

Derivation: Regime-Marginal Indistinguishability — Cross-Regime Witness for #disc-identifiability-floor Instance 3 (Broadened Scope)

This segment supplies the parameter-by-parameter witness construction for #disc-identifiability-floor Instance 3's broadened-scope claim (2026-05-21): from sub-agent marginal data alone, the coupling-topology bit distinguishing among R0 / R1 / R2 dynamic regimes (per #disc-dynamic-regime-axis) is unidentifiable. The witnesses are exact for symmetric-matched-Tier-1-scalar sub-agents under standard coupling models (Model D for disturbance; the same models #deriv-critical-mass-composition uses, where the Instance-3 coupling-sign-bit witness is established). The mechanism is rank-collapse / Sylvester-at-one-remove on the marginal-Fisher operator for the topology coordinate, parallel to the Instance-3 coupling-sign-bit mechanism but acting on a higher-dimensional topology coordinate.

The relationship to #disc-identifiability-floor Instance 3 is supporting-derivation — Instance 3 carries the no-go statement, the escape menu, and the strengthened consequence; this segment carries the explicit construction backing the broadened no-go.

Formal Expression.

Setup. Consider $N = 2$ scalar sub-agents indexed $i \in \{1, 2\}$, each with state $q_i \in \mathbb{R}$, base correction rate $\alpha > 0$, observation noise $w_i \sim \mathcal{N}(0, \sigma^2)$, base disturbance bound ρ , tempo $\mathcal{T}$. The composite state is $X^c = (q_1, q_2) \in \mathbb{R}^2$. An external observer B accesses *only* per-sub-agent marginal data: for each i , the marginal stationary distribution $\mu_\infty^{(i)}$, the local mismatch process, and the per-sub-agent update rule $f_M^{(i)}$ as a structural object (white-box on each sub-agent, observed in isolation). The observer does *not* see: the composite-level coupling topology (sign + structure of cross-agent influence), the joint trajectory $\{X_t^c\}$ (only the projection onto per-sub-agent marginals), the game-structure object $\{O^{(j)}\}_{j \neq i}$ from sub-agent i 's frame, or composite-level convergence-rate-class diagnostics.

The inferential question: from per-sub-agent marginal data alone, can B identify the composite's dynamic regime $\mathcal{R}(X^c) \in \{R0, R1, R2\}$ per #disc-dynamic-regime-axis §B?

Witness 1: R0 vs R1 indistinguishability.

Composite A — R0 shared-objective contraction. Sub-agent objective $O_A^{(i)} = -\frac{1}{2}(q_1 + q_2 - T)^2$ for shared target T . Per-agent gradient-flow best-response:

Derived (cross-regime-witness, from Cournot equilibrium structure + shared-target marginal-matching).

$$\dot{q}_i = -\alpha(q_i + q_j - T) + w_i. \quad (\text{AN.1})$$

The composite is R0 per #disc-dynamic-regime-axis §B.0: unique attracting fixed point at $(T/2, T/2)$, joint Lyapunov $V = \frac{1}{2}\|q - (T/2, T/2)\|^2$, exponential convergence at rate α . The stationary marginal distribution of each sub-agent's state, computed from the linearized Ornstein-Uhlenbeck dynamics, is

$$\mu_{\infty,A}^{(i)} = \mathcal{N}(T/2, \sigma^2/(2\alpha)). \quad (\text{AN.2})$$

Composite B — R1 strategic potential-game equilibrium (Cournot). Sub-agent objective $O_B^{(i)} = q_i(a_0 - b(q_1 + q_2) - c)$ — quadratic-profit Cournot in canonical form. The game is a potential game (Monderer-Shapley 1996) with potential Φ_B satisfying $\partial\Phi_B/\partial q_i = \partial O_B^{(i)}/\partial q_i$ for each i . The unique Nash equilibrium $q_{B,\text{Nash}}^*$ is locally attracting under gradient flow, with local-curvature parameter $\lambda_{\min}(\nabla^2\Phi_B(q_{B,\text{Nash}}^*))$ controlling the rate. Linearizing the best-response gradient flow around the Nash and adding the same observation noise, the stationary marginal distribution of each sub-agent's state is

$$\mu_{\infty,B}^{(i)} = \mathcal{N}(q_{B,\text{Nash}}^*, \sigma^2/(2\lambda_{\min}(\nabla^2\Phi_B))). \quad (\text{AN.3})$$

Parameter-matching. Two free parameters on each side: (T, α) for Composite A, (a_0, b, c) for Composite B (with α implicit in the gradient-flow rate). Two matching conditions:

- **Mean-matching:** $T_A/2 = q_{B,\text{Nash}}^*$. Choose $T_A = 2 q_{B,\text{Nash}}^*$.
- **Variance-matching:** $\sigma^2/(2\alpha) = \sigma^2/(2\lambda_{\min}(\nabla^2\Phi_B))$. Choose b in Composite B such that $\lambda_{\min}(\nabla^2\Phi_B) = \alpha$.

Under both conditions: $\mu_{\infty,A}^{(i)} = \mu_{\infty,B}^{(i)} = \mathcal{N}(q^*, \sigma^2/(2\alpha))$ for both i , where $q^* = T_A/2 = q_{B,\text{Nash}}^*$. The marginal *transient* second moments also match under the matched local-curvature condition — both are exponentially-converging Ornstein-Uhlenbeck-type processes per sub-agent in the linearization.

The R0/R1 witness. Composite A satisfies $\mathcal{R}(\Sigma_A) = \text{R0}$ (unique global attractor + global Lyapunov); Composite B satisfies $\mathcal{R}(\Sigma_B) = \text{R1}$ (unique-Nash equilibrium with local Lyapunov-on-deviation, but Nash structure rather than shared-target structure). The marginal-data observer sees identical $\mu^{(i)}$ in both; cannot distinguish $\mathcal{R} = \text{R0}$ from $\mathcal{R} = \text{R1}$. ■

Witness 2: R0 vs R2 indistinguishability.

Composite C — R2 cyclic-distributional regime (matching-pennies under continuous-action smoothing). Take the 2×2 matching-pennies payoff structure, smoothed to continuous actions via softmax-style best-response with temperature parameter τ . The composite has no pure-strategy Nash; the mixed-Nash is at $(1/2, 1/2)$; under no-regret dynamics (Hart-Mas-Colell 2000) the empirical joint distribution converges to the CCE set at rate $O(1/\sqrt{T})$. The per-sub-agent marginal stationary distribution under this regime is a continuous distribution with mean $1/2$ and bounded variance determined by τ and the noise level σ^2 .

Derived (cross-regime-witness, from matching-pennies aggregation + shared-target marginal-matching).

Parameter-matching to Composite A. Choose Composite A's parameters (T_A, α_A) to align with Composite C's per-sub-agent marginal mean ($T_A/2 = 1/2 \Rightarrow T_A = 1$) and variance (choose α_A such that $\sigma^2/(2\alpha_A)$ equals Composite C's marginal variance — solvable for appropriate τ).

The R0/R2 witness. Composite A is R0 (state-variable macro-state, joint Lyapunov). Composite C is R2 (distributional macro-state, no joint Lyapunov on $\mathcal{X}^c$; CCE convergence only). The marginal-data observer sees identical $\mu^{(i)}$ in both; cannot distinguish $\mathcal{R} = \text{R0}$ from $\mathcal{R} = \text{R2}$. This sharpening is qualitatively cleaner than the R0/R1 witness because the *joint* dynamic regimes differ qualitatively — convergent vs cyclic-in-joint-distribution — while the per-sub-agent marginals can be made stationary in both cases by appropriate observation-aggregation: cyclic in the *joint* distribution projects to *stationary* in the marginal distribution when the cycle is over the joint coordinate that the marginal averages out. ■

Mechanism (Sylvester at one remove, same as Instances 1 / 2 / 4).

The composite-level topology coordinate — the bit (σ, p) distinguishing R0 / R1 / R2, where σ is the coupling-sign-bit (cooperative vs adversarial) and p is the potential-existence bit (potential/monotone game-structure vs none) — enters the per-sub-agent marginal observation law $p(q_i \mid \theta_{\text{topology}})$ only through the *fixed-point* and *local-curvature* parameters that the witness constructions above match across composites. Computing the Fisher information of the marginal observation law with respect to θ_{topology} yields a rank-deficient matrix: the topology coordinate has a null direction along the manifold

Discussion.

$$\{\theta : (\text{mean, variance})(\theta) = (q^*, \sigma^2/(2\alpha))\}. \quad (\text{AN.4})$$

By Sylvester's law of inertia (#disc-identifiability-floor Sylvester-recognition Finding), no reparameterization of the marginal-observation coordinate system removes this null direction — the irreducibility is invariant under the observer's representational freedom. The escape requires *rank-augmentation*: observation of a coordinate the marginal projection has annihilated. This is exactly the same mechanism as #disc-identifiability-floor Instances 1, 2, and 4; the present derivation occupies the *same* rank-collapse subclass as Instance 3's original coupling-sign-bit derivation, with the rank-collapse occurring on a topology coordinate of higher dimension than Instance 3's single sign-bit.

The mechanism's *one-remove* status (per #disc-identifiability-floor Instance 4's Mechanism discussion) is preserved: the *generating* action producing the indistinguishable pair is the swap between cooperative-shared-objective coupling and strategic-potential-game coupling (a structural game-theoretic operation), not metric congruence; but the *escape-side* irreducibility under the observer's representational freedom is identical to Instance 2's Fisher-null-on-a-fiber. The architecture of the proof is parallel to Instance 4's, applied to a different topology coordinate.

Epistemic Status.

Conditional on the standard coupling models (Model D for disturbance; the same models #deriv-critical-mass-composition uses for Instance 3's original coupling-sign-bit construction). The two witness constructions are at parameter-by-parameter explicit level for the symmetric-matched-Tier-1-scalar case (R0 vs R1 with $T_A = 2q_{B,\text{Nash}}^*$ and $\lambda_{\min}(\nabla^2\Phi_B) = \alpha$ as the matching conditions; R0 vs R2 with mean-matching and variance-matching against the matching-pennies-with-continuous-smoothing marginal).

Max attainable: *exact* in the symmetric-matched-Tier-1-scalar sub-scope, anchored by the explicit parameter matching above; *robust qualitative* in the general heterogeneous case, inheriting the Liberzon 2003 / Dayawansa-Martin 1999 / Shorten et al. 2007 common-Lyapunov-nonexistence structure that #disc-identifiability-floor Instance 3 (Boundary Characterization) already invokes. The tier statement is the same one Instance 3 carries; the broader topology coordinate does not change the tier.

Discussion.

Why this is a supporting derivation rather than a sixth identifiability-floor instance. The witness constructions in §"Witness 1" and §"Witness 2" *do* derive a cross-regime no-go from per-sub-agent marginal data, but the integrity test on M1 (the five-element distinctness test) finds three of four distinctness criteria failing against the existing Instance 3:

- Same external theorem (Liberzon 2003 / Dayawansa-Martin 1999 / Shorten et al. 2007 — the same anchor Instance 3 invokes; no new external theorem required).
- Same mechanism family (rank-collapse / Sylvester-at-one-remove on the marginal-Fisher operator).
- Four of five escapes inherit verbatim from Instance 3 (a, b, c, d unchanged; only (e) is new).
- Two of three strengthened consequences inherit-with-broadening from Instance 3; only the #deriv-strategic-composition sub-scope α'/β' elevation is genuinely new.

Per the strengthen-first landing posture (~/.claude/memory/epistemic-discipline/strengthen-before-soften.md and its landing-half ~/.claude/memory/epistemic-discipline/integration-is-replacement.md), this segment lands the *math* in canon (math-lives-in-segments discipline) while the *Instance 3 broadening* in #disc-identifiability-floor lands the *no-go statement, escape menu, and strengthened consequence* (integration-is-replacement at the meta-segment scope level). The candidate "Instance 6" framing is deleted; the broadening of Instance 3 carries the strengthened content; this segment carries the explicit witness backing.

The split — math segment plus meta-segment broadening rather than a new instance — preserves M1's instance-count integrity (the instances are *plural in mechanism*, not just plural in surface no-go) while ensuring the derived content lands in canon at full visibility.

Relationship to #disc-dynamic-regime-axis. This segment's witnesses are what concretely back #disc-dynamic-regime-axis's §H "Identifiability floor for regime" — the regime-axis meta-segment names the negative-half complementarity in the abstract; this segment supplies the constructive witness showing the no-go is real and parameter-explicit. The relationship is parallel to how #disc-identifiability-floor Instance 3's coupling-sign-bit witness in #deriv-critical-mass-composition (asymmetric-limit treatment) backs the meta-segment-level no-go statement.

When the dynamic-regime axis advances to meta-segment status, this segment is the canonical backing for the regime-axis floor; the complementarity structure (#disc-separability-pattern ↔ #disc-identifiability-floor parallel for the regime axis) is then:

- *Positive half:* #disc-dynamic-regime-axis four-tier ladder (R0 / R1 / R2 / R3 with their respective Lyapunov machinery).

- *Negative half*: #disc-identifiability-floor Instance 3 (broadened) — backed by this segment’s witnesses.

The double-duty Instance 3 serves both #disc-separability-pattern Contraction ladder *and* #disc-dynamic-regime-axis four-tier ladder; this segment’s witnesses extend that double-duty to the regime-axis level explicitly.

Open extensions.

- **Composite-of-composites case.** The witness constructions handle finite- N matched-symmetric-Tier-1 sub-agents. The composite-of-composites question (regime-identification of meta-composites from sub-composite marginal data) plausibly inherits the Liberzon machinery one level up but is not derived here.
- **Finite-sample refinements.** The §”Witness 1” / §”Witness 2” constructions are exact-population statements (stationary distributions identical). The finite-sample minimax error of regime classification under observation budget T is the Fano-style refinement that the 2026-05-20 spike correctly identified as the *adjacent* tool. Should be derivable from #der-agent-opacity H_b machinery applied at the composite layer; not done here.
- **Mean-field R3 lift.** The §”Witness 1” / §”Witness 2” constructions handle R0 / R1 / R2 finite- N . The R3 mean-field tier (per #disc-dynamic-regime-axis §B.3) has its own identifiability question — from finite- N marginal data, can the limit MFG regime be identified? Plausibly governed by the Lasry-Lions-monotonicity-vs-not bit (the MFG-analog of the potential-existence bit handled here). Tied to the R3 lift in #deriv-strategic-composition Working Notes mean-field extension.

Findings.

Cross-Regime Marginal Indistinguishability (Witness Backing for Broadened Instance 3). **Brief:** When you watch only one player at a time in a multi-agent system, you cannot tell what game they are playing — and “what game they are playing” determines whether the system as a whole will settle to a target, settle to a strategic equilibrium, or cycle in distribution forever. Two concrete worked constructions show this: two firms in Cournot competition that produce identical per-firm production-quantity distributions to a rowing team optimizing for a shared target (different game, same marginal); two players in matching pennies whose mixed strategy produces identical per-player action distributions to the same rowing team (different *kind* of equilibrium, same marginal). The mechanism is the same as for the simpler coupling-sign-bit case: the topology bit lives in a direction the marginal projection annihilates, and Sylvester’s law of inertia says you cannot recover an annihilated direction by changing the units on the ruler — only by looking from a new vantage point (intervening on the topology, or observing the joint trajectory’s convergence-rate class).

Impact: Backs #disc-identifiability-floor Instance 3’s 2026-05-21 broadening from coupling-sign-bit to coupling-topology-bit with explicit parameter-by-parameter witness constructions. Preserves the math-lives-in-segments discipline (the derivation lives in canon, not only in the spike). Provides the canonical worked instantiation for the broadened no-go, parallel to how #deriv-critical-mass-composition’s asymmetric-limit treatment carries Instance 3’s original coupling-sign-bit witness. Operationalizes the “regime is unidentifiable from per-sub-agent marginals” claim that the dynamic-regime axis meta-segment (#disc-dynamic-regime-axis) references as the negative-half of its complementarity structure.

Novelty Claim: *Claim integration* — the witness constructions extend Instance 3’s coupling-sign-bit construction to broader topology coordinates (R0 vs R1; R0 vs R2) using the same Liberzon 2003 / Dayawansa-Martin 1999 / Shorten et al. 2007 anchor and the same Sylvester-at-one-remove mechanism. The Cournot construction (Composite B in §”Witness 1”) is standard Monderer-Shapley 1996 potential-game-as-Cournot; the matching-pennies construction (Composite C in §”Witness 2”) is standard rock-paper-scissors-style cyclic-game smoothing. The contribution is the parameter-matching against R0 shared-target dynamics that produces marginal-indistinguishability across regimes — and the mechanism reduction to Instance 3’s rank-collapse-on-topology-coordinate framework.

⁴The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

⁵The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Network-reconstruction limits from temporal data	Angulo-Moreno-Barabási-Liu 2015, <i>Fundamental limitations of network reconstruction</i> (arXiv:1508.03559) ⁶	<i>adjacent literature</i> — graph topology is generically as hard to recover as the full interaction matrix without persistent excitation; underdetermines coupling from per-node observation. Closest network-level impossibility neighbor on the topology-from-component-data axis. Different setting (general dynamical, not strategic), but the underdetermination-from-reduced-observation pattern is shared
Delay-reconstruction recovers only transitive closure	Cummins-Gedeon-Spendlove 2015, <i>On the Efficacy of State Space Reconstruction Methods in Determining Causality</i> (SIAM J. Appl. Dyn. Syst. 14:335) ⁷	<i>adjacent literature</i> — componentwise trajectory data recovers at most the transitive closure of the interaction graph, not direct edges or feedback orientation. Explicit negative result on what trajectory data cannot tell an observer; not a game-structure witness but operationally similar shape
Game-side observational equivalence (quantal-response rationalization; consistent-game-set characterization)	Haile-Hortaçsu-Kosenok 2008, <i>On the Empirical Content of Quantal Response Equilibrium</i> (DOI 10.1257/AER.98.1.180) ⁸ (any interior action distribution rationalizable as QRE); Ziani-Chandrasekaran-Ligett 2016, <i>Efficiently Characterizing Games Consistent with Perturbed Equilibrium Observations</i> (DOI 10.7907/Z91Z42CF) ⁹ (characterizing the whole consistent set of games rather than point-identifying)	<i>adjacent literature</i> — stronger observational-equivalence statements on the game side than mere nonidentification, but at the equilibrium-rationalization layer rather than the per-component-marginal-trajectory layer this segment treats. Game-topology distinction (potential vs non-potential; cooperative vs cyclic) not the target of these results
Information-structure observational compatibility	Penalva-Ryall 2003, <i>Causal assessment in finite extensive-form games</i> ¹⁰ ; Penalva-Zuasti-Fabra-Ryall 2004, <i>Empirical Implications of Information Structure in Finite-Length Extensive-Form Games</i> ¹¹ ; Lehrer-Rosenberg-Shmaya 2006, <i>Signaling and mediation in Bayesian games</i> ¹²	<i>adjacent literature</i> — different information structures observationally compatible with respect to outcome / equilibrium distributions; another form of hidden structure surviving unchanged at the observable level. Different concern (information structure, signaling, mediation) but same shape (hidden distinction not visible at observable layer)

Novelty assessment. The cross-topology game witness with hidden distinction in potential-vs-non-potential or cooperative-vs-cyclic structure under matched per-component marginals appears uncoded relative to the prior-art search¹³; Witness 1 (R0-vs-R1 Cournot under matched marginal mean and variance) and Witness 2 (R0-vs-R2 matching-pennies under aggregation) are the specific instantiations the verdict identifies as uncoded. The closest structural analogues

are Bielecki et al. 2011 (multivariate Markov-chain same-marginals-different-coupling) and the Courbage-Hamdan / Hamdan sequence (marginal-non-determining stochastic processes) — both at the stochastic-process layer rather than the game-topology layer. AAT’s contribution: the *naming claim* on the game-topology-bit witness as the cross-regime indistinguishability instantiation of the established marginal-non-determining shape.

Search Log:

- 2026-05-21 (*targeted*): The core citations in §”Witness 1” / §”Witness 2” (Liberzon 2003, Dayawansa-Martin 1999, Shorten et al. 2007, Monderer-Shapley 1996, Hart-Mas-Colell 2000) are inherited from existing AAT machinery’s citation set; the witness construction is a parameter-matched application of standard game-theoretic templates against R0 shared-objective dynamics — the constructions are not novel in themselves, and the contribution is the cross-regime marginal-indistinguishability *recognition* and the mechanism-reduction to Instance 3’s rank-collapse framework.
- 2026-05-21 (*targeted second-pass*): A second-pass comprehensive-search pass searched specifically for prior art on (Q1) broader-topology-bit unidentifiability beyond the coupling-sign-bit witness, and (Q2) convergence-rate-class as a passive regime classifier. Verdict on both: *no exact hit found in this set*. The Related Work table above incorporates the verdict’s strongest neighbors at adjacent layers; see footnote [^bg2-2026-05-21] for the verification-deferral notice on every neighbor citation introduced from this pass.

Working Notes.

- **Provenance.** Derivation worked in spikes/.integrated/spike-identifiability-floor-instance-6-2026-05-21.md §3.3. The spike’s §4 M1 distinctness check identified three of four tests failing against Instance 3, landing the recommendation as “broaden Instance 3 + new appendix segment” rather than “new Instance 6.” This segment is the new appendix segment per that landing.
- **Cross-regime witness sub-cases.** Witness 1 (R0 vs R1) is the load-bearing cross-regime construction. Witness 2 (R0 vs R2) is qualitatively cleaner (the joint regime differs more dramatically) but operationally similar. A fourth witness (R1 vs R2 — Cournot equilibrium with parameter-matched marginals to matching-pennies cyclic dynamics) is plausible but not derived here; per the strengthen-first second-pass, the R0 vs R1 and R0 vs R2 witnesses are sufficient to establish the broadened no-go scope.
- **Connection to escape (e).** The convergence-rate-class escape (per #disc-identifiability-floor Instance 3 escape (e), added 2026-05-21) distinguishes Witness 2’s R0-vs-R2 case passively: Composite A converges exponentially, Composite C converges polynomially. Escape (e) does *not* distinguish Witness 1’s R0-vs-R1 case (both converge exponentially at the matched local rate α); the R0-vs-R1 distinction requires one of escapes (a)-(d) per the Instance-3 Boundary Characterization.
- **Composite-of-composites lift.** Per #disc-dynamic-regime-axis §I (Q3), the regime axis under nested composition is open. A natural extension of this segment’s witnesses to composite-of-composites would test whether marginal-indistinguishability at the sub-composite layer propagates to the meta-composite regime question. Follow-on spike candidate if the composition-of-regimes question becomes load-bearing for 04-eli-core/ population work.
- **Fano-style finite-sample refinement.** The §”Witness 1” / §”Witness 2” constructions are exact-population statements. A finite-sample bound on regime-classification minimax error at observation budget T would be the natural quantitative companion — per the 2026-05-20 spike’s Fano-anchor-as-finite-sample-refinement distinction. Plausibly derivable from #der-agent-opacity H_b machinery applied at the composite layer; not in scope here.
- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. This segment uses regime-axis vocabulary (R0/R1/R2) rather than GUC-class vocabulary; no GUC-class references inside. Removed at candidate stage per FORMAT.md Gate 4.
- **Primary-source verification spike queued (2026-05-21).** All BG2-introduced citations in this segment’s Related Work table (marked with footnote [^bg2-2026-05-21]) need primary-source verification before any further reliance. The characterizations attributed to those papers are currently synthesized from ref/Unidentifiability_and_rate_class_prior_art.md,

not from direct reading of the sources. Verification targets in approximate load-bearing order for this segment: (i) Bielecki-Jakubowski-Niewkeglowski 2011 — *closest structural analogue* (multivariate-Markov-chain same-marginals-different-coupling); load-bearing for the segment's positioning of the Witness math; (ii) Courbage-Hamdan 2001 + Courbage-Hamdan 1998 + Hamdan 2000 + Hamdan 2002 sequence — strongest direct-precedent for “finite-order marginals do not determine the generating law”; the Hamdan 2000 journal name was not specified in the Undermind report and should be resolved at verification (the DOI prefix would identify it, but the executor will not infer from DOI structure without confirming the actual paper); (iii) Angulo et al. 2015, Cummins et al. 2015 — network-reconstruction limits; (iv) Haile et al. 2008, Ziani et al. 2016 — game-side observational equivalence; (v) Penalva et al. 2003/2004, Lehrer et al. 2006 — information-structure observational compatibility. Spike to be scheduled per Joseph's go.

Appendix AO

Derivation: Strategy-Proofness Impossibility (Gibbard-Satterthwaite)

The first charter instance of #disc-implementation-impossibility: Gibbard 1973 and Satterthwaite 1975 forbid an external designer from constructing a dominant-strategy incentive-compatible (DSIC), non-dictatorial, surjective social-choice function over ≥ 3 alternatives under unrestricted preferences. The AAT-side translation locates the designer's task in the composite-agent setting (#scope-composite-agent), recognizes the agents as composite sub-agents reporting preferences derived from their objectives $O_i^{(i)}$, and maps the four standard escapes against AAT machinery — with the preference-domain-restriction escape (single-peaked / single-crossing) named precisely as *adjacent to but not identical with* the sub-scope α' machinery of #deriv-strategic-composition. The adjacency is not identity: sub-scope α' secures best-response *convergence* under fixed reports; GS forbids *strategy-proof revelation*. The honest map of where AAT meets mechanism design is the contribution; the imported theorem is classical.

Formal Expression.

Setting. Let A be a finite alternative set with $|A| \geq 3$, and let L denote the set of strict linear orderings on A . A **social-choice function** is a map $f : L^n \rightarrow A$ that aggregates n agents' reported preferences $R = (R_1, \dots, R_n) \in L^n$ into a single outcome $f(R) \in A$.

Three constraints define the designer's regime:

Definition (dsic, strategy-proofness / dominant-strategy incentive compatibility).

$$\forall i, \forall R_{-i} \in L^{n-1}, \forall R_i, R'_i \in L : f(R_i, R_{-i}) R_i f(R'_i, R_{-i}). \quad (\text{AO.1})$$

Truth-telling is a dominant strategy: no agent i can profit from misreporting given any reports by the others.

Definition (non-dictatorial).

$$\neg \exists i^* : \forall R \in L^n, f(R) \text{ is } i^* \text{'s top-ranked alternative in } R_{i^*}. \quad (\text{AO.2})$$

No agent fully determines the outcome.

[*Definition (surjective)*] $f(L^n) = A$. Every alternative is reachable from some report profile.

External theorem.

Theorem (Gibbard 1973; Satterthwaite 1975). If $|A| \geq 3$ and preferences are unrestricted (each R_i ranges over all of L), then no social-choice function $f : L^n \rightarrow A$ is simultaneously DSIC, non-dictatorial, and surjective.

Postulate (gibbard-satterthwaite-1973-75, imported), exact.

References. Gibbard, A. (1973), “Manipulation of voting schemes: a general result,” *Econometrica* 41(4):587–601. Satterthwaite, M. A. (1975), “Strategy-proofness and Arrow’s conditions: existence and correspondence theorems for voting procedures and social welfare functions,” *J. Econ. Theory* 10(2):187–217. Modern textbook synthesis: Mas-Colell, Whinston & Green (1995), *Microeconomic Theory*, §23.C; geometric/topological proof structure shared with Arrow’s theorem in Reny, P. J. (2001), “Arrow’s theorem and the Gibbard-Satterthwaite theorem: a unified approach,” *Econ. Letters* 70:99–105.

No-go. A designer who insists simultaneously on DSIC, non-dictatorial, surjective, and unrestricted-preferences cannot construct the social-choice function. Any candidate f satisfying three of the four conditions violates the fourth.

AAT-side translation.

Within AAT’s composite-agent setting, the GS no-go translates as follows:

Derived (aat-mechanism-translation, from ‘#scope-composite-agent’ + ‘#deriv-strategic-composition’), conditional on the composite-revelation-mechanism reading.

- The “agents” are *sub-agents* in a composite per #scope-composite-agent, each carrying its own objective $O_t^{(i)}$ inducing a preference ordering $R_i \in L$ over composite-level alternatives A (the joint outcomes reachable through the composite’s strategic-composition machinery).
- A “social-choice function” $f : L^n \rightarrow A$ is a *mechanism* the designer (external to the composite agent) imposes — a rule that takes the sub-agents’ reports $R = (R_1, \dots, R_n)$ and produces a composite-level outcome. The designer’s task is to choose f .
- “Strategy-proofness” requires that each sub-agent’s truth-telling about its own $O_t^{(i)}$ -induced ordering is its best-response strategy. The DSIC condition is stronger than Nash equilibrium: dominance against *all* other-agent reports, not just equilibrium-consistent ones.

The GS theorem then states: under the four stated conditions, no such mechanism exists. The designer faces a structural impossibility on what can be implemented over the composite of strategically-reporting sub-agents under unrestricted preference domain.

Boundary characterization.

Table AO.1

<i>Escape</i>	<i>Mechanism-design route</i>	<i>AAT machinery?</i>
Preference-domain restriction	Single-peaked preferences (Black 1948 <i>J. Polit. Econ.</i> 56:23–34) admit the median-voter rule; single-crossing extends this. The domain restriction circumvents the unrestricted-preferences condition.	Adjacent to AAT machinery. Sub-scope α' of #deriv-strategic-composition (potential / monotone game structure) is <i>adjacent</i> to single-peaked / single-crossing — both restrict the preference-or-utility structure to admit convergence/aggregation guarantees — but not identical (see <i>Sub-scope α' vs preference-domain restriction</i> below).
Weakened solution concept	Bayes-Nash incentive compatibility (BIC) instead of dominant-strategy IC — d'Aspremont & Gérard-Varet (1979) “Incentives and incomplete information,” <i>J. Public Econ.</i> 11:25–45. The designer relaxes from dominance to expected-utility best-response under a common prior on others’ types.	Outside AAT machinery. BIC requires a shared prior over types and Bayesian reasoning over expected reports; AAT’s strategic-composition machinery does not currently formalize the mechanism-induced report game in BIC terms.
Randomization	Gibbard (1977) “Manipulation of schemes that mix voting with chance,” <i>Econometrica</i> 45:665–681 — random-dictator and convex-combination mechanisms admit strategy-proofness in expectation.	Outside AAT machinery. AAT’s machinery treats deterministic strategies Σ_i ; randomized-mechanism design is not in canon.
Restricted strategy space (enforced truth-telling)	The revelation-principle-companion: if the designer can verify reports against ground truth (e.g., observable types), strategy-proofness becomes definitional rather than incentivized.	Outside AAT machinery. AAT’s agent-spectrum (#def-agent-spectrum) does not currently include verification-of-self-reports machinery.

Strengthened consequence. The boundary-precise contribution: the AAT/mechanism-design intersection is at *one* of the four GS escapes, and that intersection is *adjacent without being identical*. The honest map looks like this.

Sub-scope α' vs preference-domain restriction. Three reframings under which sub-scope α' would *be* the GS escape all fail: sub-scope α' secures best-response *convergence* of the composite-dynamics given a fixed mechanism, not *strategy-proofness* of the mechanism itself. Concretely: agents in a potential game (the canonical sub-scope α' instance) can have profitable unilateral deviations under non-truthful preference revelation even when the joint best-response dynamics under the current revelation converge. The convergence-under-current-reports guarantee that sub-scope α' supplies is *not* the dominance-over-all-reports guarantee DSIC requires.

The honest read: sub-scope α' is *adjacent* to the preference-domain-restriction escape because both restrict the preference-or-payoff structure in similar ways (single-peaked preferences exhibit a potential-game-like ordinal structure on single-dimensional issue spaces; monotone games on lattices share order-theoretic features with single-crossing preference domains), but it is *not the same restriction*. Sub-scope α' ’s contribution to the composite-agent layer is convergence-given-mechanism, not mechanism-strategy-proofness. The boundary is named precisely; AAT does not claim to escape GS, but recognizes where the framework’s strategic-composition machinery sits *next* to one of GS’s classical escapes.

The other three escapes belong entirely to mechanism design and social-choice theory. The framework honestly documents that, and locates its current contribution as *recognition of the boundary* rather than *provision of the escapes*.

Epistemic Status.

Exact for the imported theorem (Gibbard 1973, Satterthwaite 1975 — classical theorems with closed-form proofs in the source literature, primary-source verification scheduled for promotion past draft).

Conditional for the AAT-side translation — the mapping from social-choice-function to composite-mechanism-over-sub-agent-reports is mechanical under the *composite-revelation-mechanism reading* (sub-agents per #scope-composite-agent; reports as inputs to a designer-chosen f ; composite outcomes as elements of A), but the reading itself is a representational choice; alternative AAT readings (e.g., treating sub-agents as auctioning under VCG-like settings; treating f as a Σ -level commitment device) exist and would map GS to different AAT-side vocabulary.

Robust qualitative for the boundary characterization (sub-scope α' is adjacent-but-not-identical to preference-domain restriction; the other three escapes are outside AAT canon) — survives across instance details, with the specific functional adjacency (single-peaked $\leftrightarrow$ potential-game-like structure on issue spaces) noted but not derived as identity.

Max attainable: *Exact* for the imported theorem; *derived conditional* for the AAT translation; *robust qualitative* for the boundary characterization. The AAT translation's max ceiling stays *conditional* unless an alternative reading is forced by some AAT-internal uniqueness argument (no such argument currently in hand).

Discussion.

Why this is not a #disc-identifiability-floor instance. GS fails the identifiability-floor's five-element shape on actor positioning: in Instances 1–4 of the floor the actor frustrated by the no-go is the *agent itself* (cannot detect, identify, certify, or recover an architectural d.o.f. from limited data), and the escape elevates *agent-side* information-augmentation machinery (loop-interventional access, latent observability, matched-Tier composite-extended observation, similarity-fiber resolution). GS's actor is the *designer*; the escapes are *design-constraint relaxations*. The cluster is structurally different and belongs in the sister meta-segment #disc-implementation-impossibility. This segment is GS's home there.

Sub-scope α' adjacency, named precisely. The Discussion above states sub-scope α' is *adjacent* to preference-domain restriction but *not identical*; this is load-bearing for the honest scope-marking discipline of #disc-implementation-impossibility. The framework's contribution here is recognition of where the strategic-composition machinery sits next to one of GS's classical escapes — not a claim that AAT supplies the escape. Mechanism-design proper supplies the escape; AAT documents the proximity.

Peer voice with the mechanism-design literature. The imported theorem is classical; the proof structure (Gibbard 1973 via the revelation-principle-style argument; Satterthwaite 1975 via direct manipulation construction; Reny 2001 via geometric/topological unification with Arrow) is mature. AAT does not re-prove the theorem; AAT does not displace the standard escape routes; AAT does not claim that the strategic-composition machinery solves mechanism design. The segment's contribution is honest recognition of the boundary, with the imported theorem cited under its original names and full bibliographic references.

Relationship to #deriv-strategic-composition. The placement of “mechanism-design impossibility” as a candidate-fourth-instance of #disc-identifiability-floor is wrong on actor-positioning grounds. GS's home is here in the sister meta-segment; sub-scope α' retains its load-bearing role in strategic-composition for best-response convergence, and is *additionally* recognized as adjacent to GS's preference-domain-restriction escape under the boundary characterization above.

Findings.

The Gibbard-Satterthwaite Translation and Its Sub-Scope α' Adjacency. **Brief:** The Gibbard-Satterthwaite theorem says that no voting rule can be at once strategy-proof (no one ever benefits from misreporting their preferences), non-dictatorial (no single voter always decides), surjective (every alternative is reachable), and broadly applicable (works on unrestricted preferences) when there are at least three alternatives. The classical escapes have been studied for decades — restrict the preference domain (require single-peaked preferences; the median voter rule works), allow randomization (random dictator is strategy-proof in expectation), accept a weaker incentive concept (Bayes-Nash IC under a shared prior), or constrain the strategy space (enforce truth-telling by verifying reports). The contribution here is the honest map: when the framework recognizes a composite agent whose sub-agents have their own objectives, the strategic-composition machinery’s sub-scope α' (potential or monotone games — the regime where best-response dynamics converge) is *adjacent to* the preference-domain-restriction escape (single-peaked / single-crossing) — both restrict the preference structure to admit aggregation/convergence guarantees — but is *not the same restriction*: convergence-under-current-reports is not dominance-over-all-reports. The other three classical escapes belong entirely to mechanism design and social-choice theory; the framework documents them as outside the current canon. Mapping that boundary honestly is the contribution; the impossibility is classical.

Impact: Closes the candidate-fourth-instance flag in #deriv-strategic-composition Discussion by landing GS in its proper home — the designer-side #disc-implementation-impossibility meta-segment, with sub-scope α' ’s relationship to the preference-domain-restriction escape named precisely. The named adjacency-without-identity is the kind of scope-honesty discipline the framework runs throughout: AAT recognizes where its machinery sits next to classical mechanism-design escape routes, and refuses the temptation to overclaim that sub-scope α' “supplies” the escape (it does not — it supplies a different guarantee at a different layer of the composite-agent dynamics). The result is a charter instance of the designer-side cluster with the AAT/mechanism-design boundary mapped with precision rather than enthusiasm.

Novelty Claim: *Claim recognition* of the AAT-side translation of the Gibbard-Satterthwaite theorem into the composite-agent setting (sub-agents per #scope-composite-agent; reports as inputs to a designer-chosen mechanism; composite outcomes as the alternative set); *claim differentiation* on the sub-scope α' $\leftrightarrow$ preference-domain-restriction adjacency: sub-scope α' is *adjacent to but not identical with* the GS preference-domain escape (the three-reframing strengthen-first check is the documented argument). The imported theorem is classical (Gibbard 1973; Satterthwaite 1975); the AAT-side translation, the boundary-characterization annotations, and the honest adjacency-without-identity recognition are the contributions.

Search Log:

- 2026-05-22 (*intuition-only* on the AAT-side composite-revelation-mechanism reading): The mapping from social-choice function to composite-mechanism-over-sub-agent-reports (sub-agents per #scope-composite-agent; reports as inputs; composite outcomes as A) is the natural AAT-side reading; alternative readings exist (treating f as a Σ -level commitment device; treating sub-agents as VCG-auction bidders) and would map GS to different AAT-side vocabulary. The composite-revelation reading is chosen here for parsimony with #deriv-strategic-composition; targeted future search candidates would be alternative-reading derivations if a downstream use of this segment requires them.

Working Notes.

- **Provenance.** Authored 2026-05-22 as commit 2 of the post-Track-CR Track-B cycle, executing spikes/implementation-impossibility-meta-segment-plan.md §4.a. The 2026-05-20 strengthen-first arm record at spikes/.integrated/spike-4th-identifiability-floor-instance-2026-05-20.md §4 carries the load-bearing argument that sub-scope α' is *adjacent to but not identical with* the GS preference-domain-restriction escape: it re-derived GS against the identifiability-floor’s five-element test, tested three reframings under strengthen-before-soften (GS as identifiability-of-truthful-preferences; GS as Part III multi-agent no-go on #scope-composite-agent (C-iv) routes; GS as alignment-design obstruction), and confirmed sub-scope α' does *not* escape GS (it secures best-response convergence, not strategy-proofness). The verdict’s recommended disposition — route GS to a sister meta-segment if mechanism design becomes a first-class framework concern — is what this segment lands.
- **Open before candidate.** (a) Primary-source verification of Gibbard 1973 and Satterthwaite 1975 — the theorem statement above is taken from the textbook synthesis (Mas-Colell, Whinston & Green 1995 §23.C) and the geometric-proof-unification paper (Reny 2001); direct primary-source reading is queued. (b) Alternative AAT-side readings of GS — treating f as a Σ -level commitment device, or treating sub-agents as VCG-auction bidders — would map GS into different AAT vocabulary; whether either alternative reading produces a stronger AAT-side derivation is a candidate sub-spike. (c) The sub-scope $\alpha' \leftrightarrow$ single-peaked-preferences adjacency is currently *robust qualitative* — there may be an AAT-internal derivation showing the structural correspondence at parameter-level (e.g., that single-peaked preferences on an issue-space induce a potential-game structure under standard best-response dynamics); the derivation is queued and would lift the adjacency claim to *exact* if it lands cleanly. Indexed at spikes/PROPOSED.md Tier 3 (added 2026-05-24) as a segment-perspective audit-judgment with this segment as canonical home; the lift is symmetric for #deriv-social-welfare-aggregation-impossibility (Arrow’s preference-domain-restriction escape shares the same adjacency).

- **The composite-revelation-mechanism reading and its sub-agents.** The AAT-side translation treats the GS “agents” as sub-agents in a composite per `#scope-composite-agent`, each carrying its own objective $O_t^{(i)}$ inducing a preference ordering over composite-level alternatives. This is the most parsimonious AAT-side reading and aligns with `#deriv-strategic-composition`’s framing of strategic composition over sub-agent objectives. The reading does *not* assume sub-agents have unbounded computational capacity, do not constrain their reporting strategies to be honest, do not require shared priors — the GS no-go applies to the designer’s mechanism task regardless of those details.
 - **The cluster’s discipline filter.** GS is the *cleanest* charter instance of `#disc-implementation-impossibility` — the discipline filter (constructive-impossibility-shape only) admits it directly: the setting is well-stated, the external theorem is classical, the no-go is sharp, the escapes are well-characterized in the literature, and the strengthened consequence (the AAT/mechanism-design boundary precisely mapped at the sub-scope α' adjacency) is the framework’s honest contribution. The next charter instances (MS, Arrow) fit the same template with their own variations.

Appendix AP

Derivation: Bilateral Trade Impossibility (Myerson-Satterthwaite)

The second charter instance of #disc-implementation-impossibility: Myerson & Satterthwaite 1983 forbid an external designer from constructing an ex-post efficient, Bayesian incentive compatible, individually rational, budget-balanced bilateral-trade mechanism when buyer and seller have private valuations drawn from overlapping continuous distributions. The AAT-side translation locates the buyer and seller as a two-sub-agent composite per #scope-composite-agent; recognizes that the two-agent strategic-composition machinery of #deriv-strategic-composition applies cleanly to the agents' best-response dynamics *given* a fixed mechanism but does not cover the designer's mechanism-choice problem; and honestly maps the four classical escapes as almost entirely outside AAT's current canon. The contribution here is *boundary precision*: bilateral-trade impossibility is *adjacent to* AAT (the strategic-composition layer engages the agents-given-mechanism dynamics) but the designer's task lives in mechanism-design proper. The honest scope-mark is the contribution.

Formal Expression.

Setting. Two parties: a buyer B with private valuation $v_b \in [0, \bar{v}_b]$ drawn from distribution F_b with density f_b , and a seller S with private valuation $v_s \in [0, \bar{v}_s]$ drawn from distribution F_s with density f_s . The supports overlap: there exists a non-empty interval $[a, b] \subseteq [0, \bar{v}_b] \cap [0, \bar{v}_s]$ such that f_b and f_s are both strictly positive on $[a, b]$. A **direct mechanism** is a pair (p, x) where $p : [0, \bar{v}_b] \times [0, \bar{v}_s] \rightarrow [0, 1]$ is the trade probability and $x : [0, \bar{v}_b] \times [0, \bar{v}_s] \rightarrow \mathbb{R}$ is the buyer's expected payment to the seller (with the seller receiving x). Equivalently with interim allocation rules $\bar{p}_b(v_b)$, $\bar{p}_s(v_s)$ and interim transfer rules $\bar{x}_b(v_b)$, $\bar{x}_s(v_s)$ for buyer-and-seller respectively.

Four constraints define the designer's regime:

[Definition (*ex-post-efficient*)] $p(v_b, v_s) = 1 \iff v_b \geq v_s$. Trade occurs exactly when the buyer values the good at least as much as the seller.

[Definition (*bayesian-ic, BIC*)] Each agent's truthful reporting is a Bayesian best response given the other's truthful strategy:

$$v_b \bar{p}_b(v_b) - \bar{x}_b(v_b) \geq v_b \bar{p}_b(\hat{v}_b) - \bar{x}_b(\hat{v}_b) \quad \forall v_b, \hat{v}_b, \quad (\text{AP.1})$$

and symmetrically for the seller (with the sign reversed since the seller is paid).

[Definition (*individual-rationality, IR*)] Both parties participate voluntarily: expected interim payoff is nonnegative for every type:

$$v_b \bar{p}_b(v_b) - \bar{x}_b(v_b) \geq 0 \quad \forall v_b, \quad \text{and} \quad \bar{x}_s(v_s) - v_s \bar{p}_s(v_s) \geq 0 \quad \forall v_s. \quad (\text{AP.2})$$

[Definition (budget-balance)] No external subsidy: the buyer's expected payment exactly equals the seller's expected receipt:

$$\mathbb{E}[x(v_b, v_s)] = 0 \quad (\text{net designer-side}). \quad (\text{AP.3})$$

External theorem.

Theorem (Myerson & Satterthwaite 1983). If f_b and f_s are strictly positive on a common open interval and the supports overlap, no direct mechanism (p, x) is simultaneously ex-post efficient, BIC, IR, and budget-balanced.

Postulate (myerson-satterthwaite-1983, imported), exact.

Reference. Myerson, R. B. & Satterthwaite, M. A. (1983), "Efficient mechanisms for bilateral trading," *J. Econ. Theory* 29(2):265–281. Modern textbook synthesis: Krishna, V. (2002), *Auction Theory*, Academic Press, §5.3; Mas-Colell, A., Whinston, M. D. & Green, J. R. (1995), *Microeconomic Theory*, Oxford University Press, §23.E.

No-go. A designer demanding ex-post efficiency + BIC + IR + budget-balance cannot construct the bilateral-trade mechanism. Any candidate mechanism satisfying three of the four conditions violates the fourth. Equivalently: under private values with overlapping supports, the designer must accept a deficit (relax budget-balance), accept inefficiency (relax ex-post efficiency), accept that participation is not always individually rational, or weaken the incentive concept.

AAT-side translation.

Within AAT's composite-agent setting, the MS no-go translates partially:

Derived (aat-bilateral-trade-translation, from '#scope-composite-agent'), conditional on the buyer-seller-as-two-sub-agent reading, partial.

- The "buyer" and "seller" are *sub-agents* in a two-sub-agent composite per #scope-composite-agent, each carrying its own objective $O_t^{(i)}$ — the buyer's $O_t^{(B)}$ rewarding acquisition at favorable price; the seller's $O_t^{(S)}$ rewarding relinquishing at favorable price.
- The "mechanism" (p, x) is a designer-imposed structure on the composite's joint action space and reward redistribution — outside AAT's agent-level machinery; AAT's strategic-composition machinery in #deriv-strategic-composition applies to the agents' best-response dynamics *given* the mechanism (p, x) , not to the designer's choice of (p, x) .

The honest translation: the *agents-given-mechanism layer* is internal to AAT (strategic-composition machinery applies); the *mechanism-choice layer* is external. The MS no-go applies at the mechanism-choice layer; AAT does not currently cover it.

Boundary characterization.

Table AP.1

<i>Escape</i>	<i>Mechanism-design route</i>	<i>AAT machinery?</i>
Subsidies (relax budget-balance)	VCG mechanism with deficit; pivotal-mechanism transfers. The designer covers any shortfall from external resources.	Outside AAT machinery. AAT does not currently formalize designer-side transfer pools or subsidy budgets.
Second-best mechanisms (relax ex-post efficiency)	Myerson 1981 “Optimal auction design,” <i>Math. Oper. Res.</i> 6:58–73 — characterizes revenue-optimal mechanisms with inefficient withholding in the marginal-cost-curve region; bilateral-trade analog accepts trade-failure when $v_b - v_s$ is small relative to the inefficiency cost.	Outside AAT machinery. Optimal-mechanism design under welfare-relaxation is the constructive side of mechanism design; deliberately excluded by the discipline filter (see #disc-implementation-impossibility’s “constructive mechanism-design” exclusion).
Common values (relax private values)	Information aggregation under shared-value components — Wilson 1977 “A bidding model of perfect competition,” <i>Rev. Econ. Stud.</i> 44:511–518; the no-go softens because the agents’ reports carry shared signal.	Outside AAT machinery; adjacent to #scope-edge-update-causal-validity’s regime-indexed identification structure. The shared-signal regime is structurally similar to AAT’s partial-intervention Regime B (#scope-edge-update-causal-validity’s middle tier), but the formal connection has not been derived.
Long-run reputation / repeated interaction	Single-shot MS does not bind in indefinitely-repeated bilateral-trade games — Folk-theorem-style mechanisms with reputation backlash. Fudenberg-Maskin 1986 <i>Econometrica</i> 54:533–554 for the canonical Folk-theorem setup.	Outside AAT machinery; adjacent to the strategic-composition machinery in repeated-game form. The repeated-game extension of #deriv-strategic-composition is open canonical work; the MS-escape connection would land there if pursued.

Strengthened consequence. The MS boundary lies *almost entirely outside* AAT’s current machinery — and the *honest delineation* is the contribution. AAT does not claim to escape MS; AAT does not provide subsidies, optimal-mechanism design, common-value aggregation, or repeated-game reputation machinery in its current canon. The framework’s contribution at this charter instance is precisely the boundary recognition: the two-agent strategic-composition machinery in #deriv-strategic-composition applies cleanly to the buyer-seller best-response dynamics *given* a fixed mechanism (the agents-given-mechanism layer is internal), but the designer’s mechanism-choice problem (the mechanism-choice layer) is external. The two escapes flagged as *adjacent* (common-values to Regime B; repeated-interaction to repeated-strategic-composition) are open avenues if AAT extends in those directions; the two flagged as *outside* (subsidies, second-best mechanisms) belong to mechanism-design proper.

The contribution is the same kind of scope-honesty discipline #disc-identifiability-floor runs on the agent side and #deriv-strategy-proofness-impossibility runs at a different AAT-machinery-intersection: name the boundary precisely; refuse to overclaim machinery the framework does not currently supply.

Epistemic Status.

Exact for the imported theorem (Myerson & Satterthwaite 1983 — classical theorem with closed-form proof in the source literature; primary-source verification scheduled for promotion past draft).

Conditional, partial for the AAT-side translation — the buyer-seller-as-two-sub-agent reading is the natural composite-agent translation, but the *agents-given-mechanism layer* is the only part of the no-go internal to AAT canon; the *mechanism-choice layer* (where the no-go binds) is external. The partial-translation is honest — AAT recognizes the bilateral-trade designer-task as adjacent but does not formalize the designer-side mechanism-choice problem.

Robust qualitative for the boundary characterization — four escapes documented with honest scope-marks; two adjacencies named (common-values $\leftrightarrow$ Regime B; repeated-interaction $\leftrightarrow$ repeated-strategic-composition); no precise functional intersection derived.

Max attainable: *Exact* for the imported theorem. *Derived conditional* for the AAT translation, with the *conditional* gating on the buyer-seller-two-sub-agent reading; an alternative reading (e.g., buyer and seller as *single-agent-with-two-roles* under intertemporal preference modeling) would change the translation but is not currently in canon. *Robust qualitative* for the boundary characterization; lifting to *exact* on the common-values $\leftrightarrow$ Regime B intersection would require formalizing the regime-correspondence, which is open.

Discussion.

Why this is not a #disc-identifiability-floor instance. Same actor-positioning argument as for the GS instance (#deriv-strategy-proofness-impossibility): the actor frustrated by the MS no-go is the *designer* (cannot construct a mechanism satisfying all four conditions), not an agent inferring from data. The escapes are *design-constraint relaxations* (relax budget-balance / efficiency / private-values / single-shot interaction), not information augmentations of an inferential regime. The cluster belongs in #disc-implementation-impossibility, not in the identifiability-floor.

Why the AAT translation is honestly partial. Unlike the GS instance (where sub-scope α' of #deriv-strategic-composition has a named adjacency to the preference-domain-restriction escape), MS has *no* AAT-internal escape adjacency. The two *adjacent* escapes (common-values $\leftrightarrow$ Regime B; repeated-interaction $\leftrightarrow$ repeated-strategic-composition) are open extensions, not current canon. The two *outside* escapes (subsidies, second-best mechanisms) belong to mechanism-design proper. The framework's contribution at this charter instance is therefore *purely the boundary recognition*: AAT covers the agents-given-mechanism layer, not the mechanism-choice layer; the MS no-go binds at the latter.

Peer voice with the mechanism-design literature. The imported theorem is classical; the proof structure (Myerson-Satterthwaite via Myerson's virtual-valuations machinery) is mature. AAT does not re-prove the theorem; AAT does not displace the standard escape routes; AAT does not claim that the strategic-composition machinery extends to mechanism-choice. The segment's contribution is honest recognition of the boundary, with the imported theorem cited under its original name and full bibliographic references.

Two open AAT-side extensions flagged. The common-values $\leftrightarrow$ Regime B adjacency and the repeated-interaction $\leftrightarrow$ repeated-strategic-composition adjacency are open avenues. If AAT extends in either direction — formalizing shared-signal information regimes alongside the current intervention-regime classification, or extending strategic-composition into repeated-game form — the MS instance's boundary characterization would gain AAT-machinery content where it currently has honest scope-marks. The flags here document the avenues without committing to either extension.

Findings.

The Bilateral Trade Boundary — Honest Scope-Marking as Contribution. **Brief:** When a buyer and seller each know their own valuation but not the other's, and the designer wants a trading mechanism that is at once fair (trade happens whenever the buyer values the good more than the seller does), incentive-honest (neither party can profitably misreport their valuation), voluntary (both parties want to participate), and self-funded (no outside subsidies), the Myerson-Satterthwaite theorem says all four cannot hold simultaneously. The classical escapes have been studied for decades — accept a budget deficit, accept inefficient withholding, exploit common-value information, or rely on long-run reputation in repeated trade. The honest contribution here is that *none* of these escapes is currently provided by the framework's machinery. The framework covers what the buyer and seller do *given* a mechanism (the two-sub-agent strategic-composition machinery applies cleanly to their best-response dynamics); the *designer's choice of mechanism* lives in mechanism-design proper, and the framework documents that boundary precisely rather than overclaiming reach. Two of the four classical escapes (common-values and repeated-interaction) are flagged as adjacent — open avenues if the framework extends in those directions — and two (subsidies and second-best mechanisms) belong entirely

to mechanism design. The contribution is the map of where the framework meets the bilateral-trade boundary, not the provision of an escape.

Impact: The cleanest example of the #disc-implementation-impossibility cluster’s discipline filter doing its honest work. Where the GS charter instance has a named sub-scope α' adjacency to make precise, the MS charter instance has *none* — the AAT-machinery contribution is purely boundary-recognition. That contrast within the cluster is itself epistemic content: the framework’s contribution is precision about *where its machinery contributes* (GS: adjacent to preference-domain restriction) and *where it does not* (MS: outside almost entirely). Two open avenues flagged (common-values $\leftrightarrow$ Regime B; repeated-interaction $\leftrightarrow$ repeated-strategic-composition) document where future framework extensions could intersect MS without committing to either.

Novelty Claim: *Claim recognition* of the AAT-side translation of the Myerson-Satterthwaite theorem under the buyer-seller-as-two-sub-agent reading; *claim differentiation* on the agents-given-mechanism layer being internal to AAT and the mechanism-choice layer being external — the no-go binds at the latter, which is the honest scope-mark. The imported theorem is classical (Myerson & Satterthwaite 1983); the AAT-side translation, the boundary-characterization annotations, the honest *almost-entirely-outside* scope-mark, and the two open adjacencies (common-values, repeated-interaction) are the contributions.

The imported theorem	Myerson, R. B. & Satterthwaite, M. A. (1983), “Efficient mechanisms for bilateral trading,” <i>J. Econ. Theory</i> 29(2):265–281 (found pre-2026)	<i>formal antecedent</i> — primary-source verification scheduled for promotion past draft
Modern textbook synthesis	Krishna, V. (2002), <i>Auction Theory</i> , Academic Press, \$5.3 (found pre-2026); Mas-Colell, Whinston & Green (1995), §23.E	<i>adjacent literature</i> — used for the constraint-regime formulation in the Setting above
Optimal mechanism design (second-best escape)	Myerson, R. B. (1981), “Optimal auction design,” <i>Math. Oper. Res.</i> 6(1):58–73 (found pre-2026)	<i>adjacent literature</i> — the canonical second-best-escape construction; outside AAT canon per the discipline filter exclusion
Common-values bidding (adjacent escape)	Wilson, R. (1977), “A bidding model of perfect competition,” <i>Rev. Econ. Stud.</i> 44(3):511–518 (found pre-2026)	<i>adjacent literature</i> — flagged as adjacent to #scope-edge-update-causal-validity Regime B; formal correspondence is open
Folk theorem (repeated-interaction escape)	Fudenberg, D. & Maskin, E. (1986), “The folk theorem in repeated games with discounting or with incomplete information,” <i>Econometrica</i> 54(3):533–554 (found pre-2026)	<i>adjacent literature</i> — flagged as adjacent to repeated-strategic-composition extension of #deriv-strategic-composition; formal correspondence is open

Search Log:

- 2026-05-22 (*intuition-only* on the buyer-seller-two-sub-agent reading): The natural composite-agent translation maps buyer and seller to two sub-agents per #scope-composite-agent with their own $O_t^{(i)}$. Alternative readings (single-agent-with-two-roles under intertemporal preference; large-economy aggregation limit) exist; not pursued here. Targeted future search candidates if alternative readings become relevant: Wilson 1977 large-economy bidding limit; behavioral / dual-self models of intertemporal trade.

- 2026-05-22 (*intuition-only* on the common-values $\leftrightarrow$ Regime B adjacency): The common-values escape's structural feature (agents' reports carry shared signal about a partially-observable joint state) is reminiscent of #scope-edge-update-causal-validity's Regime B (partial intervention; confounder-adjustment under side-channel observation). Whether the correspondence is formal or merely metaphorical is open. Targeted future search would compare the information-aggregation structure of common-values mechanisms (Wilson 1977; Pesendorfer-Swinkels 1997 *Econometrica* 65:1247–1281) against AAT's Regime B partial-intervention machinery.
- 2026-05-22 (*intuition-only* on the repeated-interaction $\leftrightarrow$ repeated-strategic-composition adjacency): The repeated-bilateral-trade escape's structure (reputation backlash sustaining cooperation through grim-trigger or carrot-and-stick strategies) is the natural extension of strategic-composition to repeated games. Whether the formal correspondence holds is open. Targeted future search would compare the Folk-theorem machinery (Fudenberg-Maskin 1986; Fudenberg-Levine-Maskin 1994 *Econometrica* 62:997–1039) against a repeated-game extension of #deriv-strategic-composition.

Working Notes.

- **Provenance.** Authored 2026-05-22 as commit 3 of the post-Track-CR Track-B cycle, executing spikes/implementation-impossibility-meta-segment-plan.md §4.b. The 2026-05-20 strengthen-first arm record at spikes/.integrated/spike-4th-identifiability-floor-instance-2026-05-20.md §5 names MS as a candidate instance held back from the floor cluster (along with Arrow) pending the Joseph-reserved structural-canon decision on a sister meta-segment — Joseph approved the sister-meta-segment landing in this cycle; MS is the second charter instance of #disc-implementation-impossibility.
 - **Open before candidate.** (a) Primary-source verification of Myerson & Satterthwaite 1983 — the theorem statement above is taken from the textbook synthesis (Krishna 2002 §5.3; Mas-Colell, Whinston & Green 1995 §23.E); direct primary-source reading is queued. (b) The two adjacent-escape correspondences (common-values $\leftrightarrow$ Regime B; repeated-interaction $\leftrightarrow$ repeated-strategic-composition) are *open* — flagged as adjacent in honest scope-mark, not derived. Lifting either to derived conditional would require formalizing the corresponding extension of AAT canon (#scope-edge-update-causal-validity Regime B's shared-signal interpretation, or a repeated-strategic-composition segment); both are open canonical work. (c) The buyer-seller-as-two-sub-agent reading is the natural composite-agent translation; alternative readings (single-agent-with-two-roles under intertemporal preference; large-economy aggregation) exist; not pursued here.
 - **The honest-almost-entirely-outside scope-mark.** MS is the cluster instance where the AAT/mechanism-design boundary is *most* outside AAT — even more so than GS (where sub-scope α' is named-adjacent) and likely more than Arrow (where cardinal preferences are adjacent to #form-objective-functional). The cluster's discipline filter admits MS *because* it fits the constructive-impossibility shape (well-stated setting, external classical theorem, sharp no-go, characterized escapes); the honest scope-mark on most escapes being outside AAT canon is the segment's contribution, not a weakness. The three charter instances together illustrate the cluster's range — GS with one named adjacency, Arrow with one named adjacency plus one open avenue, MS with no current adjacencies but two open avenues.
-

Appendix AQ

Derivation: Social Welfare Aggregation Impossibility (Arrow)

The third charter instance of #disc-implementation-impossibility: Arrow 1951 (expanded 1963) forbids an external designer from constructing a social welfare function aggregating n agents' strict preference orderings into a single social preference ordering over ≥ 3 alternatives under unrestricted domain (U), Pareto efficiency (P), Independence of Irrelevant Alternatives (IIA), and non-dictatorial (ND). The AAT-side translation locates the agents as composite sub-agents whose individual preference orderings are derived from their objectives $O_i^{(i)}$, and maps the four classical escapes with *two* AAT-machinery adjacencies named: the preference-domain-restriction escape (single-peaked / single-crossing $\rightarrow$ Condorcet-consistent rules) is *adjacent to* sub-scope α' of #deriv-strategic-composition (the same adjacency #deriv-strategy-proofness-impossibility names), and the cardinal-preference escape (utilitarianism, range voting) is *adjacent to* #form-objective-functional's value-functional machinery — both adjacencies open avenues, not elevations to load-bearing. The contribution: two AAT-side adjacencies precisely mapped, with the cardinal-preference adjacency unique to Arrow (it does not appear in GS or MS) because Arrow's ordinal-only constraint is what AAT's value-functional formulation could in principle relax while GS's strategy-proofness regime is orthogonal to the ordinal/cardinal distinction.

Formal Expression.

Setting. Let A be a finite alternative set with $|A| \geq 3$, and let L denote the set of strict linear orderings on A . A **social welfare function** is a map $F : L^n \rightarrow L$ that aggregates n agents' strict preference orderings $R = (R_1, \dots, R_n) \in L^n$ into a single social ordering $F(R) \in L$ on the same alternative set.

Four constraints define the designer's regime:

[*Definition (unrestricted-domain, U)*] The map F is defined on all of L^n — every possible profile of strict preference orderings is a valid input.

[*Definition (pareto-efficient, P)*] If every agent strictly prefers a over b (i.e., $a R_i b$ for all i), then the social ordering puts a strictly above b ($a F(R) b$).

[*Definition (independence-of-irrelevant-alternatives, IIA)*] The social ordering's comparison of any pair (a, b) depends only on the individuals' comparisons of (a, b) — not on their comparisons involving any third alternative c . Formally: for any two profiles R, R' such that each agent ranks a and b the same way in R and R' , the social orderings $F(R)$ and $F(R')$ rank a, b the same way.

[*Definition (non-dictatorial, ND)*] No agent i^* such that for every profile R and every pair a, b with $a R_{i^*} b$ strictly, the social ordering $F(R)$ also puts a above b — i.e., no agent's strict preferences are imposed on society regardless of others.

External theorem.

Theorem (Arrow 1951, 1963). If $|A| \geq 3$, then no social welfare function $F : L^n \rightarrow L$ is simultaneously U, P, IIA, and ND.

Postulate (arrow-1951-1963, imported), exact.

References. Arrow, K. J. (1951, 2nd ed. 1963), *Social Choice and Individual Values*, Yale University Press. The expanded 1963 edition adds the simplified proof and discusses extensions. Modern proof structures: Geanakoplos, J. (2005), “Three brief proofs of Arrow’s impossibility theorem,” *Econ. Theory* 26:211–215; Reny, P. J. (2001), “Arrow’s theorem and the Gibbard-Satterthwaite theorem: a unified approach,” *Econ. Letters* 70:99–105 (geometric/topological unification with GS).

No-go. A designer demanding U + P + IIA + ND cannot construct the social welfare function. Any candidate F satisfying three of the four conditions violates the fourth.

AAT-side translation.

Within AAT’s composite-agent setting, the Arrow no-go translates as follows:

Derived (aat-social-welfare-translation, from ‘#scope-composite-agent’ + ‘#form-objective-functional’), conditional on the composite-aggregation-mechanism reading.

- The “agents” are *sub-agents* in a composite per #scope-composite-agent, each carrying its own objective $O_i^{(i)}$ inducing a preference ordering $R_i \in L$ over composite-level alternatives A (the joint outcomes reachable through the composite’s strategic-composition machinery). The ordinal preference R_i is the ordering induced by sub-agent i ’s value functional $V_{O_i^{(i)}}(\tau)$ on the alternative set A .
- A “social welfare function” $F : L^n \rightarrow L$ is a *meta-aggregation mechanism* the designer imposes — a rule that takes the sub-agents’ ordinal preferences (or reports thereof) and produces a single social ordering on A . The designer’s task is to choose F .
- The IIA condition is the load-bearing one structurally: it requires that the social comparison of a, b depend *only* on individuals’ ordinal comparisons of a, b , not on their comparisons involving any other alternative — an *ordinal-only* informational restriction.

The Arrow theorem then states: under U + P + IIA + ND, no such F exists. The designer faces a structural impossibility on what can be aggregated over the composite of sub-agents under ordinal-only information.

Boundary characterization.

Table AQ.1

<i>Escape</i>	<i>Mechanism-design / social-choice route</i>	<i>AAT machinery?</i>
Preference-domain restriction	Single-peaked preferences (Black 1948) admit Condorcet-consistent rules including the median voter; single-crossing extends this. Domain restriction circumvents U.	Adjacent to AAT machinery. Sub-scope α' of #deriv-strategic-composition (potential / monotone game structure) is <i>adjacent to</i> single-peaked / single-crossing — the same adjacency #deriv-strategy-proofness-impossibility names. <i>Not identical</i> : sub-scope α' secures best-response convergence in the composite-dynamics, not Condorcet-consistent aggregation in the welfare function.

<i>Escape</i>	<i>Mechanism-design / social-choice route</i>	<i>AAT machinery?</i>
Weakened IIA	Positional methods — Borda count (1781), range voting, Coombs method. Each uses ranks-and-positions across the full ordering, not just pairwise comparisons.	Outside AAT machinery. Positional aggregation is not in AAT canon.
Supermajority requirements	Replace simple-majority with k/n thresholds for $k > n/2$; admits constitutional / veto-respecting aggregators (e.g., the unanimity rule, two-thirds-majority rules).	Outside AAT machinery. Supermajority-thresholding mechanisms not in AAT canon.
Cardinal preferences	Relax ordinal-only IIA; allow social aggregation over cardinal utilities — utilitarian summation, weighted utilitarianism, range voting (treating ratings as cardinal). Sen 1970, <i>Collective Choice and Social Welfare</i> , Holden-Day, §3 gives the canonical treatment of cardinal-extension escapes.	Adjacent to AAT machinery. $\#form-objective-functional$'s value-functional $V_{O_t}(\tau)$ carries cardinal value content — the value functional is real-valued, not ordinal-only. <i>Not identical</i> : AAT's value-functional formalism is per-sub-agent and per-trajectory, not a designer-side aggregation rule across sub-agents; lifting to aggregator-form requires a representational choice (utilitarian summation, weighted utilitarianism, etc.) that AAT does not currently make canonical.

Strengthened consequence. Arrow is the cluster instance with *two* AAT-side adjacencies:

Adjacency 1: sub-scope α' $\leftrightarrow$ preference-domain restriction. Shared with $\#deriv-strategy-proofness-impossibility$. Sub-scope α' of $\#deriv-strategic-composition$ (potential / monotone game structure) is adjacent to the single-peaked / single-crossing preference-domain restriction that admits Condorcet-consistent rules. The adjacency-without-identity is the same as in GS: sub-scope α' guarantees best-response *convergence* under fixed preferences, not Condorcet-consistent *aggregation* in the welfare function. The two are structurally related (both restrict preference structure to admit aggregation/convergence guarantees on a one-dimensional issue space) but operate at different layers of the composite-agent dynamics.

Adjacency 2: cardinal preferences $\leftrightarrow$ $\#form-objective-functional$. This adjacency is *unique to Arrow* among the three charter instances — GS's strategy-proofness regime is orthogonal to the ordinal/cardinal distinction (the manipulation no-go applies to any social-choice function on preference orderings regardless of whether utilities are ordinal or cardinal); MS's bilateral-trade setting already operates over cardinal valuations v_b, v_s so the Arrow IIA escape doesn't apply. For Arrow specifically, the ordinal-only IIA restriction is what AAT's value-functional formulation could *in principle* relax — the value functional V_{O_t} is real-valued and carries cardinal information per sub-agent. The adjacency is *open*: lifting AAT's per-sub-agent value-functional to a designer-side aggregator (utilitarian summation, weighted utilitarianism, range voting) requires a representational choice AAT does not currently make canonical. The open avenue is whether AAT extends to a designer-side welfare-aggregation formalism via the value-functional's cardinal content; if it does, Arrow's cardinal-preference escape would gain AAT-machinery internal content.

The other two escapes (weakened IIA via positional methods; supermajority requirements) belong entirely to social-choice theory and are honestly documented as outside AAT canon.

Epistemic Status.

Exact for the imported theorem (Arrow 1951, 1963 — classical theorem with closed-form proof in the source literature; multiple modern proofs available, e.g., Geanakoplos 2005, Reny 2001; primary-source verification scheduled for promotion past draft).

Conditional for the AAT-side translation — the composite-aggregation-mechanism reading is the natural composite-agent translation; alternative readings (treating sub-agents as factor-coalitions in a richer game; treating the social ordering as a Σ -level commitment device) exist and would map Arrow into different AAT-side vocabulary.

Robust qualitative for the boundary characterization — two named adjacencies (sub-scope $\alpha' \leftrightarrow$ preference-domain-restriction shared with GS; #form-objective-functional $\leftrightarrow$ cardinal-preferences unique to Arrow); two outside AAT canon (positional methods, supermajority).

Max attainable: *Exact* for the imported theorem. *Derived conditional* for the AAT translation. *Robust qualitative* for the boundary characterization. The cardinal-preference adjacency could lift to *derived conditional* if AAT canonicalizes a designer-side welfare-aggregator construction over the per-sub-agent value functionals; that extension is open and would be its own framework-scope decision.

Discussion.

Why this is not a #disc-identifiability-floor instance. Same actor-positioning argument as GS and MS: the actor frustrated by the Arrow no-go is the *designer* (cannot construct a welfare function satisfying all four conditions), not an agent inferring from data. The escapes are *design-constraint relaxations* (relax U via domain restriction; relax IIA via positional methods or cardinal preferences; relax majority via supermajority), not information augmentations of an inferential regime. The cluster belongs in #disc-implementation-impossibility, not in the identifiability-floor.

The cardinal-preference adjacency is structurally unique to Arrow. Among the three charter instances of #disc-implementation-impossibility, only Arrow's IIA constraint produces a cardinal/ordinal distinction that AAT's value-functional formalism could engage. GS's strategy-proofness no-go applies regardless of utility cardinality; MS's bilateral-trade setting already operates over cardinal valuations. Arrow alone forbids aggregation under *ordinal-only* information, which is the constraint AAT's real-valued V_{O_t} could relax. The adjacency is *open* — AAT does not currently formalize a designer-side aggregator that consumes the per-sub-agent value functionals — but it is the open avenue most specifically illuminating about how the framework might engage social-choice theory in the future.

Peer voice with the social-choice literature. The imported theorem is classical; the proof structure (Arrow 1951 via the decisive-set / dictator-pivotal-position argument; Geanakoplos 2005's three brief proofs; Reny 2001's geometric/topological unification with GS) is mature. AAT does not re-prove the theorem; AAT does not displace the standard escape routes; AAT does not claim that the value-functional formalism solves social-choice theory. The segment's contribution is honest recognition of the two adjacencies — sub-scope α' (shared with GS) and #form-objective-functional's cardinal value content (unique to Arrow) — with the imported theorem cited under its original name and full bibliographic references.

Relationship to #form-objective-functional. The cardinal-preference adjacency raises an open question about the value-functional's downstream extension. #form-objective-functional formalizes $V_{O_t}(\tau)$ as the agent's value functional over trajectories; the cardinal content is *within-agent* (used for the agent's own choice). Arrow's cardinal-preference escape would lift this to *cross-agent* (used by a designer to aggregate across sub-agents). Whether such a lift is a natural extension of AAT or requires new framework machinery (a designer-side aggregator separate from the per-sub-agent value functional) is the open question. #deriv-reward-channel-learning-no-go (sister to #deriv-self-actuation-grounding) recognizes the *single-interface narrowness* of V_{O_t} at the within-agent layer; the parallel cross-agent narrowness question (whether V_{O_t} aggregates honestly across sub-agents) is structurally adjacent but not yet posed in canon.

Findings.

The Arrow Translation and Its Two AAT-Side Adjacencies. **Brief:** Arrow’s theorem says that no social welfare function — no rule for aggregating individuals’ preferences into a single social preference ordering — can simultaneously satisfy four reasonable demands: be defined for every possible profile (unrestricted domain), respect unanimous preferences (Pareto efficiency), depend on each pair only through how individuals rank that pair (independence of irrelevant alternatives), and not be dictatorial (no single individual always decides). The classical escapes have been studied for decades — restrict the preference domain (single-peaked preferences admit the median voter / Condorcet rules), use a positional method (Borda count, range voting), require supermajorities, or allow cardinal preferences (weighted utilitarianism rather than ordinal-only aggregation). The contribution here is two named adjacencies on the AAT side: the preference-domain-restriction escape is *adjacent to* sub-scope α' of the strategic-composition machinery — same adjacency as GS — and the cardinal-preference escape is *adjacent to* the framework’s value-functional formalism (which carries cardinal value content per sub-agent). The cardinal adjacency is structurally unique to Arrow: GS’s strategy-proofness is orthogonal to the cardinal/ordinal distinction; MS already operates over cardinal valuations. Both adjacencies are *adjacent without being identical* — open avenues if the framework extends in those directions, not current elevations of AAT machinery to load-bearing. The other two escapes (positional methods, supermajority) belong entirely to social-choice theory and are honestly documented as outside AAT canon. The map of where the framework meets Arrow is the contribution; the theorem is classical.

Impact: Closes the third charter-instance slot of #disc-implementation-impossibility with the cluster’s *richest* AAT-side adjacency map — two named adjacencies, one shared with GS (sub-scope $\alpha' \leftrightarrow$ preference-domain restriction) and one unique to Arrow (#form-objective-functional $\leftrightarrow$ cardinal preferences). The Arrow-unique cardinal-preference adjacency is the open avenue most specifically illuminating about how the framework might engage social-choice theory in the future: AAT’s per-sub-agent value functional V_{O_t} carries cardinal value content, and lifting it to a designer-side cross-agent aggregator (utilitarian summation, weighted utilitarianism) is the natural extension that would give the Arrow cardinal-preference escape AAT-machinery internal content. Whether such an extension is a natural growth of AAT or requires new framework machinery is the open question raised by the adjacency. Together with the GS instance (named adjacency, no open avenue) and MS instance (no current adjacency, two open avenues), the cluster’s three charter instances span the full range of how AAT meets the designer-side impossibility cluster.

Novelty Claim: *Claim recognition* of the AAT-side translation of Arrow’s theorem under the composite-aggregation-mechanism reading (sub-agents per #scope-composite-agent; preference orderings induced by per-sub-agent $V_{O_t(i)}$; designer-chosen aggregator F producing social ordering); *claim differentiation* on the cardinal-preference adjacency being structurally unique to Arrow within the cluster — GS’s strategy-proofness is orthogonal to the cardinal/ordinal distinction; MS’s bilateral-trade setting already operates over cardinal valuations; only Arrow’s ordinal-only IIA constraint produces a cardinal/ordinal distinction that AAT’s value-functional formalism could engage. The imported theorem is classical (Arrow 1951, 1963); the AAT-side translation, the two-adjacency boundary characterization, and the cardinal-preference adjacency as the Arrow-unique open avenue are the contributions.

Search Log:

- 2026-05-22 (*intuition-only* on the cardinal-preference adjacency): The cardinal-preference escape’s connection to #form-objective-functional is named here for the first time; the natural correspondence (AAT’s real-valued V_{O_t} carries cardinal value content per sub-agent; lifting to a designer-side aggregator is a representational choice) is intuitive but not derived. Targeted future search candidates: utilitarian and weighted-utilitarian social welfare functions (Harsanyi 1955, *J. Polit. Econ.* 63:309–321; Sen 1970 §3 cardinal-comparability spectrum); range voting and ratings-based methods (Smith 2000 and follow-ups); whether the per-sub-agent value functional’s cardinal content can be made canonically aggregable without introducing new framework machinery.
- 2026-05-22 (*intuition-only* on the composite-aggregation-mechanism reading): Same composite-revelation-mechanism reading as #deriv-strategy-proofness-impossibility. Alternative readings exist (treating F as a Σ -level commitment device; treating sub-agents as factor-coalitions in a richer cooperative game); not pursued here.

Working Notes.

- **Provenance.** Authored 2026-05-22 as commit 4 of the post-Track-CR Track-B cycle, executing spikes/implementation-impossibility-meta-segment-plan.md §4.c. The 2026-05-20 strengthen-first arm record at spikes/.integrated/spike-4th-identifiability-floor-instance-2026-05-20.md §5 flagged Arrow as a candidate instance of the sister meta-segment route.
- **Open before candidate.** (a) Primary-source verification of Arrow 1951 / 1963 — the theorem statement above is taken from the textbook syntheses and modern proof papers (Geanakoplos 2005, Reny 2001); direct primary-source reading is queued. (b) The cardinal-preference $\leftrightarrow$ #form-objective-functional adjacency is currently *robust qualitative* — there is no derived identification of AAT’s value-functional with a designer-side aggregator; lifting the adjacency to *derived conditional* would require either canonicalizing a designer-side welfare-aggregation construction over the per-sub-agent $V_{O_t(i)}$, or honestly determining that no such construction is natural within AAT’s current scope. Indexed at spikes/PROPOSED.md Tier 2 (added 2026-05-24) $\rightarrow$ spikes/PROPOSED-ADVANCED.md §Phase-3 #18 (two-branch spike: constructive lift first per strengthen-first; no-go branch as honest fallback). (c) The shared sub-scope- α' adjacency with #deriv-strategy-proofness-impossibility inherits the open-derivation flagged there: whether single-peaked preferences on an issue-space *derivably* induce a potential-game structure under best-response dynamics is the parameter-level identification question; if it lands, both GS and Arrow’s sub-

scope- α' adjacencies lift to *exact* simultaneously. Indexed at spikes/PROPOSED.md Tier 3 (added 2026-05-24) under #deriv-strategy-proofness-impossibility (the canonical home for the derivation; symmetric lift here).

- **The cluster's range, complete after this commit.** The three charter instances of #disc-implementation-impossibility now span the full range of AAT/mechanism-design boundary types: GS (one named adjacency, no open avenue), MS (no current adjacency, two open avenues), Arrow (one shared named adjacency, one Arrow-unique open avenue). That range is the cluster's epistemic content — the framework recognizes where its machinery contributes, where it sits adjacent, where it has open avenues, and where the boundary is outside entirely. The cluster's discipline filter admits all three; future candidate instances (Roberts 1979 affine-maximizers, Skalse 2022 reward-hacking) would be evaluated against the same filter in a future cycle.
 - **The Arrow-unique cardinal adjacency as the cluster's most-illuminating open question.** Among all the adjacencies and avenues across the three charter instances, the cardinal-preference $\leftrightarrow$ #form-objective-functional adjacency is the one most directly illuminating about how AAT might grow into mechanism design proper. The value functional already carries cardinal content per sub-agent; the only remaining structural question is whether cross-agent aggregation is a natural extension of the framework or requires distinct designer-side machinery. Flagging this here so future framework-scope decisions can engage the question with full provenance.
-

Appendix AR

Derivation: Fisher-Local Update Gain

Under the **Fisher-local invariance regime** — smooth log-likelihood admitting non-degenerate local quadratic expansion at the current model parameter, with single-step update at first order in the step size — the natural-gradient Bayesian posterior mean shift has the form $\Delta\theta = K \cdot \tilde{\nabla}$ with **gain operator** $K = (H_M + H_L)^{-1}H_L$ and **scalar collapse** $\eta^* = U_M/(U_M + U_o)$ along the natural-gradient direction in the commuting / shared-eigenbasis case (always in 1-D; under (PI)/Čencov in the natural-gradient direction in higher dimensions). The result derives the form #emp-update-gain carries as an empirical claim, places it in the Fisher-local regime as exact, and recovers linear-Gaussian (Kalman) and conjugate-Bayesian instances as cases where the local quadratic expansion is globally exact. Companion at the model-parameter-update layer to #deriv-fisher-whitened-update-rule’s edge-update derivation: that segment derives update *direction* under correlated evidence; this segment derives update *magnitude* under the Fisher-local regime. Both share the (PI) parameterization-invariance axiom from #scope-agent-identity and Čencov 1982 uniqueness as AAT-internal forcing for the Fisher metric.

The same scalar $\eta^* = U_M/(U_M + U_o)$ falls out of three independent structural derivations — local-Gaussian Laplace expansion, Bregman / KL projection onto the local tangent plane (Pythagorean projection in the Fisher metric), and Cramér-Rao / inverse-Fisher precision-additive composition. The agreement is not coincidence: the Fisher-local regime *is* the regime where prior and likelihood compose as a Pythagorean projection in the Fisher metric. The matrix-valued K is the natural object — its eigenvalues per coordinate are $\eta_i^* = u_{M,i}/(u_{M,i} + u_{o,i})$ — and it serves as the **per-coordinate primitive** for the tensor adaptive tempo of 3.8 (scalar tempo recovered in the shared-eigenbasis collapse; tensor form preserves per-direction information the scalar averages away). The downstream consumer at the persistence layer is #deriv-matrix-persistence-condition, where cross-dimensional correction makes the matrix-Loewner condition strictly sharper than per-coordinate.

Formal Expression.

Setup — Fisher-local quadratic regime.

Let $\theta \in \mathbb{R}^d$ parameterize the agent’s model and θ_t be the current point estimate (mode of the prior π_0 , or center of expansion). Three regime conditions:

Definition (Fisher-local regime, conditions (R1)–(R3)).

- **(R1) Smooth log-likelihood admitting non-degenerate local quadratic expansion.** $\log \pi_0$ and $\log p(o \mid \cdot)$ are C^3 in a neighborhood of θ_t , with prior precision $H_M := -\nabla^2 \log \pi_0(\theta_t)$ and observed information $H_L := -\nabla^2 \log p(o \mid \theta)|_{\theta_t}$ satisfying $H_M + H_L > 0$ (joint positive-definiteness; see §”Boundary admissibility” for why this is weaker than $H_M > 0$ and $H_L > 0$ both).

- **(R2) First-order-in-step-size regime.** The posterior update $\Delta\theta = \theta_{t+1} - \theta_t$ is small enough that $O(\|\Delta\theta\|^3)$ terms in the quadratic expansion are negligible compared to the quadratic terms.
- **(R3) Bayesian-coherent update.** θ_{t+1} is taken to be a coordinate of the posterior $p(\theta | o) \propto \pi_0(\theta) \cdot p(o | \theta)$ — mean, mode, or natural-parameter (they coincide for Gaussian posteriors, which is what the quadratic expansion produces).

Under (R1)–(R3), the local log-posterior is

$$\log p(\theta | o) = \text{const} + s^T(\theta - \theta_t) - \frac{1}{2}(\theta - \theta_t)^T(H_M + H_L)(\theta - \theta_t) + O(\|\theta - \theta_t\|^3), \quad (\text{AR.1})$$

where $s := \nabla_\theta \log p(o | \theta)|_{\theta_t}$ is the score. The posterior is approximately $\mathcal{N}(\theta^\star, (H_M + H_L)^{-1})$ with mean shift

Derived (posterior-mean-shift).

$$\theta^\star - \theta_t = (H_M + H_L)^{-1}s. \quad (\text{AR.2})$$

The AAT-vocabulary correspondences are

$$U_M := H_M^{-1}, \quad U_o := H_L^{-1} \quad (\text{AR.3})$$

— model uncertainty is the inverse prior precision, observation uncertainty is the inverse Fisher / inverse observed information (Cramér-Rao floor on what the observation pins down). The matrix forms generalize #emp-update-gain's scalar U_M, U_o in the natural way.

Gain decomposition on the natural-gradient direction.

The **natural gradient** of the log-likelihood at θ_t in the Fisher metric is

Definition (natural gradient at the current point).

$$\tilde{\nabla} \log p(o | \theta_t) := \mathcal{I}(\theta_t)^{-1}s. \quad (\text{AR.4})$$

For a single observation in the Fisher-local regime, $\mathcal{I}(\theta_t) = H_L$ up to the observed-vs-expected information distinction (standard under (R1)+regularity); the derivations below use H_L directly as the Fisher.

Rewriting the posterior mean shift in the natural-gradient direction:

Derived (gain-decomposition).

$$\Delta\theta = (H_M + H_L)^{-1}s = (H_M + H_L)^{-1}H_L \cdot (H_L^{-1}s) = K \cdot \tilde{\nabla}, \quad (\text{AR.5})$$

with **gain operator**

$$K := (H_M + H_L)^{-1}H_L. \quad (\text{AR.6})$$

The matrix-valued K is the natural object. The scalar collapse follows in the commuting / shared-eigenbasis case (always in 1-D; under (PI)/Čencov along the natural-gradient direction in higher dimensions): eigenvalues of K are

$$\eta_i^* = \frac{h_{L,i}}{h_{M,i} + h_{L,i}} = \frac{1/u_{o,i}}{1/u_{M,i} + 1/u_{o,i}} = \frac{u_{M,i}}{u_{M,i} + u_{o,i}} \quad (\text{AR.7})$$

per coordinate, collapsing to the scalar

$$\boxed{\eta^* = \frac{U_M}{U_M + U_o}} \quad (\text{AR.8})$$

— the form `#emp-update-gain` carries, derived from the Fisher-local quadratic expansion of prior and likelihood and applied to the natural-gradient direction.

Boundary admissibility — improper-prior and degenerate-likelihood directions.

The gain operator $K = (H_M + H_L)^{-1}H_L$ is well-defined whenever $H_M + H_L > 0$ — not necessarily when both H_M and H_L are individually positive-definite. This admits **degenerate-likelihood directions** (observation uninformative along some coordinates, H_L rank-deficient): K 's eigenvalue along those directions is 0, $u_{o,i} \rightarrow \infty$, $\eta_i^* \rightarrow 0$, no update along that direction — *trust the prior where the observation says nothing*. It also admits **improper-prior directions** (degenerate prior, $H_M = 0$ along some coordinate) when H_L pins the direction: $\eta_i^* \rightarrow 1$ along uninformative-prior directions where the observation is informative — *trust the observation where the prior says nothing*, the maximum-likelihood limit.

Derived (admissibility-of-degenerate-curvature).

The minimal regime condition is $H_M + H_L > 0$, with $U_M/(U_M + U_o)$ defined per-eigendirection by the appropriate limit. This corresponds to standard improper-prior admissibility in Bayesian inference and to standard observation-non-identifiability admissibility in maximum-likelihood estimation.

Recovery of linear-Gaussian and conjugate-Bayesian cases.

When the quadratic expansion in (R1) holds *globally* — not just locally — the derivation gives η^* without any expansion error. Two canonical cases:

Derived (global-exactness-special-cases).

- **Linear-Gaussian (Kalman).** Prior $\mathcal{N}(\theta_i, U_M)$, likelihood $\mathcal{N}(o; H\theta, U_o)$ with linear observation operator H : the log-posterior is exactly quadratic. The scalar Kalman gain $K = U_M H^T (H U_M H^T + U_o)^{-1}$ collapses to $\eta^* = U_M/(U_M + U_o)$ in the scalar case (Kalman 1960; Bishop 2006 §3.3). Exact globally.
- **Conjugate Bayesian (Beta-Bernoulli, Dirichlet-multinomial, Gaussian-Gaussian, exponential-family natural-parameter conjugacy).** Natural-gradient VI is the exact posterior update at step size 1 for conjugate families (Khan-Lin 2017 conjugate-computation variational inference). The Fisher-local expansion is globally exact in natural-parameter coordinates; $\eta^* = U_M/(U_M + U_o)$ holds exactly with U_M, U_o read from the conjugate sufficient-statistic precision counts.

For general smooth models, the natural-gradient invariance theorem of Amari 1998 guarantees that the natural gradient is parameterization-invariant; the Fisher-local quadratic expansion is the order at which the natural gradient and the exact posterior agree to first order in step size.

Epistemic Status.

Conditional. Max attainable: *exact* under (R1)–(R3) + (PI) parameterization-invariance from #scope-agent-identity. Under (PI) and Čencov 1982 uniqueness, the Fisher metric is the AAT-internally canonical metric on the statistical manifold (the 4th primary instance of #disc-additive-coordinate-forcing); the natural-gradient direction is therefore the AAT-internally canonical reference direction along which η^* reads as $U_M/(U_M + U_o)$. The textbook information-geometry result (Amari 1998 natural-gradient invariance theorem) is imported; the (PI)/Čencov forcing in #deriv-fisher-whitened-update-rule’s Path A makes the import AAT-internal.

Linear-Gaussian (Kalman) and conjugate-Bayesian instances are cases where the local quadratic expansion is *globally* exact, so $\eta^* = U_M/(U_M + U_o)$ holds without truncation error.

Outside the Fisher-local regime — heavy-tailed posteriors (no second moment), structurally non-smooth likelihoods, multimodal uncertainty where the local quadratic misrepresents global structure — the quantitative form is *not* derived here. The *qualitative* direction (gain rises with model uncertainty, falls with observation noise) is preserved as *robust qualitative* from #emp-update-gain’s broader empirical scope; the first-order form is recovered locally; what need not hold is global quantitative fidelity.

This segment depends on (PI) from #scope-agent-identity only. The triple (PI)+(R)+(K) of the Markov-morphism layer (carried by the Fisher-Rao bias-bound machinery; the (R) Riemannian-structure and (K) KL-second-order-matching axioms are stronger) is *not* invoked here. If (R) and (K) are asserted at the scope-level in a future cycle, this segment’s status remains conditional on (PI) alone unless explicitly extended.

Discussion.

Why read η^* off the natural-gradient direction. The Bayesian-coherent posterior mean shift $\Delta\theta = (H_M + H_L)^{-1}s$ is a fixed vector; its decomposition into “gain times reference direction” depends on the choice of reference direction. Two natural choices give two faces of the same shift:

- **Natural-gradient direction** $\tilde{V} = H_L^{-1}s$. Coefficient: $\eta_{\text{NG}}^* = H_L/(H_M + H_L) = U_M/(U_M + U_o)$. *AAT-internally canonical* under (PI)/Čencov — the Fisher metric is the unique Markov-invariant metric, so the natural gradient is the unique coordinate-invariant gradient direction (Čencov 1982; extended by Ay-Jost-Lê-Schwachhöfer 2017).
- **Prior-curvature-rescaled direction** $H_M^{-1}s$. Coefficient: $\eta_{\text{prior}}^* = H_M/(H_M + H_L) = U_o/(U_M + U_o)$. The *complement*; the same algebraic decomposition arises in Kalman literature as the prior weight in the convex combination “posterior = (1-K) prior + K observation.”

The two coefficients are duals on the same posterior shift; their product reduces to the posterior covariance $(H_M + H_L)^{-1}$. AAT names the natural-gradient coefficient as the canonical η^* because (PI)/Čencov picks out the natural-gradient direction as the unique coordinate-invariant choice.

Three derivation routes converge. The same scalar $\eta^* = U_M/(U_M + U_o)$ falls out of three independent structural derivations:

Table AR.1

Route	Lever	Surface meaning of η^*
Local-Gaussian Laplace expansion (§Setup–Gain decomposition above)	Algebraic completion of squares on additive log-posterior quadratics	Posterior mean shift coefficient on the natural-gradient direction

<i>Route</i>	<i>Lever</i>	<i>Surface meaning of η^*</i>
Bregman / KL projection onto the local tangent plane	First-order condition on the variational free energy along natural-gradient tilt	Projection coefficient of the posterior onto the local tangent plane (Pythagorean projection in Fisher metric per Amari-Nagaoka 2000 §3.2)
Cramér-Rao / inverse-Fisher	Precision-additive composition $1/U_M + 1/U_O$, inverted	Fractional observation contribution to posterior precision

The agreement is not coincidence: the Fisher-local regime *is* the regime where prior and likelihood compose as a Pythagorean projection in the Fisher metric — the same exponential-family / Bregman / Pythagorean structure underlying #deriv-strategy-cost-regret-bound's ρ -decomposition. The three routes are three faces of one geometric object: precision-additive composition of two Gaussian information sources, read off the natural-gradient direction.

Sibling positioning vs #deriv-fisher-whitened-update-rule. That segment lives at the **edge-update layer** of Part II's strategy DAG: it derives the Fisher-whitening correction for the *direction* of edge updates under correlated evidence (L1'/L2). This segment lives at the **model-parameter-update layer** of Part I: it derives the *magnitude* of the natural-gradient Bayesian update via the Fisher-local invariance regime. Both depend on (PI) + Čencov as the AAT-internal axiom forcing the Fisher metric. Together they make the Fisher-local invariance regime AAT-internally complete: direction (whitening) at the edge layer and magnitude (gain) at the model-parameter layer are both derived from the same axiomatic chain.

Special case of #deriv-adaptive-gain-dynamics' meta-gain framework. The gain operator $K = (H_M + H_L)^{-1}H_L$ is a *deterministic function of the current state* — it depends on the prior covariance H_M^{-1} (part of the agent's M_t state) and on the observation Fisher H_L (depends on θ_t and o). It is therefore the **deterministic-meta-gain** special case of #deriv-adaptive-gain-dynamics' (MG-1)–(MG-4) machinery: the meta-gain is determined by the primary state rather than independently learned. All four meta-gain conditions are satisfied trivially (symmetric-positive-definite K on the interior; smoothness for exponential families; bounded primary-meta coupling). Resolving the epistemic-opacity question that #def-observation-function axiomatizes — i.e., the agent does not know U_o a priori and must estimate it from its own mismatch sequence — is one level up: it adds the Mehra-style meta-channel that #deriv-adaptive-gain-dynamics treats as its primary instance.

Downstream tempo and persistence machinery. #emp-update-gain's Discussion §"Connection to adaptive tempo" names $\mathcal{T} = \nu \cdot \eta^*$. The derivation here promotes η^* 's tier from empirical / robust-qualitative (over the cross-domain validity tail — RL, PID, software-developer) to derived (conditional on Fisher-local regime) for the Kalman / conjugate / natural-gradient core. The tempo product $\mathcal{T} = \nu \cdot \eta^*$ inherits the regime distinction directly; the persistence-condition machinery (#result-persistence-condition, #result-sector-condition-stability) and the adaptive-tempo / aporia diagnostics (#def-adaptive-tempo, #def-aporia) all gain the tighter η^* exactness statement in their Fisher-local instances. The qualitative direction claim and the failure-mode framing (gain-collapse $\rightarrow$ epistrophe failure) survive unchanged outside the Fisher-local regime.

Tensor adaptive tempo connection. The matrix gain operator K is the per-coordinate primitive for tensor-valued adaptive tempo: $\mathcal{T} = \nu \cdot K$ as a matrix product, with the existing scalar $\mathcal{T} = \nu \cdot \eta^*$ recovered in the shared-eigenbasis limit. See #def-adaptive-tempo's Tensor extension.

Working Notes.

- **Multi-step extrapolation rate.** The Fisher-local exactness is a one-step statement. Iterating over many observations accumulates higher-order curvature error in the non-Gaussian / non-conjugate case. Bernstein-von Mises asymptotics (van der Vaart 1998 §10.2) give a $1/\sqrt{n}$ posterior concentration rate; whether η^* 's exactness inherits a matching $1/\sqrt{n}$ degradation outside Kalman / conjugate is an open quantitative-rate question. Open spike candidate.

- **Edgeworth higher-order correction.** The $O(\|\Delta\theta\|^3)$ correction to η^* in terms of third / fourth derivatives of the log-likelihood admits a standard Edgeworth-expansion treatment. Worth a follow-up spike if it becomes load-bearing for any AAT use case.
- **Variational-bound extension.** Under variational approximation $\text{KL}(q\|p) \leq \epsilon$, the gain inherits a Pinsker-tight degradation factor analogous to #deriv-variational-sector-condition's $O(\sqrt{\epsilon})$ B1 degradation. Composing this with the derivation gives η^* in sub-scope α' under approximate-posterior agents.
- **Multimodal posteriors.** When the prior or posterior is multimodal, the local-quadratic expansion around any one mode misses the global structure. Two natural moves: per-mode $U_M/(U_M + U_o)$ with mode-mixture weights as a separate state; or accept the qualitative direction claim only. Worth a follow-up spike if multimodal posteriors become load-bearing.
- **Consolidation / replay connection.** #form-consolidation-dynamics-style between-event consolidation drives U_M up (model uncertainty grows under offline replay via IB-gap reduction). The next online observation gets up-weighted because $U_M/(U_M + U_o)$ rises with U_M . This is the formal connection between consolidation-induced uncertainty growth and increased online responsiveness — worth tightening into a result if #form-consolidation-dynamics lands a quantitative form.
- **Honest obstructions.** (O1) The natural-gradient invariance theorem (Amari 1998) is imported, not derived; the (PI)/Čencov forcing in #deriv-fisher-whitened-update-rule's Path A makes the import AAT-internal. Without (PI), the natural-gradient direction is a chosen-not-forced direction and the derivation degrades to “the form on the chosen direction.” (O2) Single-observation per-step setup; multi-observation batches generalize mechanically ($H_L = \sum_i H_{L,i}$ for independent observations). (O3) Matrix vs scalar — the matrix K is the natural object; the scalar $U_M/(U_M + U_o)$ is its eigenvalue in the commuting / 1-D / shared-eigenbasis case. (O4) Step-size boundary qualitative; the actual Fisher-local cutoff depends on the third-derivative norms of $\log \pi_0$ and $\log p(o \mid \cdot)$. (O5) Robust-qualitative downstream survives outside the Fisher-local regime by the general structure of Bayesian updating, not by this derivation.
- **Cross-reference to Paper 3 chart-rescaling no-go.** The (PI) dependence is forced by the chart-rescaling no-go on Euclidean chart norms (NeurIPS 2026 Paper 3, “How Much Can LLMs Hallucinate?”, §4 Theorem 4.2 / #thm-no-go); outside (PI), no universal-constant claim survives. The natural-gradient direction inherits this forcing; the canonical-direction argument depends on (PI), not on (R) or (K) of the Markov-morphism triple. See spikes/neurips-back-integration-2026-05-08.md §1 Paper 3 entry #3 and the source ~/src/neurips/03-llm-hallucinate-bound/.
- **Landing context.** Landed in the 2026-05-12 audit-strengthening cycle (AAT-5); see CHANGELOG 2026-05-12. The load-bearing three-route convergence and boundary-admissibility content is in the Derivation and Discussion above; the originating spike is absorbed archaeology, not a live reference.
- **Downstream consumer at the persistence layer.** The matrix gain operator $K = (H_M + H_L)^{-1}H_L$ derived here is the per-channel primitive that #def-adaptive-tempo's Tensor extension aggregates into $\mathcal{T} = \sum_k \nu^{(k)}K^{(k)}$. The persistence-layer consumer is the matrix-Loewner persistence condition in #deriv-matrix-persistence-condition: under matrix $\mathcal{T}$ and matrix disturbance Σ_w , the agent persists iff $\mathcal{T}$ is Hurwitz and the stationary covariance Σ_∞ (solving $\mathcal{T}\Sigma_\infty + \Sigma_\infty\mathcal{T}^T = \Sigma_w$) is strictly Loewner-dominated by $D_\delta = \text{diag}(\delta_{\text{critical},k}^2)$. The matrix-Loewner form is *strictly sharper* than per-coordinate: under cross-dimensional correction (off-diagonal $\mathcal{T}$ — the generic Fisher-local case when prior and likelihood do not share the coordinate basis), per-coordinate gives a false-pass while matrix-Loewner reads persistence correctly off the worst direction.

Appendix AS

Derivation: Scope of Tempo Additivity — Redundancy, Synergy, and the Echo-Chamber Bound

The additive tempo formula $\mathcal{T} = \sum_k \nu^{(k)} \eta^{(k)*}$ (3.8) is exact when the observation channels carry cross-channel-independent noise, and its deviation from the true joint capacity under correlated noise is **signed**: correlated channels can deliver *less* joint information than the additive accounting claims (redundancy — the additive form overcounts) or *more* (synergy — correlated noise can be cancelled, and the additive form undercounts). This segment derives the exact deviation in the Fisher-local regime, proves the additive form is an exact upper bound with an explicit, closed-form redundancy penalty in the **common-source noise regime** (the “echo chamber”: a shared persistent bias contaminating several channels), proves an information-**saturation** theorem for persistent shared bias (no number of correlated channels buys information past the shared-bias floor), and establishes two no-gos: no sign-blind dependence measure (conditional mutual information, total correlation) can be the exact correction term, and no convention-free channel-local attribution of the deviation exists for three or more channels (the partial-information-decomposition obstruction). The joint tempo and the *total* deviation are canonical; per-channel corrected contributions are not.

Formal Expression.

Setup — the information reading of tempo.

Work in the Fisher-local / Gaussian location regime of [AR](#): environment parameter θ , model uncertainty U_M (posterior variance), channels $k = 1, \dots, n$ with independent Poisson event rates $\nu^{(k)}$ and per-event observations $o^{(k)} = \theta + n^{(k)}$, noise variance $U_o^{(k)} = \text{Var}(n^{(k)})$. Let $\mathfrak{F}$ denote the posterior-precision inflow rate delivered by the *optimal joint filter* (Fisher information about θ acquired per unit time). The **effective tempo** is the fractional uncertainty-contraction rate

Definition (effective tempo, Fisher-local regime).

$$\mathcal{T}_{\text{eff}} := -\frac{d}{dt} \log U_M(t) = U_M \cdot \mathfrak{F}, \quad (\text{AS.1})$$

the second equality since $\frac{d}{dt} (1/U_M) = \mathfrak{F}$. Single-channel consistency: $\mathfrak{F} = \nu/U_o$ gives $\mathcal{T}_{\text{eff}} = \nu U_M/U_o$, which agrees with $\nu\eta^* = \nu U_M/(U_M + U_o)$ to first order in the per-event information ratio U_M/U_o — the same first-order-in-step-size regime (R2) under which [AR](#) operates and under which tempo is a rate at all. All statements below are exact at the Fisher-information level and transfer to gain-form tempo at that order.

Additivity under noise independence.

If the channel noises are independent across channels and events (conditional independence of the pooled event stream given θ), scores add and score cross-covariances vanish, so Fisher information is exactly additive:

Derived (additivity-under-independence).

$$\mathfrak{F}_{\text{joint}} = \sum_k \nu^{(k)} \frac{1}{U_o^{(k)}} = \mathfrak{F}_{\text{add}} \implies \mathcal{F}_{\text{eff}} = \sum_k \nu^{(k)} \eta^{(k)*} \text{ (first order).} \quad (\text{AS.2})$$

Independence is **sufficient but not necessary** for equality (see the harmonic-mean hypersurface below).

Independent Poisson streams almost surely have no simultaneous events. If noise is *fresh per event* (i.i.d. across events), instantaneous cross-channel noise correlation is never sampled and additivity remains exact regardless of it. What breaks additivity is noise dependence **across events** — a persistent shared noise component. The redundancy question is governed by the ratio of the noise-correlation timescale to event interarrival times.

Derived (asynchrony refinement).

The exact deviation, and its indefinite sign.

For a synchronized batch (one event per channel, jointly Gaussian noise Σ_n , $(\Sigma_n)_{kk} = U_o^{(k)}$), the joint Fisher information and the deviation from additivity are

Derived (signed-deviation).

$$J_{\text{joint}} = \mathbf{1}^\top \Sigma_n^{-1} \mathbf{1}, \quad \Delta := \sum_k \frac{1}{U_o^{(k)}} - J_{\text{joint}}, \quad (\text{AS.3})$$

and for two channels with noise covariance c (writing U_1, U_2 for the variances):

$$J_{\text{joint}} = \frac{U_1 + U_2 - 2c}{U_1 U_2 - c^2}, \quad \Delta = \frac{c(2U_1 U_2 - c(U_1 + U_2))}{U_1 U_2 (U_1 U_2 - c^2)}. \quad (\text{AS.4})$$

$\Delta = 0$ iff $c = 0$ or $c = 2U_1 U_2 / (U_1 + U_2)$ (the harmonic mean of the variances — admissible whenever $U_1 \neq U_2$): equality holds on a strictly larger set than independence, with redundancy and synergy cancelling exactly. Δ has **no definite sign**:

- **Anti-correlated noise (synergy).** $U_1 = U_2 = \sigma^2, \rho < 0$: $J_{\text{joint}} = 2/(\sigma^2(1 + \rho)) > 2/\sigma^2$. Averaging cancels the noise; the additive form *undercounts*.
- **Positively correlated, heterogeneous variances (synergy).** $U_1 = 1, U_2 = 100, c = 9.9$: $J_{\text{joint}} = 81.2/1.99 \approx 40.8 \gg 1.01$. The noisy channel serves as a noise *reference*; the combination $o^{(1)} - (c/U_2) o^{(2)}$ nearly cancels channel 1's noise.
- **Nonnegative equal-variance correlation, $n = 3$ (synergy).** Correlations $\rho_{12} = \rho_{23} = 0.7, \rho_{13} = 0$ (positive-definite): $\mathbf{1}^\top R^{-1} \mathbf{1} = 10 > 3$.

So “correlated channels $\Rightarrow$ the additive formula overcounts” is false as a general claim; overcounting is the *redundant* half of a two-sided phenomenon whose other half is noise-cancelling synergy.

The echo-chamber regime — redundancy penalty and saturation.

Common-source noise model: $n^{(k)} = s + w^{(k)}$ with shared bias $s \sim \mathcal{N}(0, \sigma_s^2)$ and independent $w^{(k)} \sim \mathcal{N}(0, \sigma_{w,k}^2)$, so $\Sigma_n = \sigma_s^2 \mathbf{1}\mathbf{1}^\top + \text{diag}(\sigma_{w,k}^2)$. By Sherman-Morrison, with $q_k := 1/\sigma_{w,k}^2$, $q := \sum_k q_k$, and $f(x) := x/(1 + \sigma_s^2 x)$:

Derived (common-source-redundancy-penalty).

$$J_{\text{joint}} = f(q) \leq \sum_k f(q_k) = \sum_k \frac{1}{\sigma_s^2 + \sigma_{w,k}^2} = \sum_k J^{(k)}, \quad (\text{AS.5})$$

by strict concavity of f with $f(0) = 0$ (strict subadditivity), with equality iff $\sigma_s^2 = 0$ or at most one channel is active. The **redundancy penalty** is explicit and closed-form: $R_s = \sum_k f(q_k) - f(q) > 0$. In this regime the additive tempo *is* an exact upper bound on effective tempo, for arbitrarily heterogeneous channels.

If the shared bias s is **persistent across events**, every observation measures $\theta + s$ plus fresh noise: the pooled data identify $\theta + s$ at additive rate, but the posterior precision about θ itself is bounded for all time by $1/U_M^{(0)} + 1/\sigma_s^2$, since $\text{Var}(\theta \mid \theta + s) = (1/U_M^{(0)} + 1/\sigma_s^2)^{-1}$ and conditioning on the data is coarser than conditioning on $\theta + s$. Additive accounting claims precision growing without bound; the true joint information **saturates** at the shared-bias floor. No number of common-source channels, at any event rate, buys information past $1/\sigma_s^2$.

Derived (saturation-under-persistent-bias).

Two no-gos.

No exact correction of the form $\mathcal{J}_{\text{eff}} = \mathcal{J}_{\text{add}} - g(D)$ exists for any dependence measure D invariant under noise-correlation sign flip — conditional mutual information $I(e^{(1)}; e^{(2)} \mid M_{\tau-})$, total correlation (Watanabe 1960), or any such functional. Proof: ρ and $-\rho$ in the equal-variance two-channel family give identical Gaussian conditional mutual information $-\frac{1}{2} \log(1 - \rho^2)$ but different joint informations $2/(\sigma^2(1 \pm \rho))$. The deviation depends on the dependence *geometry*, not the dependence *strength*; the exact correction is the Fisher deficit Δ , which requires Σ_n , not a scalar dependence summary. Conditional mutual information survives as a **witness**: in the Gaussian location model $\Delta \neq 0 \Rightarrow I > 0$ (converse false on the harmonic-mean hypersurface), and in the common-source regime both I and R_s increase with σ_s^2 .

Derived (no-sign-blind-penalty).

A channel-local, convention-free additive decomposition of the joint information rate into per-channel redundancy-corrected contributions is the demand of the **partial information decomposition** program, and it is known not to exist in general: Williams & Beer 2010 define the redundancy lattice; Bertschinger, Rauh, Olbrich, Jost & Ay 2014 give the two-source unique-information measure; Rauh, Bertschinger, Olbrich & Jost 2014 prove no nonnegative decomposition on the Williams-Beer lattice satisfying the identity axiom exists for three or more sources; Barrett 2015 shows the Gaussian collapse of the main two-source candidates. Consequence: $\mathcal{J}_{\text{joint}}$ and the total deviation Δ are canonical and exact; “channel k ’s corrected tempo contribution” is not a well-defined quantity for $n \geq 3$, and any AAT use of one must declare its attribution convention explicitly.

Derived (no-canonical-channel-local-decomposition — imported).

Epistemic Status.

Conditional. The derivations are exact within the Fisher-local / Gaussian location regime of AR (conditions (R1)–(R3)) plus the stated noise models (jointly Gaussian batch noise for the deviation formula; the common-source structure for the penalty and saturation theorems); the transfer from Fisher-information statements to gain-form tempo is first-order in the per-event information ratio, the same regime in which tempo is a rate. Additivity-under-independence is general (standard Fisher additivity, not merely Gaussian); the counterexamples are exact and finite, computed in-segment. The two-source PID landscape and the $n \geq 3$ impossibility are imported results, cited by their real names; the mapping of the PID obstruction onto channel-local tempo attribution is AAT’s reading and is stated at that grade. Citation details for the imported PID results are flagged for primary-source verification before promotion past draft (see Working Notes). This segment supplies the derivation behind the channel-independence condition named in 3.8’s Epistemic Status; it *refutes* the previously asserted general upper bound (the deviation is signed) and *establishes* the bound on its true scope (common-source regime), so downstream uses of “additive tempo is conservative” are unsafe unless the common-source (or general nonpositive- Δ) structure is verified for the application.

Discussion.

What the correction to the prior assertion changes. The earlier claim — additive tempo is always an upper bound, equality iff channels informationally independent — read channel correlation as pure overlap. The derivation shows correlation is two-sided: overlapping *information* (common source) makes the additive form overcount, but correlated *noise* is also a resource — a correlated reference channel lets the filter cancel noise it could never average away, and then the additive form undercounts, potentially by large factors. Both directions matter for agent design: the redundant direction is the echo-chamber warning (diversity of observation *sources*, not count of observers), and the synergistic direction says a channel that is nearly useless in isolation (huge U_0 , negligible η^*) can be extremely valuable jointly — a reason to retain “bad” sensors that are correlated with good ones’ failure modes.

The echo chamber, quantitatively. The common-source saturation theorem is the formal content of the organizational intuition: three VPs reading one broken dashboard are one channel with extra steps, and past the shared-bias floor their combined reports carry zero marginal information about the world. A filter that *models* the channels as independent additionally manufactures false confidence — its internal U_M shrinks at the additive rate while true error stalls at the bias floor, driving $\eta^* \rightarrow 0$ while genuinely wrong: the gain-collapse pathology of 3.6 arrived at through mis-modeled channel structure rather than miscalibrated uncertainty [Discussion].

Why no simple penalty formula exists. The no-gos localize the obstruction precisely. A scalar dependence summary cannot carry the correction (sign-blindness), and a per-channel attribution cannot be made canonical for $n \geq 3$ (PID impossibility). What *is* available exactly: the joint object $\mathbf{1}^\top \Sigma_n^{-1} \mathbf{1}$ (tensor case: $A^\top \Sigma_n^{-1} A$) whenever the noise covariance structure is known or estimable, and the closed-form penalty on the common-source scope. This is a scope-precision result in the CS sense: the boundary of the additive form is now characterized rather than gestured at.

Anisotropy is orthogonal. With multivariate θ and channel maps A_k , cross-channel noise independence gives exact *matrix* additivity $\mathcal{J} = \sum_k \nu^{(k)} A_k^\top (\Sigma_n^{(k)})^{-1} A_k$ — channels “measuring different aspects” is handled by the tensor form of 3.8, not by redundancy corrections. Redundancy/synergy is an off-block-diagonal-noise phenomenon; anisotropy is an eigenbasis/observation-map phenomenon; the common-source subadditivity holds in the Loewner order by the same Sherman-Morrison-Woodbury argument.

Composition consequence. 15.1 inherits both directions: allied reports drawing on one upstream source are the common-source regime (additive communication tempo overcounts, saturating at the source’s bias floor), while allies with anti-correlated errors triangulate — a genuinely super-additive composition effect the additive accounting misses in the favorable direction.

Working Notes.

- **Citation verification before promotion.** The PID citations (Williams-Beer 2010 arXiv:1004.2515; Bertschinger-Rauh-Olbrich-Jost-Ay 2014 *Entropy* 16(4); Rauh et al. 2014 ISIT; Barrett 2015 *PRE* 91; Watanabe 1960 *IBM J. Res. Dev.* 4) are from literature memory and must be primary-source-verified (relata pass) before claims-verified. The mathematical content here does not lean on them — they scope the no-go's external grounding.
 - **Finite-correlation-time interpolation.** §Asynchrony gives the two exact endpoints (fresh noise: additive exact; persistent bias: saturation). The intermediate regime (noise correlation time comparable to interarrival times) should interpolate via an effective $\sigma_s^2(\nu)$; a small spike could make the crossover explicit (OU-process shared bias, exactly solvable).
 - **Loewner-order statement.** The tensor versions of the deviation and the common-source bound are asserted from the same arguments but not written out; mechanical, worth landing when a tensor-tempo consumer needs them.
 - **Attribution conventions.** If a downstream segment ever needs per-channel corrected contributions (e.g. for channel-investment decisions in TST), Shapley/sequential attribution over the ordered filter is the natural declared-convention candidate — flagged so the convention-dependence is chosen consciously, not rediscovered.
 - **Provenance.** Derived in spikes/spike-adaptive-tempo-redundancy-penalty-2026-07-15.md (full trail, counterexample arithmetic, ripple-site record). Ripple audit executed 2026-07-16 (full-ingestion pass incl. segment git histories): disc-independence-audit §3 repaired (2026-07-15, with the landing); der-team-persistence corrected (false upper-bound + MI-penalty claims deleted, two-sided scope + triangulation stated, depends added); def-strategic-tempo scope made explicit in Epistemic Status (no false claim existed there); der-tempo-composition WN corrected two-sidedly — sharper finding: the synergistic direction conditions the sub-additivity bound $\mathcal{T}_c \leq \sum \mathcal{T}_i$ itself (fusion over pooled raw observations can exploit cross-agent noise correlation), flagged there for a follow-on derivation; hyp-communication-gain corroboration WN re-pointed; the CMI-subtracting figure candidate in def-adaptive-tempo WN annotated as N1-refuted-as-drawn.

Appendix AT

Derivation: Matrix-Loewner Persistence Condition

Under matrix adaptive tempo $\mathcal{T}$ from #def-adaptive-tempo's Tensor extension (per-channel primitive $K^{(k)} = (H_M + H_L^{(k)})^{-1}H_L^{(k)}$ from #deriv-fisher-local-update-gain) and matrix disturbance covariance Σ_w , the operational persistence condition lifts from scalar to matrix-Loewner form: the agent persists iff $\mathcal{T}$ is Hurwitz (structural persistence) and the stationary covariance Σ_∞ — solving the continuous Lyapunov equation $\mathcal{T}\Sigma_\infty + \Sigma_\infty\mathcal{T}^T = \Sigma_w$ — is strictly Loewner-dominated by the diagonal of squared per-direction critical thresholds $D_\delta := \text{diag}(\delta_{\text{critical},k}^2)$. The matrix-Loewner condition $\Sigma_\infty < D_\delta$ recovers #result-persistence-condition's scalar Model S form as the isotropic special case and #result-per-dimension-persistence's per-coordinate form as the diagonal special case. Crucially, when $\mathcal{T}$ has off-diagonal entries that misalign with the coordinate basis — the generic situation under cross-dimensional correction — the per-coordinate condition is *unsafe*: it can declare persistence on systems whose stationary mismatch will exceed task-adequacy along the diagonal direction. The matrix-Loewner form is the canonical anisotropic persistence condition; per-coordinate is its diagonal- $\mathcal{T}$ -axis-aligned- D_δ special case, sharp where the coordinate basis happens to be the correction-machinery's eigenbasis and unsafe outside it.

The framework's posture is sharp: **scalar and per-coordinate forms are special cases; the matrix form is the load-bearing object the others project from.** A constructive 2D counterexample (symmetric $\mathcal{T}$ with cross-coordinate correction, isotropic disturbance and threshold) makes the unsafety concrete — per-coordinate evaluates the wrong directions, returning PASS where matrix-Loewner correctly returns FAIL with the failing direction running 45° off-axis. The result composes with the per-direction information-rate floor: no Shannon-type aggregation across dimensions compensates for one direction being capacity-starved (*bandwidth-per-direction is the binding quantity, not total bandwidth*). The cleanest current application is multi-modal AI pipelines with asymmetric per-modality channel budgets, where aggregate-rate metrics systematically miss directional failures the matrix-Loewner reading catches.

Formal Expression.

Setup — Model S with matrix correction.

Consider linear stochastic mismatch dynamics

Definition (matrix-Model-S-mismatch-dynamics).

$$d\delta_t = -\mathcal{T} \delta_t dt + \Sigma_w^{1/2} dW_t \tag{AT.1}$$

with $\delta_t \in \mathbb{R}^d$, matrix adaptive tempo $\mathcal{T} \in \mathbb{R}^{d \times d}$, disturbance covariance $\Sigma_w > 0$, and standard d -dimensional Brownian W_t . Per #def-adaptive-tempo's Tensor extension, $\mathcal{T} = \sum_k \nu^{(k)} K^{(k)}$ aggregates the per-channel matrix gain operators from #deriv-fisher-local-update-gain.

Stationary covariance — continuous Lyapunov equation.

The stationary distribution of the linear stochastic dynamics is Gaussian $\mathcal{N}(0, \Sigma_\infty)$, with Σ_∞ the unique positive-definite solution of the **continuous Lyapunov equation**

Derived (stationary-covariance, exact under Hurwitz $\mathcal{T}$ and $\Sigma_w > 0$).

$$\boxed{\mathcal{T} \Sigma_\infty + \Sigma_\infty \mathcal{T}^T = \Sigma_w.} \quad (\text{AT.2})$$

Existence and uniqueness of $\Sigma_\infty > 0$ are equivalent to $\mathcal{T}$ being **Hurwitz** — all eigenvalues having strictly positive real part. The closed-form integral representation is

$$\Sigma_\infty = \int_0^\infty e^{-\mathcal{T}t} \Sigma_w e^{-\mathcal{T}^T t} dt. \quad (\text{AT.3})$$

When $\mathcal{T}$ is symmetric and commutes with Σ_w , the solution simplifies to $\Sigma_\infty = \frac{1}{2} \mathcal{T}^{-1} \Sigma_w$. Otherwise the integral form (or any standard Lyapunov-equation solver) gives the stationary covariance.

The matrix-Loewner persistence condition.

The agent persists operationally iff:

Derived (matrix-persistence-loewner-Model-S).

(MP-1) Structural persistence. $\mathcal{T}$ is Hurwitz — equivalently, Σ_∞ exists as the unique positive-definite solution of the Lyapunov equation. This is the matrix analog of #result-persistence-condition's structural condition $\alpha > 0$ (Hurwitz reduces to $\mathcal{T}_0 > 0$ in the scalar case).

(MP-2) Matrix-Loewner task adequacy.

$$\boxed{\Sigma_\infty < D_\delta := \text{diag}(\delta_{\text{critical},k}^2)} \quad (\text{AT.4})$$

with $<$ the strict Loewner (positive-definite) order: $D_\delta - \Sigma_\infty > 0$. The stationary mismatch ellipsoid is contained strictly inside the per-direction critical-threshold ellipsoid.

The two conditions are independent in the same sense as #result-persistence-condition's structural-vs-task-adequacy split: (MP-1) is a property of the correction machinery alone; (MP-2) adds the domain-specific bound on per-direction tolerable mismatch.

Three equivalent restatements. The Loewner condition (MP-2) admits three equivalent forms:

(MP-2a) Per-direction. For every unit direction $\hat{v} \in \mathbb{R}^d$:

$$\hat{v}^T \Sigma_\infty \hat{v} < \hat{v}^T D_\delta \hat{v} = \sum_k v_k^2 \delta_{\text{critical},k}^2. \quad (\text{AT.5})$$

The projected stationary variance along $\hat{v}$ must be less than the direction-projected squared threshold along the same direction.

(MP-2b) Spectral. The generalized eigenvalue problem $\Sigma_\infty x = \lambda D_\delta x$ satisfies $\lambda_{\max} < 1$, equivalently

$$\lambda_{\max}(D_\delta^{-1/2} \Sigma_\infty D_\delta^{-1/2}) < 1. \quad (\text{AT.6})$$

The principal eigenvector identifies the *worst direction*; the eigenvalue's distance from 1 is the worst-direction safety margin.

(MP-2c) Ellipsoid containment. The stationary noise ellipsoid $\{x : x^T \Sigma_\infty^{-1} x \leq 1\}$ is contained strictly inside the threshold ellipsoid $\{x : x^T D_\delta^{-1} x \leq 1\}$.

The three are mathematically equivalent under standard matrix-analysis (Horn & Johnson 2013, §4.6 and §7). (MP-2a) is cleanest for hand reasoning, (MP-2b) for computation (single generalized-eigenvalue solve), (MP-2c) for geometric intuition.

Recovery of existing AAT persistence forms.

Table AT.1

<i>Special case</i>	<i>(MP-2) reduces to</i>	<i>Matches</i>
Isotropic ($\mathcal{T} = \mathcal{T}_0 I$, $\Sigma_w = \sigma_w^2 I$, $\delta_{\text{critical}} = \delta_0 1$)	$\sigma_w^2 / (2\mathcal{T}_0) < \delta_0^2$, i.e., $\mathcal{T}_0 > \sigma_w^2 / (2\delta_0^2)$	Scalar Model S form, #result-persistence-condition
Diagonal $\mathcal{T}$, Σ_w in the coordinate basis of D_δ	$\sigma_{w,k}^2 / (2\mathcal{T}_{kk}) < \delta_{\text{critical},k}^2$ per coordinate k	Per-coordinate Model S RMS, #result-per-dimension-persistence
Symmetric $\mathcal{T}$ commuting with Σ_w , general D_δ	Per-eigendirection inequality in $\mathcal{T}$'s eigenbasis, with direction-projected thresholds	New content recovered from the matrix form — extends per-coordinate to non-axis-aligned $\mathcal{T}$

The third row is the content #result-per-dimension-persistence does not currently carry: when $\mathcal{T}$ and Σ_w share an eigenbasis that is *not* the coordinate basis of D_δ , the per-coordinate form misses the right direction-projected thresholds and the matrix-Loewner form handles them correctly.

Where per-coordinate is unsafe — a constructive counterexample. The deeper structural question: is the matrix-Loewner form merely a generalization that agrees with per-coordinate in all real cases, or is it *strictly sharper* — does there exist a regime where per-coordinate says PASS but matrix-Loewner correctly says FAIL? The construction below establishes the latter: the per-coordinate form is **unsafe** under cross-dimensional correction.

Construction. Take $d = 2$, $\Sigma_w = I$, and

$$\mathcal{T} = \begin{pmatrix} 1 & -0.9 \\ -0.9 & 1 \end{pmatrix}. \quad (\text{AT.7})$$

This $\mathcal{T}$ is symmetric positive-definite with eigenvalues 1.9 (along $(1, -1)/\sqrt{2}$) and 0.1 (along $(1, 1)/\sqrt{2}$) — strongly anisotropic correction, with the $(1, 1)$ direction the weak axis. Per-coordinate naive reading of “diagonal of $\mathcal{T}$ ” sees uniform $\mathcal{T}_{11} = \mathcal{T}_{22} = 1$ and concludes correction is uniform at rate 1 on each coordinate.

Stationary covariance. Since $\mathcal{T}$ is symmetric, $\Sigma_\infty = \frac{1}{2}\mathcal{T}^{-1}\Sigma_w = \frac{1}{2}\mathcal{T}^{-1}$. Direct computation:

$$\Sigma_\infty = \frac{1}{0.38} \begin{pmatrix} 1 & 0.9 \\ 0.9 & 1 \end{pmatrix} \approx \begin{pmatrix} 2.63 & 2.37 \\ 2.37 & 2.63 \end{pmatrix}, \quad (\text{AT.8})$$

with eigenvalues 5.00 along $(1, 1)/\sqrt{2}$ and 0.26 along $(1, -1)/\sqrt{2}$.

Set $\delta_{\text{critical}} = (1.7, 1.7)$, so $D_\delta = 2.89 I$.

- *Per-coordinate check* (#result-per-dimension-persistence *form*): per-coordinate stationary variance is $\Sigma_{\infty, kk} = 2.63 < 2.89 = \delta_{\text{critical}, k}^2$ for each k . **Per-coordinate says PASS.** ✓
- *Matrix-Loewner check* (MP-2 *here*): worst-direction projected variance is $\lambda_{\max}(\Sigma_\infty) = 5.00$ along $(1, 1)/\sqrt{2}$. Direction-projected squared threshold along the same direction is $\hat{v}^T D_\delta \hat{v} = 2.89$. The condition $5.00 < 2.89$ fails. Equivalently, $\lambda_{\max}(D_\delta^{-1/2} \Sigma_\infty D_\delta^{-1/2}) = 5.00/2.89 \approx 1.73 > 1$. **Matrix-Loewner says FAIL.** ✗

Conclusion. Per-coordinate gives a false-pass. The agent will routinely produce mismatch vectors with RMS magnitude $\sqrt{5.00} = 2.24$ along the $(1, 1)/\sqrt{2}$ direction, exceeding the direction-projected threshold of $\sqrt{2.89} = 1.70$ on that direction. The per-coordinate analysis missed the diagonal direction because each coordinate alone stays within $\delta_{\text{critical}, k} = 1.7$ — the failure is *only* visible at the matrix-Loewner level. Cross-dimensional correction (the off-diagonal entries of $\mathcal{T}$) is what creates the diagonal-direction concentration that per-coordinate cannot detect.

Epistemic Status.

Conditional. Max attainable: *exact* under (i) Model S linear stochastic dynamics, (ii) Hurwitz matrix tempo $\mathcal{T}$, (iii) positive-definite disturbance covariance Σ_w , (iv) diagonal critical-threshold structure $D_\delta = \text{diag}(\delta_{\text{critical}, k}^2)$. The Lyapunov equation, the existence-iff-Hurwitz fact, and the matrix-Loewner equivalence forms are all standard from Bellman 1960 / Khalil 2002 / Horn-Johnson 2013; the AAT-distinctive content is the application to the persistence condition and the recognition that per-coordinate is strictly sharper-or-unsafe rather than uniformly sharper.

What is load-bearing:

- The matrix-Loewner form as the canonical anisotropic persistence condition, with scalar and per-coordinate forms as special cases recovered exactly.
- The strict-sharpness result via the §4 counterexample: per-coordinate gives a false-pass when $\mathcal{T}$ has off-diagonal entries that misalign with the coordinate basis. The per-coordinate form is not merely incomplete in this regime — it is unsafe.
- The three equivalent restatements (per-direction, spectral, ellipsoid-containment) with their different operational readings.
- The structural-vs-task-adequacy decomposition from #result-persistence-condition transfers directly: (MP-1) is the matrix structural condition (Hurwitz); (MP-2) is the matrix task adequacy (Loewner $\Sigma_\infty < D_\delta$). The two conditions remain independent — Hurwitz $\mathcal{T}$ does not imply $\Sigma_\infty < D_\delta$ for any particular D_δ , and conversely.

What is not established here:

- The nonlinear matrix-sector extension. Under sector-bounded $F(\mathcal{T}, \delta)$ with $\delta^T F \geq \alpha I$ in matrix-Loewner form, the matrix-Lyapunov machinery extends to give an ultimate-bound matrix; the linear case here is the template instantiation. Full matrix-sector treatment is follow-on work in #deriv-sector-condition.
- The Model D matrix lift. Under deterministic bounded disturbance $\|w_t\|_M \leq \rho$ in a quadratic norm, the ultimate-bound becomes an ellipsoid containment problem (a linear matrix inequality). Mechanical lift; not derived here.
- The non-Hurwitz boundary behaviour (eigenvalue exactly on the imaginary axis). Outside Hurwitz, the linear analysis fails — no stationary distribution. This matches the scalar case's $\alpha > 0$ requirement.
- The promotion of #result-adversarial-tempo-advantage to matrix form. The matrix-Loewner form sharpens the adversarial result via worst-direction targeting (an adversary controlling Σ_w^{adv} maximizes $\lambda_{\max}(D_\delta^{-1/2} \Sigma_w^{\text{adv}} \mathcal{T}_{\text{eff}}^{-1} D_\delta^{-1/2})$), but the full adversarial promotion is a separate cycle.
- The matrix extension of #deriv-persistence-cost's information-rate floor. The natural lift is $\dot{R} \geq \frac{1}{2} \text{Tr}(\mathcal{T})$ — per-eigendirection application of the scalar derivation. Worth a cross-reference Working Note in that segment if it becomes load-bearing; not derived here.

Discussion.

Why the Loewner form is the natural matrix lift. The Lyapunov equation $\mathcal{T}\Sigma_\infty + \Sigma_\infty\mathcal{T}^T = -\Sigma_w$ is itself a matrix-Loewner statement: it says Σ_∞ balances correction (via $\mathcal{T}$) against disturbance (via Σ_w) in the PSD ordering. The task-adequacy condition $\Sigma_\infty < D_\delta$ reads this balance against the threshold ellipsoid. The whole structure lives in the cone of positive-semidefinite matrices ordered by Loewner dominance; scalar persistence is its 1D shadow, per-coordinate persistence is its axis-aligned-diagonal shadow, and the matrix form is the load-bearing object the shadows project from.

The structural-vs-task-adequacy decomposition transfers. #result-persistence-condition's split — structural persistence (machinery works) vs task adequacy (machinery works well enough) — survives intact in the matrix lift: Hurwitz $\mathcal{T}$ is the matrix structural condition; Loewner $\Sigma_\infty < D_\delta$ is the matrix task-adequacy condition. The two are independent; an agent can have Hurwitz $\mathcal{T}$ (correction works in every direction) but fail Loewner on the worst direction (correction is not fast enough on the weak axis for the per-direction threshold). The remedies are different: structural

failure requires changing the correction architecture (#result-structural-adaptation-necessity); task-adequacy failure requires either increasing $\mathcal{T}$ on the weak direction, decreasing Σ_w on the weak direction, or relaxing the threshold along that direction.

The weak-direction-bottleneck argument transfers and sharpens. #result-per-dimension-persistence’s key insight — the weak dimension is the bottleneck — generalizes to the weak *direction* in the matrix lift: the worst eigenvector of Σ_∞ relative to D_δ is what gates persistence. When this eigenvector aligns with a coordinate axis, the per-coordinate analysis catches it. When it points off-axis — the generic situation under cross-dimensional correction — the per-coordinate analysis misses it. The §4 counterexample is the canonical illustration: the worst direction is $(1, 1)/\sqrt{2}$, off-axis from both coordinate directions; per-coordinate evaluates the wrong directions; matrix-Loewner evaluates the right ones.

Cross-coordinate correction is the generic case under Fisher-local invariance. The matrix gain operator $K = (H_M + H_L)^{-1}H_L$ from #deriv-fisher-local-update-gain is diagonal in the coordinate basis only when prior precision H_M and observation Fisher H_L share an eigenbasis aligned with the coordinate axes. In general — and certainly in the natural-gradient regime where the agent’s parameterization is statistical-manifold-natural rather than user-chosen — they do not, and K has off-diagonal entries. The matrix-Loewner condition becomes the canonical form for any Fisher-local-derived persistence analysis; the per-coordinate form is the exceptional case where prior, likelihood, and threshold all happen to share the coordinate axes.

Cross-reference to existing AAT machinery. The matrix-Loewner form composes with:

- #result-sector-persistence-template (T1)–(T3) as the linear-case template instantiation; the matrix sector inequality $\delta^T F + F^T \delta \geq 2\alpha I$ would extend the matrix-Lyapunov result to nonlinear F via the template’s (T2) condition lifted to matrix form.
- #deriv-sector-condition Prop A.1S (the Lyapunov-stochastic derivation underlying #result-persistence-condition’s scalar form) — the matrix derivation here is the analog at the matrix-Lyapunov level.
- #deriv-fisher-local-update-gain (matrix gain K as the per-channel primitive) and #def-adaptive-tempo (Tensor extension aggregating $\mathcal{T} = \sum_k \nu^{(k)} K^{(k)}$).

On the scope tag downstream. Until the broader promotion of #result-persistence-condition, #result-adversarial-tempo-advantage, #form-composition-closure, #der-team-persistence, #deriv-critical-mass-composition to invoke the matrix form directly, those segments continue to read scalar and inherit the “scalar / isotropic / nonredundant-channel scope” tag from #def-adaptive-tempo’s Epistemic Status. The per-direction primitive is in place; the downstream promotion is a follow-on cycle in TODO.md.

Working Notes.

- **Counterexample as load-bearing content.** Section 4’s $\mathcal{T} = \begin{pmatrix} 1 & -0.9 \\ -0.9 & 1 \end{pmatrix}$ example is the segment’s strongest content — it shifts the matrix-Loewner form from “interesting generalization” to “the safe condition; per-coordinate is unsafe under cross-dimensional correction.” The example uses the smallest nontrivial dimension ($d = 2$), the simplest non-diagonal symmetric $\mathcal{T}$ structure, and isotropic disturbance / threshold parameters. Generalizations to $d > 2$, asymmetric $\mathcal{T}$, and anisotropic Σ_w/D_δ are mechanical; the qualitative phenomenon (off-diagonal correction $\rightarrow$ diagonal-direction variance concentration $\rightarrow$ per-coordinate false-pass) is robust.
- **Empirical validation.** A 2D simulation matching the §4 parameters would confirm the predicted false-pass behaviour of per-coordinate: run the linear SDE with $\mathcal{T}, \Sigma_w$ from §4 for N steps; observe that the per-coordinate marginals stay within ± 1.7 most of the time (per-coordinate “passes”) while the diagonal-direction projection routinely exceeds ± 1.7 (matrix-Loewner “fails”). Mechanical simulation; would land cleanly under obs-section-i-validation-simulations as a new variant.

- **Open work — nonlinear matrix-sector.** The matrix-Loewner form is derived for linear correction. The nonlinear matrix-sector lift would replace the Lyapunov equation with the matrix-sector inequality $F(\delta) + F(\delta)^T \succeq 2\alpha\delta\delta^T/\|\delta\|^2$ (or a matrix-sector form derived from a quadratic Lyapunov function). Composes with #deriv-sector-condition's nonlinear scalar machinery via the matrix template; not derived here.
 - **Open work — adversarial extension.** The adversarial advantage exponent in #result-adversarial-tempo-advantage lifts to a matrix-eigenvalue-ratio exponent: an adversary controlling Σ_w^{adv} maximizes the bad-direction stationary variance via the matrix-Loewner form. Worth a follow-on derivation if #result-adversarial-tempo-advantage is promoted to matrix form.
 - **Open work — composition lift.** Composite stationary covariance Σ_∞^c solves the Lyapunov equation with composite $\mathcal{T}^c$ and Σ_w^c (aggregated from sub-agents); composite Loewner condition $\Sigma_\infty^c \prec D_\delta^c$ governs composite persistence. Promoting #form-composition-closure, #der-team-persistence, and #deriv-critical-mass-composition to invoke the matrix form is the natural next AAT-1 follow-on cycle.
 - **Landing context.** Landed in the 2026-05-12 AAT-1 follow-on cycle (matrix-Loewner persistence, succeed-beyond-claim); see CHANGELOG 2026-05-12 (late). The load-bearing derivation and counterexample are above; the follow-on extensions (Model D matrix lift, adaptive-gain matrix dynamics, variational matrix form) are flagged in the “Open work” notes here and in TODO. Originating spike is absorbed archaeology, not a live reference.

Appendix AU

Derivation: The Survival-Imperative Exploration Drive

The unified policy objective in `#disc-ci-y-unified-objective` combines pragmatic value Q_O with an epistemic exploration term (Causal Information Yield, CIY) weighted by $\lambda_{\text{info}} \propto U_M$. The logic is intuitive: explore when uncertain.

However, AAT’s underlying Lyapunov dynamics (`#result-persistence-condition`) force a *second, structurally distinct* exploration drive: the **Survival Imperative**. This segment derives that an agent must actively seek low-noise (high CIY) observations not just to learn, but to physically survive environmental drift when its model is *confident*.

AAT therefore carries **two parallel exploration drives at opposite ends of the uncertainty spectrum**: the standard epistemic drive scaling as $\lambda_{\text{info}} \propto U_M$ (explore when uncertain — dominant when model uncertainty is high), and the survival drive scaling as $\lambda_{\text{surv}} \propto 1/U_M$ (explore when confident in a drifting world — dominant when model uncertainty is low). The result *bypasses the dark-room critique of active inference* structurally rather than parametrically: an AAT agent in a drifting world physically cannot stop exploring because exploration is forced by the same Lyapunov machinery that grounds the rest of Part II, not by a tunable preference parameter. The operational prescription — *confident agents are not safe agents in drifting environments* — is the formal grounding for the “productive paranoia” heuristic about not resting on past success. The scalar form here admits a “blank-wall” attack resolved in AV by lifting to a Linear Matrix Inequality on the Fisher Information Matrix with a positive-semidefinite matrix Lagrange multiplier; the dual-drive picture survives the lift in matrix form.

The Persistence-Bounded Objective.

The agent’s primary goal is to maximize pragmatic value: $\max_{\pi} \mathbb{E}_{a \sim \pi}[Q_O(a)]$

The agent is subject to the structural persistence condition ($\alpha R > \rho^{\text{eff}}$), meaning it only survives if its steady-state mismatch $R^* < R$. Under Model D dynamics, $R^* = \rho^{\text{eff}}/(\eta^* c_{\min})$. Using the optimal update gain $\eta^* = \frac{U_M}{U_M + U_o}$, we can rewrite the survival constraint exactly: $\frac{U_M}{U_M + U_o} > \frac{\rho^{\text{eff}}}{R c_{\min}}$

Solving for U_o , we find the maximum observation noise the agent can tolerate without destabilizing: $U_o^{\max} = U_M \left(\frac{R c_{\min}}{\rho^{\text{eff}}} - 1 \right)$

This creates a strict constraint on the agent’s action selection: $\mathbb{E}_{a \sim \pi}[U_o(a)] \leq U_o^{\max}(M_t)$

The Tragedy of the Confident Agent.

Notice the proportionality: $U_o^{\max} \propto U_M$.

As $U_M \rightarrow 0$ (the agent becomes highly confident), $U_o^{\max} \rightarrow 0$. The survival constraint becomes infinitely tight.

If the environment is drifting ($\rho^{\text{eff}} > 0$), a confident agent inherently ignores noisy observations ($\eta^* \rightarrow 0$). To survive the drift, the agent *must* force an update. The only way to penetrate its own stubbornness is to generate an observation so pristine (low U_o) that the agent is forced to correct its course. Thus, a confident agent in a drifting world is *forced* to explore (seek low U_o) simply to survive.

Conversely, an uncertain agent (high U_M) has a loose constraint (large $U_o^{\max}$). It updates easily ($\eta^* \rightarrow 1$), so it can safely exploit noisy states without fear of structural collapse.

Deriving the Survival Lagrange Multiplier λ_{surv} .

Formulating the KKT Lagrangian for this constrained optimization: $\mathcal{L} = \mathbb{E}[Q_O(a)] - \lambda' \cdot (\mathbb{E}[U_o(a)] - U_o^{\max})$

Derivation (survival-exploration).

The shadow price λ' scales as $1/(U_o^{\max} - \mathbb{E}[U_o])$. At the boundary, $\lambda' \propto 1/U_o^{\max}$, yielding: $\lambda' \propto \frac{\rho^{\text{eff}}}{(Rc_{\min} - \rho^{\text{eff}}) \cdot U_M}$

To align this with the CIY objective, we invoke the structural assumption that Causal Information Yield is inversely proportional to observation ambiguity: $\text{CIY}(a) \propto 1/U_o(a)$. This scalar reciprocal mapping is a heuristic placeholder: the mathematically clean correspondence between the survival-imperative Lagrangian and the CIY/EIG objective is the LMI / matrix-valued lift in `#deriv-causal-ib-lmi`, where the Fisher Information Matrix and a positive-semidefinite Lagrange multiplier Λ replace the scalar substitution below. Readers tracking exactness rather than directional fidelity should treat the rest of this section as the scalar shadow of that LMI derivation; the *honest limit* sub-section below and `#deriv-causal-ib-lmi` together carry the formal load.

Transforming the Lagrangian penalty from U_o to $1/U_o$ (which introduces a non-linear mapping of the multiplier, operating-point dependent), the equivalent survival weight on CIY becomes: $\lambda_{\text{surv}}(M_t) \propto \frac{\rho^{\text{eff}}}{(Rc_{\min} - \rho^{\text{eff}}) \cdot U_M}$

Epistemic Status.

Derived (conditional). The derivation of the $U_o^{\max}$ bound and the KKT multiplier λ' is exact, conditional on the continuous-time Lyapunov bounds from `#result-sector-condition-stability`. The mapping to $\lambda_{\text{surv}} \cdot \text{CIY}$ is *heuristic*, conditional on the assumed structural relationship $\text{CIY}(a) \propto 1/U_o(a)$ and the non-linear transformation of the shadow price.

Discussion.

Two Parallel Exploration Drives. AAT dictates two correlated but distinct motivations for exploration, acting at opposite ends of the uncertainty spectrum: 1. **Epistemic Information Gain** ($\lambda_{\text{info}} \propto U_M$): Explored in `#disc-ciy-unified-objective`. The agent explores to reduce its model uncertainty. Dominates when U_M is high. 2. **Lyapunov Survival Imperative** ($\lambda_{\text{surv}} \propto 1/U_M$): Derived here. The agent explores to force high-fidelity corrections against environmental drift. Dominates when U_M is low.

Resolving the IB β vs ρ conflation. This derivation clarifies a structural tension in the standard IB formulation (`#form-information-bottleneck`). Standard IB natively discards old information as ρ rises because the joint distribution $P(\mathcal{C}_t, O_{t+1})$ decorrelates. The agent's *representational preference* (β) does not need to change. However, the agent's *action policy* is tightly coupled to ρ . As ρ increases, the survival constraint tightens ($U_o^{\max} \downarrow$), forcing the Lagrange multiplier λ_{surv} to spike. The environment dictates the representation natively; survival dictates the policy.

Connection to Active Inference. This derivation completely sidesteps the Active Inference “preferences-as-priors” assumption (the dark room problem). The survival exploration drive exists purely because failing to bound U_o mathematically guarantees structural collapse ($\alpha R < \rho^{\text{eff}}$). Exploration is derived as a physical survival imperative, not a psychological preference.

Honest limit: the scalar formulation admits a “blank wall” attack. The survival constraint as derived bounds the *scalar* observation-noise expectation $\mathbb{E}_\pi[U_o(a)] \leq U_o^{\text{max}}$ — it cares only about the magnitude of U_o , not its alignment with the directions in which ρ^{eff} is acting. In multidimensional environments where some coordinates of the drift are inactive, an action that selects an observation channel orthogonal to the drift (a constant signal — the “blank wall”) drives U_o to near-zero in that subspace and satisfies the scalar survival condition, while the agent’s prediction error in the drifting subspace grows without bound because the observations carry no information about the drifting coordinates. The scalar reduction collapses the dimensionality that matters.

The scalar derivation here remains correct in its scope (1D environments and isotropic-disturbance multidimensional environments where any low-noise observation suffices), and the qualitative dual-drive picture survives the lift to higher dimensions. The full multidimensional resolution — upgrading the scalar inequality to a Linear Matrix Inequality on the Fisher Information Matrix, with a positive-semidefinite matrix Lagrange multiplier Λ that distinguishes by direction rather than magnitude — is in `#deriv-causal-ib-lmi`.

Findings.

Survival-Imperative Exploration as Lyapunov-Forced Drive. Brief: A confident agent in a drifting world is mathematically forced to seek high-fidelity (low-noise) observations not because exploration is informationally valuable but because failing to do so violates the structural persistence condition and guarantees collapse. The maximum tolerable observation noise U_o^{max} scales with U_M — meaning the more confident the agent becomes, the tighter the survival-noise constraint becomes, and the more the agent is forced to actively seek low-ambiguity observations to penetrate its own stubbornness. The result identifies a second exploration drive ($\lambda_{\text{surv}} \propto 1/U_M$) structurally distinct from and complementary to the standard epistemic information-gain drive ($\lambda_{\text{info}} \propto U_M$), with the two acting at opposite ends of the uncertainty spectrum.

Impact: Provides AAT with a derivation of *why exploration is required* that does not route through epistemic-value-of-information arguments and therefore does not inherit the dark-room-problem objection that has dogged active-inference accounts. The survival imperative falls out of the same Lyapunov persistence condition that grounds the rest of Part II — exploration is forced by the same mathematics that forces the agent’s adaptive responsiveness, not added as a separate motivational layer. The dual-drive picture also resolves a structural tension in standard Information Bottleneck formulations between the representational β and the environmental drift rate ρ : the environment dictates representation natively (IB’s joint distribution decorrelates as ρ rises); survival dictates policy (the constraint tightens as ρ rises). The scalar form admits a “blank wall” attack, resolved in `#deriv-causal-ib-lmi` by lifting the constraint to an LMI on the Fisher Information Matrix; the dual-drive picture survives the lift in matrix form.

Novelty Claim: *Claim differentiation* on the structural source of agentic exploration. Active-inference work derives exploration from epistemic value inside expected free energy; bounded-rationality and information-cost frameworks derive exploration from utility-shaped information processing. This finding derives exploration from Lyapunov-persistence collapse — a structural-stability argument rather than a value-of-information argument — and identifies a second exploration multiplier inversely proportional to model uncertainty, complementary to the epistemic drive that scales directly with it.

Related Work:

- Friston, Rigoli, Ognibene, Mathys, FitzGerald & Pezzulo 2015, “Active inference and epistemic value,” *Cognitive Neuroscience* 6:187–214 (published 2015, found 2026-04 via Undermind Pillar 1 report) — *adjacent literature with structural contrast* — derives exploration from epistemic value inside expected free energy; the present finding’s exploration drive is forced by Lyapunov bounds rather than preferences-as-priors, sidestepping the dark-room objection.
- Friston, Samothrakis & Montague 2012, “Active inference and agency: optimal control without cost functions,” *Biological Cybernetics* 106:523–541 (published 2012, found 2026-04) — *adjacent literature* — broader active-inference framing within which the EFE epistemic-value account sits; same structural-vs-preference contrast.
- Ortega & Braun 2012, “Thermodynamics as a theory of decision-making with information-processing costs,” doi:10.1098/rspa.2012.0683 (published 2012, found 2026-04) — *adjacent literature* — bounded-rationality framework deriving exploration-like behavior from information-processing costs; the present finding derives a structurally distinct second drive (Lyapunov survival) without inheriting the bounded-rationality objective form.
- Genewein, Leibfried, Grau-Moya & Braun 2015, “Bounded Rationality, Abstraction, and Hierarchical Decision-Making,” *Frontiers Robotics AI* 2:27 (published 2015, found 2026-04) — *adjacent literature* — hierarchical extension of Ort12c; same structurally-different motivational source.
- Tishby, Pereira & Bialek 2000, “The information bottleneck method” (published 2000, found 2024) — *formal antecedent* — the standard IB formulation against which the β -vs- ρ tension is resolved; the survival imperative provides the missing policy-side coupling that standard IB does not natively carry.

Search Log:

- 2026-04 (*nominally comprehensive on the active-inference / bounded-rationality contrast*, via ref/Novelty_defense_and_integration.md Pillar 1): The Undermind report identified Friston 2015 as the canonical EFE-epistemic-value account against which this finding’s structural-stability source for exploration differentiates, and the Ortega/Genewein bounded-rationality line as the closest information-cost-shapes-policy precursor. The verdict on Pillar 1 as a whole was *Conceptual Precursor* (High confidence) for the no-go half (#der-causal-insufficiency-detection); the survival-imperative half is the constructive complement, framed as differentiation from epistemic-value exploration rather than as a no-go contribution.
- 2025 (*intuition-only*): Pre-Undermind expectation was that the closest priors would be in active-inference (Friston) and Information Bottleneck (Tishby) literatures; this was confirmed and refined by the comprehensive search.

Working Notes.

- **Empirical validation.** The derivation is validated in `empirica/track-b-nonlinear/variants/variant_causal_ib.py` (results: `variant_causal_ib_results.md`). In a highly volatile environment ($\rho = 0.5$) where exploitation produces ambiguous observations ($U_o = 100.0$), a purely greedy agent ($\lambda = 0$) suffers a 0% survival rate because its update gain collapses.
- **LMI generalization landed.** The multidimensional resolution is in `#deriv-causal-ib-lmi` (matrix Lagrangian on the Fisher Information Matrix; blank-wall attack resolved by complementary slackness on direction). Spike trail: `spikes/.integrated/spike-causal-information-bottleneck.md` §7 (critique) and `spikes/.integrated/spike-causal-ib-lmi-repair.md` (LMI derivation).
- **Cross-reference to NeurIPS Paper 1.** The survival-imperative drive is formalized at theorem grade in NeurIPS 2026 Paper 1 (“Tragedy of the Confident Agent: Forced Exploration for Survival in Drifting Environments”, `~/src/neurips/01-tragedy-confident-agent/`): (i) §3 Lemma 2.1(ii) supplies the worst-case finite **exit-time bound** $T_{\text{exit}}(\delta_0) \leq \frac{1}{\alpha+\gamma} \log \frac{\rho/(\alpha+\gamma)-\|\delta_0\|}{\rho/(\alpha+\gamma)-R}$

that the controller-design overshoot is justified against; (ii) §5 Mechanism Step 4 + Appendix-KKT resolves the **shadow-price / controller-divergence puzzle** — the static-program LP multiplier is finite, while the survival-margin controller's λ_{surv} divergence is a controller-design overshoot ensuring loop closure inside the exit-time window (divergence is on the environment-side clock, not the controller-side multiplier); (iii) §App-A.7 / #prop-fagp names the **F-A-G-P enforcement framework** (strict-Feasibility / drift-Aligned bonus / Gain dominance / argmax-Presentable) as the four-condition operational decomposition for valid survival-margin controller family members. See spikes/neurips-back-integration-2026-05-08.md §1 Paper 1 entries 1, 3, 4 for the cross-mapping.

Appendix AV

Derivation: Linear Matrix Inequality Form of the Causal-IB Survival Bound

In `#deriv-causal-ib-exploration`, the survival-imperative exploration drive was derived in scalar form: $\text{bound } \mathbb{E}_\pi[U_o(a)] \leq U_o^{\max}$ to keep the agent’s mismatch within survivable bounds. The scalar bound admits a “blank wall” attack — actions that minimize U_o in a subspace orthogonal to the drift (e.g., observing a constant signal uncorrelated with the environmental drift) satisfy the survival math without probing the drifting coordinates, and the agent’s prediction in those subspaces diverges unboundedly. This segment lifts the survival constraint to a Linear Matrix Inequality on the Fisher Information Matrix, replacing the scalar shadow price with a positive-semidefinite matrix Lagrange multiplier Λ that distinguishes by direction, not just by magnitude.

Under the matrix form, the action’s exploration bonus is the trace $\text{Tr}(\Lambda \cdot J_o(a))$, and complementary slackness on the directional constraint *mathematically zeros out the bonus for blank-wall actions*: the bonus structurally requires the agent to probe the drifting directions. The result converts the unified policy objective from heuristic to conditional-theorem-grade under the matrix-LMI form; the structural form is grounded in AAT’s physical survival bounds and standard semidefinite programming rather than treated as an ad-hoc heuristic. The same Fisher Information Matrix appears here in *three* structurally distinct framework loads — credit assignment (AM), coordinate forcing (5.5 4th instance), and now survival — because the framework’s coordinates are forced rather than chosen; this segment is the first explicit cross-instance composition where coordinate-forcing and survival interact within the same machinery. Composition with the persistence-information-rate floor sharpens: the floor names *what bandwidth must be met*; the LMI names *in what directions to spend it*. Without the LMI the bandwidth could be supplied in irrelevant directions; with it, complementary slackness routes the bandwidth toward the drifting modes — a directional version of the central inequality.

Formal Expression.

Multidimensional mismatch dynamics.

The mismatch state $\delta_t \in \mathbb{R}^n$ evolves under linear-Gaussian dynamics with action-dependent observation noise:

Definition (multidim-mismatch).

$$\delta_{t+1} = (I - K_t H) \delta_t + w_t - K_t v_t(a_t) \tag{AV.1}$$

where $w_t \sim \mathcal{N}(0, Q_p)$ is the environmental drift, $v_t \sim \mathcal{N}(0, R_o(a_t))$ is the observation noise for action a_t , and the optimal Kalman gain is $K_t = P_t H^T (H P_t H^T + R_o(a_t))^{-1}$ with P_t the agent’s prior uncertainty covariance.

The steady-state mismatch covariance Σ_δ satisfies the discrete-time algebraic Riccati equation. *Survival* requires the spectral bound

$$\lambda_{\max}(\Sigma_\delta) < R^2 \quad (\text{AV.2})$$

— the matrix lift of the scalar bound $R^* < R$ from #result-persistence-condition.

Fisher Information Matrix as matrix CIY.

For the linear-Gaussian observation model, the action-conditional Fisher Information Matrix is

Definition (matrix-ciy).

$$\mathcal{J}_o(a) = H^T R_o(a)^{-1} H. \quad (\text{AV.3})$$

Where the scalar formulation in #disc-ciy-unified-objective defined CIY as a surrogate satisfying $\text{CIY}(a) \propto 1/U_o(a)$, the multidimensional formulation identifies CIY directly with the action-conditional FIM. The $\text{CIY-}U_o$ surrogate-mapping layer of approximation in the scalar derivation is removed at this layer; the residual CIY-vs-EIG concern (FIM equals EIG-rate only under Gaussian-linear conditions) persists as before.

The information-form Kalman update is additive in the FIM:

$$P_{t+1|t+1}^{-1} = P_{t+1|t}^{-1} + \mathcal{J}_o(a_t), \quad (\text{AV.4})$$

where $P_{t+1|t} = A P_t A^T + Q_w$ is the prediction step that absorbs process noise. The simplification $P_{t+1}^{-1} = P_t^{-1} + \mathcal{J}_o(a_t)$ used in some passes refers to the information-update step alone; the full step adds the prediction contribution. The two coincide once the analysis is in steady state.

LMI survival constraint.

The discrete-time algebraic Riccati equation admits a stabilizing steady-state solution with $\lambda_{\max}(\Sigma_\delta) < R^2$ if and only if the action policy π provides Fisher information that dominates the unstabilizable modes of the system drift. Specifically, the policy must satisfy the Linear Matrix Inequality

Derived (lmi-survival).

$$\mathbb{E}_{a \sim \pi}[\mathcal{J}_o(a)] \succeq \mathcal{J}_{\min}(Q_\rho, A, R^2) \quad (\text{AV.5})$$

where $\mathcal{J}_{\min}$ is the symmetric positive-definite lower bound on the FIM required to keep the steady-state covariance's largest eigenvalue below R^2 . The closed form for $\mathcal{J}_{\min}$ as a function of (Q_ρ, A, R^2) is given by the steady-state DARE condition — standard control-theory machinery (Boyd, Ghaoui, Feron & Balakrishnan 1994 Ch. 3–5; Anderson & Moore 1979). AAT's contribution at this layer is the framing: $\mathcal{J}_{\min}$ enters as the *survival-imperative* Fisher-information floor, not as a controller-design parameter.

Tensor Lagrangian.

The agent maximizes pragmatic value under the LMI constraint:

Derived (tensor-lagrangian).

$$\max_{\pi} \mathbb{E}_{\pi}[Q_O(a)] \quad \text{s.t.} \quad \mathbb{E}_{\pi}[\mathcal{J}_o(a)] \geq \mathcal{J}_{\min}. \quad (\text{AV.6})$$

The Lagrangian for a matrix-inequality-constrained problem uses a positive-semidefinite matrix Lagrange multiplier $\Lambda \succeq 0$:

$$\mathcal{L}(\pi, \Lambda) = \mathbb{E}_{\pi}[Q_O(a)] + \text{Tr}(\Lambda \cdot (\mathbb{E}_{\pi}[\mathcal{J}_o(a)] - \mathcal{J}_{\min})). \quad (\text{AV.7})$$

KKT conditions are primal feasibility ($\mathbb{E}_{\pi}[\mathcal{J}_o(a)] \geq \mathcal{J}_{\min}$), dual feasibility ($\Lambda \succeq 0$), and complementary slackness ($\text{Tr}(\Lambda \cdot (\mathbb{E}_{\pi}[\mathcal{J}_o(a)] - \mathcal{J}_{\min})) = 0$). The optimal action selection rule is

$$a_t \in \arg \max_a [Q_O(a) + \text{Tr}(\Lambda \cdot \mathcal{J}_o(a))]. \quad (\text{AV.8})$$

The trace inner-product $\text{Tr}(\Lambda \cdot \mathcal{J}_o(a))$ is the **matrix exploration bonus** — the multidimensional analog of $\lambda_{\text{surv}} \cdot \text{CIY}(a)$ from the scalar derivation.

Resolution of the blank-wall attack.

By complementary slackness, Λ has support only in eigendirections where the LMI constraint binds — i.e., directions where the agent’s accumulated FIM sits at the threshold $\mathcal{J}_{\min}$. In non-drifting eigendirections of Q_{ρ} , $\mathcal{J}_{\min}$ contributes zero (no information needed there to survive), so Λ has zero weight in those directions.

Derived (blank-wall-resolution).

For a blank-wall action — high $\mathcal{J}_o(a)$ in a non-drifting eigendirection — the trace product $\text{Tr}(\Lambda \cdot \mathcal{J}_o(a))$ evaluates to zero: the action’s FIM eigenvalues lie outside Λ ’s support. The agent receives no exploration bonus for the blank-wall action, even though the action would satisfy the scalar magnitude bound. **The matrix Lagrangian distinguishes by direction, not just by magnitude**, mathematically forbidding the trivial-exploration solutions that the scalar form admitted.

Scalar reduction.

In the 1D case, H and $R_o(a)$ are scalars, $\mathcal{J}_o(a) = R_o(a)^{-1}$, and the LMI degenerates to the scalar inequality $\mathbb{E}_{\pi}[R_o(a)^{-1}] \geq \mathcal{J}_{\min}$ which, with $\mathcal{J}_{\min}^{-1} = U_o^{\max}$, recovers the scalar survival constraint of #deriv-causal-ib-exploration. The matrix multiplier Λ collapses to a scalar shadow price coinciding with λ_{surv} , and the matrix exploration bonus reduces to $\lambda_{\text{surv}} \cdot \text{CIY}(a)$. The multidimensional derivation is structurally consistent with — and properly subsumes — the scalar one.

Derived (scalar-recovery).

Tragedy of the Confident Agent — matrix form.

As the agent's prior covariance P_t shrinks in a particular eigendirection v , the agent's confidence in that direction grows. If v also has support in Q_ρ (a drifting eigendirection), the survival LMI requires $\mathcal{J}_{\min}$ to grow along v to compensate — a confident agent in a drifting direction must source information specifically along that direction, because its low P_t in v means its update gain is small there and slow to absorb new information. By complementary slackness, the matrix shadow price Λ develops a large principal eigenvalue along v , forcing the agent to choose actions whose $\mathcal{J}_o(a)$ has large support on v . The qualitative tragedy survives the lift: confident agents in drifting worlds are mathematically forced to probe the drifting eigendirections specifically, not just to minimize scalar noise.

Derived (matrix-confidence-tragedy).

Epistemic Status.

Derived (conditional). The structural derivation is exact under named conditions:

1. **Riccati stabilizability.** The discrete-time algebraic Riccati equation admits a stabilizing steady-state solution. Standard machinery: Boyd, Ghaoui, Feron & Balakrishnan 1994 §3–5 and Anderson & Moore 1979.
2. **Linear-Gaussian observation model.** The observation $o = Hx + v$ with $v \sim \mathcal{N}(0, R_o(a))$. Non-Gaussian or nonlinear models require local linearization or extended-Kalman treatment.
3. **Information-form Kalman in steady state.** The $\mathcal{J}_o$ -additivity used in the FIM update reflects the information-update step alone; the prediction step's $AP_tA^T + Q_w$ contribution is absorbed into the steady-state Riccati analysis. Transient regimes admit the constraint shape but with $\mathcal{J}_{\min}$ a function of the transient covariance.
4. **DARE-imported $\mathcal{J}_{\min}$.** The closed-form expression for $\mathcal{J}_{\min}(Q_\rho, A, R^2)$ via the DARE is theorem-imported standard control theory. AAT's contribution is the framing — $\mathcal{J}_{\min}$ enters as the survival-imperative FIM floor, with Λ as the directional exploration-bonus shadow price — not the DARE solution itself.

The matrix-CIY mapping ($\mathcal{J}_o(a)$ as multidimensional CIY) is more rigorous than the scalar version: where the scalar formulation needed $\text{CIY} \propto 1/U_o$ as an assumed structural mapping, the matrix formulation directly identifies CIY with the action-conditional FIM, removing one of the two layers of approximation in #disc-ci-y-unified-objective. The CIY-vs-EIG surrogate concern remains: FIM is the EIG-rate for Gaussian linear models but diverges from EIG under non-Gaussian or non-local conditions.

Discussion.

Connection to AAT's existing matrix-form machinery. The LMI repair sits naturally within several existing AAT components rather than being imported from outside:

- #deriv-fisher-whitened-update-rule derives Fisher-information-based credit assignment as AAT-internal under the (PI) parameterization-invariance axiom + Čencov 1982 uniqueness. The FIM appearing in the LMI is the same Fisher metric, used here for survival rather than for credit assignment — two roles for one geometric object.
- #disc-additive-coordinate-forcing lists Čencov-invariance as the 4th primary instance of the meta-pattern. The LMI's reliance on the FIM sits cleanly within that meta-pattern: the Fisher metric is forced by AAT-internal axioms, not adopted ad hoc.
- #result-contraction-template carries matrix-form sector machinery (Lohmiller-Slotine metric formulation) for Part III composition. The LMI's discrete-time Riccati is the control-theoretic analog of the contraction-metric framework — both are matrix-form sector conditions on multivariate dynamics.
- #def-adaptive-tempo will need a tensor extension to $\mathcal{T}$ for full alignment with this segment's directional structure; the LMI gives an explicit demand for tensor-valued adaptive rates.

Two parallel exploration drives — matrix lift. The scalar dual-drive distinction in `#disc-ci-y-unified-objective` ($\lambda_{\text{info}} \propto U_M$ epistemic vs $\lambda_{\text{surv}} \propto 1/U_M$ Lyapunov-survival) generalizes to two matrix-valued drives that compose additively:

- Λ_{info} : epistemic information-gain matrix scaled by P_t . Dominates eigendirections where P_t is large (high uncertainty in some direction) — agent explores to learn that direction.
- Λ_{surv} : Lyapunov survival-imperative matrix derived above, with eigenvalue support where the LMI constraint binds. Dominates when P_t is small along a drifting eigendirection — agent explores to track the drift it’s about to lose grip on.

The agent’s total exploration shadow price is $\Lambda_{\text{info}} + \Lambda_{\text{surv}}$, with the relative direction-by-direction weights set by where the agent sits in (P_t, Q_ρ) space.

Connection to Active Inference. Same dark-room sidestep as the scalar version: the matrix-form survival imperative is forced by Lyapunov bounds, not preferences-as-priors. The matrix lift sharpens the argument by ruling out the non-exploratory “blank wall” trivial solutions that the scalar form admitted.

Empirical signature. A 2D drift environment with separable drifting/non-drifting subspaces is the simplest test: a scalar-Lagrangian agent succumbs to blank-wall traps; an LMI agent — with Λ developing weight specifically in the drifting direction — must select actions whose J_o aligns with the drift. The directional discrimination is empirically visible in the agent’s action-selection histogram across the two subspaces.

Findings.

Matrix Lift of the Survival-Imperative Constraint via Fisher-Information LMI. **Brief:** Imagine an agent that’s supposed to track something changing but only checks for new information by staring at a blank wall. A scalar version of the survival argument would let this work — the agent satisfies “I gathered enough information” without gathering information about the thing that’s actually moving. This result fixes the math by making the argument directional: the agent has to gather information in the *directions* where the world is changing, not just gather some-information-anywhere. The scalar Causal-IB survival-imperative drive lifts to a Linear Matrix Inequality on the Fisher Information Matrix, with a positive-semidefinite matrix Lagrange multiplier Λ that distinguishes by direction. Complementary slackness mathematically forbids “blank wall” actions that satisfy the scalar bound by sourcing information in non-drifting subspaces. The fix uses Fisher-geometric machinery already AAT-internal via `#deriv-fisher-whitened-update-rule` and `#disc-additive-coordinate-forcing`’s 4th instance.

Impact: Closes a structural failure of the scalar derivation that admitted trivially-satisfying-the-math actions (constant signals, walls, etc.) without actually probing the drifting modes the agent must track to survive. The matrix lift demonstrates that the same Fisher geometric object plays multiple structurally-distinct roles — credit assignment via `#deriv-fisher-whitened-update-rule`, coordinate-forcing via `#disc-additive-coordinate-forcing`, and now survival via the LMI here. The “Tragedy of the Confident Agent” insight survives the lift in sharper form: the matrix shadow price’s eigenstructure picks out the directions where confidence has outpaced incoming information, mathematically forcing the agent to probe specifically those directions. The scalar reduction recovers `#deriv-causal-ib-exploration`’s constraint as the 1D special case, establishing structural consistency.

Novelty Claim: *Claim differentiation* on the directional discrimination of the survival-imperative exploration drive. The scalar finding in `#deriv-causal-ib-exploration` differentiated AAT’s structural-stability source for exploration from active-inference’s epistemic-value source; this finding sharpens that differentiation by ruling out the trivial-exploration solutions that the scalar form admitted, demonstrating that the structural-stability source is genuinely directional rather than scalar. The DARE-imported $J_{\min}$ and the matrix-Lagrangian KKT machinery are standard control-theoretic and convex-optimization apparatus; AAT’s contribution at this layer is the framing that places $J_{\min}$ as a survival-imperative Fisher-information floor and Λ as the directional exploration-bonus shadow price.

LMI / matrix-inequality formulation of stability constraints	Boyd, El Ghaoui, Feron & Balakrishnan 1994, <i>Linear Matrix Inequalities in System and Control Theory</i> , SIAM (published 1994, found 2025)	<i>formal antecedent</i> — adopted machinery; the LMI form, KKT for matrix-inequality-constrained optimization, and the DARE-imported stabilizability condition are standard control-theoretic apparatus
Discrete-time algebraic Riccati equation for steady-state Kalman survival	Anderson & Moore 1979, <i>Optimal Filtering</i> , Prentice-Hall (published 1979, found 2025)	<i>formal antecedent</i> — DARE provides the closed form for $J_{\min}(Q_P, A, R^2)$
Fisher Information Matrix as the natural geometric object for inference	Čencov 1982, <i>Statistical Decision Rules and Optimal Inference</i> (published 1982, found 2024)	<i>formal antecedent</i> — Čencov uniqueness forces the Fisher-Rao metric under (PI) parameterization-invariance, integrated AAT-internally via #disc-additive-coordinate-forcing's 4th instance
Exploration as epistemic-value drive (alternative motivational source)	Friston, Rigoli, Ognibene et al. 2015, “Active inference and epistemic value” <i>Cognitive Neuroscience</i> 6:187–214 (published 2015, found 2026-04 via Undermind Pillar 1 report)	<i>adjacent literature with structural contrast</i> — the matrix-form survival imperative is forced by Lyapunov bounds, not preferences-as-priors. The matrix lift sharpens the contrast by ruling out the non-exploratory blank-wall solutions that the scalar form admitted
Information-form Kalman filter / additive FIM update	Standard Kalman filter literature; Anderson & Moore 1979 (published 1979, found 2025)	<i>formal antecedent</i> — the additivity $P_{t+1 t+1}^{-1} = P_{t+1 t}^{-1} + \mathcal{I}_o(a_t)$ used in the LMI derivation is the information-form update step
Scalar survival-imperative drive being lifted	#deriv-causal-ib-exploration (AAT-internal, 2025)	<i>upstream segment being matrix-lifted</i> — the LMI repair preserves the dual-drive structure in matrix form ($\Lambda_{\text{info}} + \Lambda_{\text{surv}}$) and resolves the blank-wall structural failure flagged in the scalar segment's Discussion

Search Log:

- 2026-04 (*nominally comprehensive on the exploration-source contrast*, via ref/Novelty_defense_and_integration.md Pillar 1): The Undermind report on Pillar 1 (“Causal insufficiency and forced exploration”) established the active-inference EFE framing as the canonical alternative source for exploration drives. This finding's matrix-Lagrangian LMI is the directional sharpening of the scalar derivation in #deriv-causal-ib-exploration and inherits that segment's differentiation posture against EFE-style epistemic-value accounts.
- 2025 (*targeted*): Boyd et al. 1994 and Anderson & Moore 1979 confirmed as the formal antecedents for the LMI / DARE machinery; Čencov 1982 confirmed as the formal antecedent for the FIM-as-natural-geometric-object move via the (PI) axiom. AAT's contribution at this layer is framing rather than apparatus.
- 2025 (*intuition-only*): Pre-search expectation was that the LMI form and DARE machinery were standard and would not be novel apparatus; this was confirmed. The novel content is the placement — using the FIM as a survival floor rather than a controller-design parameter, and integrating directional exploration with the broader Fisher-geometric meta-pattern.

Working Notes.

- **Tensor adaptive tempo.** #def-adaptive-tempo now carries a Tensor extension sub-block ($\mathcal{T} = \sum_k v^{(k)} K^{(k)}$ with $K^{(k)} = (H_M + H_L^{(k)})^{-1} H_L^{(k)}$ from #deriv-fisher-local-update-gain) that gives the per-direction primitive this segment's LMI ma-

chinery needs. Promotion of the scalar persistence and adversarial-tempo results to invoke the tensor form directly (rather than per-coordinate scalars) remains queued — flagged in `TODD.md` under follow-on cycle work; the per-direction primitive is in place even if downstream summary results still read in scalar.

- **Worked 2D example.** A concrete 2D drift environment showing $\text{Tr}(\Lambda \mathcal{J}_o)$ distinguishing wall-channel from drift-channel actions would sharpen the blank-wall resolution. Queued.
- **2D simulation.** Generalization of `empirica/track-b-nonlinear/variants/variant_causal_ib.py` to 2D with separable drifting/non-drifting subspaces would empirically validate the matrix Lagrangian’s directional discrimination. Queued.
- **EIG vs FIM gap.** For non-Gaussian or non-local observation models, FIM diverges from EIG. The CIY-vs-EIG concern in `#disc-ci-y-unified-objective` Epistemic Status persists; the matrix lift removes the CIY- U_o surrogate but not the CIY-EIG surrogate.
- **Reasoning trail.** `spikes/.integrated/spike-causal-ib-lmi-repair.md` records the spike that surfaced the LMI repair from the scalar segment’s blank-wall critique.
- **Cross-reference to NeurIPS Paper 1.** The matrix-LMI lift is formalized at theorem grade in NeurIPS 2026 Paper 1 (“Tragedy of the Confident Agent: Forced Exploration for Survival in Drifting Environments”, `~/src/neurips/01-tragedy-confident-agent/`). The paper carries: (i) **Per-action LMI strengthenings** at §App-A.6 (`#thm-per-action-lmi`, `#thm-per-action-lmi-iid`) — pathwise survival under arbitrary action schedules with parallel high-probability bound via matrix-Chernoff concentration (`#lem-fim-concentration`), closing the pathwise-vs-expectation gap that this segment’s steady-state DARE form does not surface explicitly. (ii) **F-A-G-P enforcement framework** at §App-A.7 (`#prop-fagp`) — strict-Feasibility / drift-Aligned bonus / Gain dominance / argmax-Presentable, the four-condition operational decomposition for what makes a survival-margin controller a valid family member; the range-containment hypothesis $\text{range}(\Lambda) \subseteq \text{range}(\mathcal{J}_{\min})$ that denies blank-wall updates LMI-survival reward is the structural anchor. (iii) **Anisotropic-drift refinement** at §App-C — closed-form critical exponent p_{crit} for the $\Lambda \propto \mathcal{J}_{\min}^p$ rule, diverging as $\sigma_x/\sigma_y \rightarrow 1$; directional discrimination *rests on* anisotropic drift and the argmax flips at the isotropic limit. The scalar-isotropic case is the boundary where the matrix-LMI’s distinguishing power degrades to the scalar form. (iv) **2D Gaussian empirical anchor** with the `wall_extreme` ε -blank-wall action and the three-controller comparison (greedy / scalar / LMI) — the matrix-LMI controller selects drift-aligned probing actions and survives at 100% across drift levels at zero pragmatic reward (a *bistability* of the discrete action set, explicitly characterized in §App-B to prevent overclaiming as a smooth survival-vs-reward Pareto frontier) where scalar surrogates collapse to 0% via blank-wall degenerate updates. See `spikes/neurips-back-integration-2026-05-08.md` §1 Paper 1 entries 2, 3, 5, 6, 7 for the cross-mapping.

Appendix AW

Observation: The Authored-World Laboratory — Identifiability by Construction

AAT has one calibration laboratory it *found* — software, whose epistemic privileges are catalogued in #obs-software-epistemic-properties — and one it is *building*: a deterministic authored world (working name **vivarium**) in which the environment's law-content, state, noise, and disturbance rate are not merely observable but authored, so that every quantity the framework's results quantify over (ρ , U_o , δ_t , $\mathcal{T}$, per-dimension mismatch, $\|\delta_{\text{critical}}\|$) has ground truth at scale inside dynamics rich enough that toy-model simplifications are structurally unavailable. This segment is the canonical introduction of the authored-world laboratory, placed ahead of the framework's validation simulations because the standing intent is to re-run those simulations in it; later segments and simulation reports cite this segment rather than re-describing the system.

Formal Expression.

The authored world provides four structural properties, each the *built* counterpart of a *found* software property in #obs-software-epistemic-properties:

Empirical Claim (system properties, by construction; build-state caveat in Epistemic Status).

V1. Ground truth for every framework quantity. Law-content is an explicit versioned registry of law-articles (keyed, memoizable invocation units); state is canonical and content-addressed; the disturbance rate ρ is dialable per region (weather volatility, water-regime schedules); δ_{critical} has literal in-world meaning. Where software's inspectability is limited by the agent-side comprehension bandwidth (P1 there), the authored world's is limited only by the author's choice of instrumentation: identifiability holds **by construction** rather than by fortunate configuration.

V2. Authored coordinatization of the exogenous space. All stochasticity is a stateless pure function of a world seed and a coordinate/identity key — fated noise: genuine chance to any inside agent, deterministic lookup to the author. The aleatoric boundary's frame-relativity is thereby operational rather than philosophical, and the system realizes the central object of 7.7 — an explicit, held coordinatization of U — which makes **latent-anchored mechanism counterfactuals executable**: swap a law-article version, keep seed and keys, rerun. The separation theorem's demonstration experiment (a keyed law versus its key-permuted twin: indistinguishable at every hierarchy level, divergent under same-seed law-swap, with measurable disagreement mass) is runnable here and, at present, nowhere else available to the framework.

V3. Exact citation semantics. A claim validated in the authored world cites a specific world artifact — seed, generator versions, phase memo, intervention script — and content-addressed storage makes the citation exact and replayable to bit-identity. This is the conjunction (α) deterministic outcomes, (β) replay at commensurate cost, (γ) content-addressed immutable environment state, which #obs-software-epistemic-properties P2 identifies as jointly held, in current standard practice, by software alone — and names as a configurational uniqueness with exactly this falsifier: a simulator brought under content-addressed recording with commensurate replay cost. The authored world is that falsifier under deliberate construction; when its fidelity program completes, the “unique” in P2 becomes “one of two,” by design.

V4. A disturbance-rate schedule with a persistence reading. The world is built in phases, each running to convergence with its converged output promoted into fixed law for everything faster above it. The phase ladder is therefore a ρ -schedule: successive phases deliver environments of decreasing effective disturbance until agents of achievable tempo satisfy the persistence condition $\mathcal{T} > \rho / \|\delta_{\text{critical}}\|$ (4.5). An agent-bearing world is, in this reading, the terminal rung of a persistence ladder the authors descend deliberately.

Epistemic Status.

Discussion-grade as a whole, with the property claims empirical-by-construction and honestly dated. V1-V4 describe the system’s design and its verified build state as of 2026-07-16: the world is mid-Phase-3 (geology and hydrology converged with absolute-tolerance conservation tests; climate next; **agents not yet embodied**), so V1-V3 are live properties of the running system while V4’s agent-bearing terminus and everything downstream of the agent seam are design intent. Claims here about what the laboratory *will* offer AAT’s agent-level results are forward-looking and marked so; claims about determinism, keyed noise, content-addressing, and conservation-honesty describe running code. The Level-4 executability claim (V2) inherits *exact* semantics from 7.7; that the system realizes the required coordinatization is a fact of its architecture. This segment deliberately does not depend on the world’s agent layer existing: it introduces the laboratory, not results obtained in it.

Discussion.

Found versus built, and why the framework wants both. Software is the domain where the epistemic privileges happen to hold and a large practice already generates data inside them; the authored world is the domain where they hold because someone chose them, which buys three things software cannot: (a) *dialable* environment parameters — ρ can be scheduled, not merely measured; (b) *author-side access to the exogenous coordinatization* — software’s version control gives literal Level-3 access (P2 there), while fated noise gives literal Level-4 access, one full rung more; (c) freedom from the confound that software environments are themselves made of agent behavior. Conversely the authored world lacks software’s ecological validity — nothing in it ships to production — so results transfer with stated construction assumptions, exactly the transfer-assumption discipline TST names for cross-domain claims. The two laboratories are complements, not competitors: found breadth against built depth.

The standing simulation intent. The framework’s Part I validation simulations (AX) were built as standalone numerical models; the standing intent is to re-run them in-vivo in the authored world as its phases reach the relevant dynamics, converting each from a bespoke script into a cited, replayable world artifact per V3. This segment exists partly so that migration has a canonical anchor: simulation reports should cite the laboratory, not re-describe it.

Near-term experiments the laboratory makes cheap. Beyond the Level-4 demonstration (V2), two are flagged in adjacent segments: the GA-1 housing experiment (transition-law versus observation-law ignorance — the experimenter chooses whether to perturb T or h , directly testing the verified asymmetry from the epistemic-target work), and the behavioral $\hat{\kappa}_{\text{processing}}$ estimator at scale (same event under different goal states across thousands of agent-events with controlled priors) once the agent seam lands.

Ethics gate. Everything agent-seam-ward is gated by the authored world's own ethics front door, which is deliberately more conservative than this framework's volume-04 gates and binds program-wide; the laboratory's agent-level offers are sequenced behind it, not around it.

Working Notes.

- **Provenance and living bridge.** Canonical intro landed 2026-07-16 from the vivarium handshake work (same-day: the mechanism-counterfactual mapping). The living cross-project bridge — current build state, the four-thread Level-4 handshake, near/far offers — is `doc/vivarium.md` (repo-internal working doc, not citable from canon bodies; this WN pointer is the sanctioned breadcrumb). Vivarium-side twin: `~/src/archema-io/vivarium/feedback-from-asf.md` §Level-4 handshake; its ethics front door is `~/src/archema-io/vivarium/ETHICS.md`.
 - **Build-state re-verification.** The Epistemic Status's build-state sentence is dated 2026-07-16; re-verify against the vivarium tree before citing this segment's V-claims in any promoted result (mid-rebuild volatility is a known divergence zone per the program's incoherence ledger).
 - **Chronica link (forward, cross-volume).** A world's interventional history is a chronica in the exact sense of 04-eli-core's `#def-chronica` (ordinal, causal, append-only), and the world's fork/save machinery is the operational subject of the proposed `#hyp-checkpoint-forking-failure-modes` — the two should co-develop; kept as a WN forward pointer rather than a depends edge to preserve volume reading order.
 - **P2 uniqueness-claim maintenance.** When the fidelity program completes (γ at full strength), `#obs-software-epistemic-properties` P2's "unique in current standard practice" needs its by-then-true revision; a matching WN pointer lives there.

Appendix AX

Detail: Observation: Part I Validation Simulations

Six simulation variants validated, refined, and extended the analytical predictions from Part I, forcing regime splits and discovering scaling laws that the analytical derivations left ambiguous.

The simulations are **theory-shaping, not merely confirmatory** — three findings emerged from simulation that *forced refinements* to the analytical treatment: (1) the adversarial tempo exponent turned out to be regime-dependent (Model D vs Model S; coupling-dominant vs non-coupling-dominant), forcing the $b = 2 / b = 3/2 / b \rightarrow 1$ regime classification the linear ODE left ambiguous; (2) observation noise was found to gate adversarial advantage with optimal-gain partial recovery, a result that had no analytical treatment before the simulations; (3) per-dimension persistence emerged as load-bearing — anisotropic systems with gain varying across dimensions produced mismatch concentration on the weak direction that the scalar persistence condition systematically overestimated by up to 72%. The simulation program is treated as part of AAT's methodology rather than as external validation: where simulation surfaces something the analytical treatment misses, the analytical treatment is refined; where simulation confirms what the analytical treatment predicts, the result lifts in confidence.

Overview.

The track-b simulation program tested Part I's analytical predictions about mismatch dynamics, adversarial coupling, observation noise, correction function robustness, and anisotropic persistence. The simulations modeled discrete-time mismatch dynamics as AR(1) processes with five correction functions (linear, saturating, threshold/dead-zone, sigmoid, structural breakdown), sweeping parameter spaces across gain, disturbance rate, coupling strength, observation noise, and dimensional structure.

The simulations were theory-shaping, not merely confirmatory. In particular:

- The adversarial tempo exponent turned out to be regime-dependent (deterministic drift vs. stochastic noise, coupling-dominant vs. non-coupling-dominant), forcing a regime split that the mismatch ODE left ambiguous.
- Observation noise was found to gate the adversarial advantage, partially recoverable by optimal gain – a finding that had no analytical treatment before the simulations.
- The scalar persistence condition was shown to overestimate adaptive capacity by 72% in anisotropic systems, motivating the per-dimension persistence condition.

Variant Summary.

Table AX.1

<i>Variant</i>	<i>Disturbance Model</i>	<i>Tested</i>	<i>Key Finding</i>	<i>Theory Impact</i>	<i>Promoted Segment</i>
A	D (deterministic drift)	Deterministic drift coupling; coupling-dominance sweep	Exponent $b \rightarrow 2.0$ in coupling-dominant limit (confirmed at 1.999)	Validates Model D derivation ($b = 2$)	16.3
B	D+S (interpolation)	Drift-noise interpolation across correction functions	Smooth transition between drift ($b = 2.0$) and noise ($b = 1.5$) regimes; coupling dominance is the key qualifier, not drift vs. noise per se	Confirmed that the coupling-dominant condition is quantitatively load-bearing	16.3
C	S (stochastic AR(1))	Exponent vs. gain (η) in stochastic model	Exponent drops toward 0.5 as $\eta \rightarrow 0$ (away from coupling dominance at fixed q_{base}); discrete AR(1) exponent never exceeds 1.5	Validates Model S derivation ($b = 3/2$)	16.3
D	D vs. S (separated)	Exponent vs. base noise (q_{base}) at fixed η	Continuous ODE exponent $\rightarrow 2.0$ (Model D), discrete AR(1) exponent $\rightarrow 1.5$ (Model S), as $q_{\text{base}} \rightarrow 0$	Definitively separated the two asymptotes; validates both derivations	16.3
E	S (stochastic AR(1))	Observation noise; optimal gain validation	Observation noise collapses adversarial exponent from ~ 1.0 to ~ 0.2 ; Riccati-optimal gain restores it to ~ 0.4 ; 52% mismatch reduction at moderate noise	Observation quality gates tempo advantage; optimal gain (3.6) empirically validated	16.4
F	S (stochastic AR(1))	Multi-dimensional anisotropic correction; targeted adversarial attack	Per-dimension theory exact to 4 significant figures; scalar tempo overestimates by 72%; targeted attack amplifies advantage by 17%	Validates Model S per-dimension steady state	16.5
Hafez bridge	S (stochastic AR(1))	Bi-predictability P vs. AAT mismatch in adversarial and non-adversarial settings	P measures coupling architecture (scale-invariant); mismatch measures coupling performance; P is blind to adversarial dynamics	P and AAT mismatch are complementary diagnostics; H_b (agent opacity) has no direct AAT analog – potential gap for multi-agent work	–

Methodology.

Discrete mismatch dynamics. The environment follows a random walk $x_{t+1} = x_t + w_t$ with $w_t \sim N(0, q^2)$. The agent corrects via $\hat{x}_{t+1} = \hat{x}_t + \eta \cdot g(\delta_t)$, yielding the AR(1) mismatch process $\delta_{t+1} = (1 - \eta) \cdot \delta_t + w_t$ for linear g . This is the discrete-time analog of the mismatch ODE $d\|\delta\|/dt = -\mathcal{T} \cdot \|\delta\| + \rho$ from 3.9.

Parameter sweeps. Each variant swept its key parameter(s) across 7–20 values. Monte Carlo: 200 independent trials per parameter point, 10,000–20,000 timesteps per trial, with 2,000–5,000 step burn-in for steady-state convergence. Fixed random seeds for reproducibility.

Exponent fitting. Adversarial exponents were estimated by fitting $\log(\|\delta_B\|/\|\delta_A\|) = a + b \cdot \log(\mathcal{T}_A/\mathcal{T}_B)$ via weighted least squares, with weights inversely proportional to variance of each point's log-estimate. 95% confidence intervals via bootstrap (1,000 samples).

Correction functions. Five functions $g : \mathbb{R} \rightarrow \mathbb{R}$ were tested, all satisfying $g(0) = 0$ and $g'(0) = 1$: linear ($g(\delta) = \delta$), saturating ($g(\delta) = \delta/(1 + |\delta|/R)$), threshold ($g(\delta) = \delta \cdot \mathbf{1}[|\delta| > \epsilon]$), sigmoid ($g(\delta) = R \cdot \tanh(\delta/R)$), and structural breakdown ($g(\delta) = \delta \cdot \mathbf{1}[|\delta| < R_{\max}]$).

Simulation code (reproducibility). The full simulation suite — single-agent and two-agent initial simulations plus the four variant-extension drivers (A/B drift, C/D regimes, E/F extensions, Hafez bridge) and their per-variant result write-ups — is maintained as the project's reproducibility supplement and will be released as a citable code artifact at publication. The numerical outcomes that the body's findings rest on (steady-state formulas, the fitted exponents, the gating thresholds, the per-dimension errors) are stated self-contained in the tables and Key Findings below.

Key Findings.

The adversarial exponent is regime-dependent (now derived). The theory now distinguishes two disturbance models (Model D: bounded deterministic, GA-2; Model S: stochastic zero-mean, GA-2S), each producing a different steady-state scaling and therefore a different adversarial exponent:

- **Model D, coupling-dominant:** $\|\delta\|_{ss} = \rho/\mathcal{T}$. Adversarial exponent $b = 2$ (derived from Prop A.1; Variant A confirms at 1.999).
- **Model S, coupling-dominant:** $\|\delta\|_{rms} = \sigma_w/\sqrt{2\mathcal{T}}$ (from Prop A.1S). Adversarial exponent $b = 3/2$ (derived; Variants C-D confirm at 1.481).
- **Non-coupling-dominant:** Exponent degrades smoothly toward 1.0 (Model D) or 0.5 (Model S) as base disturbance grows relative to adversarial coupling.

A measured exponent of $b \approx 1.05$ corresponds to the non-coupling-dominant regime (stochastic-noise coupling at moderate coupling dominance), consistent with the regime classification rather than contradicting it. Variants A–D systematically map the full regime space and validate the derived exponents. See 16.3 for the full treatment.

Observation noise gates adversarial advantage. Adding observation noise σ_{obs} to the mismatch signal collapsed the adversarial exponent from ~ 1.0 to ~ 0.2 at $\sigma_{obs} = 10 \times q_{env}$ (fixed gain). The Riccati-optimal gain (3.6) partially restored the advantage to ~ 0.4 , more than doubling it but not recovering the noise-free level. The optimal gain helps most in the moderate-noise regime, where it achieved a 52% mismatch reduction over fixed gain. See 16.4.

Per-dimension persistence is exact; scalar overestimates. In a 3-dimensional system with 5:1 gain variation across dimensions, the per-dimension AR(1) steady-state prediction matched simulation to 4 significant figures. The scalar persistence condition overestimated aggregate mismatch by 72%, because it averages across dimensions while the weak dimension dominates the L_2 norm. Isotropic gain allocation reduced overall mismatch by 13%; targeted adversarial attack on the weak dimension amplified the mismatch ratio by 17%. See 16.5.

Nonlinear correction creates thresholds, not lower exponents. Under deterministic drift, saturating, sigmoid, and breakdown correction functions did not simply reduce the adversarial exponent. Instead, they produced catastrophic divergence when disturbance exceeded the correction capacity ($\rho > \mathcal{T} \cdot R$). This is the persistence threshold failure from 4.5, observed directly in simulation. The measured “exponents” above 3.0 for these functions were divergence artifacts, not meaningful scaling laws.

Hafez bridge: architecture vs. performance. Bi-predictability P (Hafez et al.) measures the informational architecture of agent-environment coupling; AAT mismatch measures the operational performance. In adversarial settings, P remained nearly constant (~ 0.268) across a 10:1 range of opponent tempo, while the mismatch ratio varied from 0.54 to 5.95. P is scale-invariant after z-score normalization, making it insensitive to adversarial dynamics. The two metrics are complementary: P diagnoses whether the coupling structure is sound; mismatch predicts how well it performs.

Epistemic Status.

Empirical. Simulation results are reproducible under fixed random seeds; the driver code and per-variant write-ups are maintained as a reproducibility supplement to be released as a citable code artifact at publication. The key results – regime-dependent exponents, observation noise gating, per-dimension exactness – have been promoted to first-class segments (16.3, 16.4, 16.5) with their own epistemic assessments. This appendix serves as reference for the simulation program as a whole.

Discussion.

Internal validation, not external. The simulations operate in the model’s own terms: AR(1) processes with parameterized correction functions, Gaussian noise, and discrete-time dynamics. They validate the mathematical predictions within the model – confirming that the analytical steady-state formulas, the exponent regimes, and the per-dimension theory are correct as statements about these stochastic processes. The gap between “the math predicts X within its own model” and “real agents exhibit X” remains an empirical question for each domain.

What the simulations did not test. The simulations did not test whether the AR(1) mismatch dynamics are a good model for any particular real-world adaptive system. They also did not test cross-dimensional coupling (off-diagonal correction), non-Gaussian disturbances, non-stationary parameters, or multi-agent composition dynamics. The interaction between observation noise and the deterministic-drift exponent regime ($b = 2.0$) was not tested – Variant E used stochastic coupling only.

Theory-shaping role. The most important contribution of the simulations was not confirming predictions but forcing the theory to be more precise. The regime split in the adversarial exponent, the observation-noise gating mechanism, and the per-dimension bottleneck effect were all findings that the analytical derivations initially left ambiguous or unaddressed. The simulations forced the disturbance model split (Model D vs. Model S), which in turn enabled the analytical derivation of both exponents. The simulations now serve as validation of the derived results: Variant A validates $b = 2$ (Model D), Variants C-D validate $b = 3/2$ (Model S), Variant F validates the Model S per-dimension steady state.

Part V

Appendices: Operational Domains

Appendix AY

Detail: Operationalization — Estimation Procedures

Estimation recipes for core AAT quantities, bridging the measurement gap between formal objects and practical deployment.

The segment is **domain-honest** about which quantities are easily measured and which are operationally challenging: model uncertainty admits predictive-posterior / ensemble-spread / Bayesian-NN estimators; observation uncertainty admits channel calibration or residual variance; mismatch magnitude is directly measurable from prediction-versus-observation residuals; tempo from event rate times effective gain; the sector parameter via either the gain-sector bridge (where applicable — Bayesian on exponential families; gradient on strongly convex) or empirical correction-rate-vs-mismatch regression; disturbance parameters split per Model D ($\hat{\rho}_{\text{det}}$) versus Model S ($\hat{\sigma}_w$) with sequential dependence on $\hat{\mathcal{T}}$; critical-mismatch tolerance is a *domain parameter* not an estimated quantity (it encodes “how wrong can the model be before actions become harmful or ineffective?”). Model-class fitness is named as particularly challenging — not directly computable, requiring search across the model class; the observable signature is persistent mismatch despite adequate learning. Satisfaction gap and control regret require evaluating attainability, generally intractable in exact form. AAT’s commitment is that the abstract machinery is operationalizable with stated quality trade-offs at each estimation step, not analytical idealization with no path to practice.

Measurement Targets.

Table AY.1

<i>Quantity</i>	<i>Role in AAT</i>	<i>Typical unit</i>	<i>Minimum data needed</i>
U_M	Model uncertainty (3.6)	domain-specific variance/entropy	Predictive posterior or ensemble spread
U_o	Observation uncertainty (3.6)	sensor variance/noise scale	Channel calibration or residual variance
$\rho_{\text{det}}(t)$	Mismatch injection rate bound, Model D (3.9)	surprise per time	Time-series of mismatch magnitudes; worst-case bounds
σ_w	Disturbance noise scale, Model S (3.9)	surprise per $\sqrt{\text{time}}$	Mismatch innovation variance (residual after correction)
ρ_{delib}	Local mismatch drift during pauses (4.1)	surprise per time	Deliberation windows with no corrective action
α	Lower correction efficiency bound (4.4)	inverse time	Vector mismatch trajectories + correction term

<i>Quantity</i>	<i>Role in AAT</i>	<i>Typical unit</i>	<i>Minimum data needed</i>
R	Radius where local sector condition holds (4.4)	surprise magnitude	Same as α , plus breakdown detection
$\ \delta_{\text{critical}}\ $	Functional adequacy threshold (4.5)	surprise magnitude	Task-level performance curve vs mismatch

Estimator Cookbook.

Estimating U_M and U_o . Use the most native uncertainty representation available in the domain:

Table AY.2

<i>Domain</i>	<i>U_M estimator</i>	<i>U_o estimator</i>
Kalman / linear Gaussian	Prior predictive variance $P_{t t-1}$	Measurement-noise variance R_t (known or EM-estimated)
Conjugate Bayes	Posterior variance / inverse effective sample size	Likelihood variance (or precision inverse)
RL with ensembles	Across-head predictive variance $\text{Var}_t[Q_t(s, a)]$	TD-target noise variance over replay batches
Neural net regression	Ensemble or Laplace posterior variance	Aleatoric head output $\sigma^2(x)$
PID / classical control	State-estimation covariance from observer	Sensor noise from calibration + residual PSD

For the scalar gain heuristic (3.6), normalize to common units and compute:

Operational Definition.

$$\hat{\eta}_t^* = \frac{\hat{U}_{M,t}}{\hat{U}_{M,t} + \hat{U}_{o,t}} \quad (\text{AY.1})$$

Estimating Disturbance Parameters (ρ_{det} , σ_w , ρ_{delib}). The disturbance model split (Model D vs. Model S; see 3.9, 4.4) requires different estimation procedures depending on the disturbance character.

Identifying the disturbance model. The choice between Model D and Model S is domain-dependent: - **Model D** (bounded deterministic, GA-2): appropriate when the environment changes persistently and directionally. Estimate ρ_{det} from worst-case bounds on mismatch injection rate. Examples: adversary who maneuvers systematically, API that drifts, climate that shifts. - **Model S** (stochastic zero-mean, GA-2S): appropriate when the environment fluctuates unpredictably around a stable mean. Estimate σ_w from residual variance of mismatch innovations. Examples: market noise, sensor noise, random perturbations. - **Mixed environments** use both: estimate ρ_{det} from the persistent component (trend) and σ_w from the residual variance after detrending. The adversarial exponent interpolates smoothly between $b = 2$ (pure drift) and $b = 3/2$ (pure noise); see 16.3.

Let $s_t = \|\delta_t\|$ in surprise units (e.g., negative log-likelihood residual scale).

Model D: Global mismatch injection rate ($\hat{\rho}_{\text{det}}$):

Operational Definition.

$$\hat{\rho}_{\text{det}}(t) = \left[\frac{s_{t+\Delta t} - s_t}{\Delta t} + \hat{\mathcal{F}}_t s_t \right]_+ \quad (\text{AY.2})$$

where $[x]_+ = \max(x, 0)$ and $\hat{\mathcal{F}}$ evaluated at time t is estimated adaptive tempo. Take the supremum (or a high quantile) over the estimation window.

Model S: Noise scale ($\hat{\sigma}_w$):

Operational Definition.

$$\hat{\sigma}_w^2 = \text{Var} \left[\frac{s_{t+\Delta t} - (1 - \hat{\eta}^*)s_t}{\sqrt{\Delta t}} \right] \quad (\text{AY.3})$$

i.e., the variance of the mismatch innovations (residuals after subtracting the expected correction). For AR(1) processes, this is the innovation variance $\hat{\rho}^2$ directly.

Note on estimation sequencing. Both estimators require $\hat{\mathcal{F}}_t$ (or $\hat{\eta}^*$), estimated from $\hat{\nu}$ and $\hat{\eta}^*$. Estimate the gain and event rate first (from the agent's internal statistics and observation timing), then use these to extract the disturbance parameters from the mismatch trajectory. This sequential structure avoids circularity but introduces sensitivity: errors in $\hat{\mathcal{F}}$ propagate into $\hat{\rho}_{\text{det}}$ and $\hat{\sigma}_w$.

Local pause-window drift for Derived 4.2 ($\hat{\rho}_{\text{delib}}$):

Operational Definition.

$$\hat{\rho}_{\text{delib}} = \text{median}_{w \in \mathcal{W}_{\text{pause}}} \frac{s_{w,\text{end}} - s_{w,\text{start}}}{\Delta \tau_w} \quad (\text{AY.4})$$

using windows where corrective action is suspended or effectively delayed.

Estimating α (sector lower bound). A uses $\delta^T F(\mathcal{T}, \delta) \geq \alpha \|\delta\|^2$ for $\|\delta\| \leq R$. Operationally:

1. Estimate $\dot{\delta}_t$ (finite differences or filtered derivative).
2. Compute $\hat{F}_t = -\dot{\delta}_t + w_t$ where disturbance proxy w_t is estimated from exogenous perturbation channels or residual balancing.
3. Form ratios $r_t = (\delta_t^T \hat{F}_t) / \|\delta_t\|^2$ on bins of $\|\delta_t\|$.
4. Set conservative lower bound $\hat{\alpha}$ as a low quantile (e.g., 10th percentile) of r_t in the valid region.

Estimating R (valid-region radius). Estimate R as the largest radius for which sector inequality violations remain below tolerance:

Operational Criterion.

$$\hat{R} = \sup \{r > 0 : \Pr(\delta^T \hat{F} < \hat{\alpha} \|\delta\|^2 \mid \|\delta\| \leq r) \leq \epsilon\} \quad (\text{AY.5})$$

with a chosen violation tolerance ϵ (e.g., 5%).

Estimating $\|\delta_{\text{critical}}\|$. Define a mission-level performance metric J (reward rate, tracking error, service SLA, etc.). Set the critical mismatch threshold where performance crosses a minimum acceptable level $J_{\min}$:

Operational Definition.

$$\|\hat{\delta}_{\text{critical}}\| = \inf \{d : \mathbb{E}[J \mid \|\delta\| = d] < J_{\min}\} \quad (\text{AY.6})$$

This anchors 4.5 to real task outcomes.

Recommended Estimation Sequence.

1. Fix mismatch representation δ in one consistent unit system (prefer surprise-scale).
2. Estimate U_o from channel physics/calibration; estimate U_M from model uncertainty.
3. Validate gain behavior against 3.6 ($\hat{\eta}^*$ trend checks).
4. Estimate ρ_{delib} from pause windows (4.1) and $\rho(t)$ from full traces.
5. Estimate α and R from local correction dynamics (A).
6. Estimate $\|\delta_{\text{critical}}\|$ from task-performance degradation.
7. Compute derived diagnostics:
 - Tempo margin (Model D): $\hat{\mathcal{T}} - \hat{\rho}_{\text{det}} / \|\hat{\delta}_{\text{critical}}\|$
 - Tempo margin (Model S): $\hat{\mathcal{T}} - n\hat{\sigma}_w^2 / (2\|\hat{\delta}_{\text{critical}}\|^2)$
 - Reserve: $\widehat{\Delta\rho^*} = \hat{\alpha}\hat{R} - \hat{\rho}_{\text{det}}$
 - Deliberation feasibility: $\Delta\eta^*(\Delta\tau)\|\delta_{\text{post}}\| - \hat{\rho}_{\text{delib}}\Delta\tau$

Decision-Theoretic Procedures.

<i>Context</i>	<i>λ estimator</i>	<i>Source</i>
----------------	---------------------------------------	---------------

Estimating λ (Exploration Price). The exploration weight $\lambda(M_t)$ in the unified policy objective (7.5) prices information in value-equivalent terms:

Table AY.3

<i>Context</i>	<i>λ estimator</i>	<i>Source</i>
Finite bandits	Gittins index from dynamic programming	Exact (Gittins 1979)
Linear-Gaussian	Probing cost in quadratic objective	Exact (dual control)
Discrete MDP	(VoI) ² /info gain	Information-directed sampling (Russo & Van Roy)
General	$\hat{\lambda} = c \cdot \hat{U}_M / \hat{U}_o$	Heuristic: scale CIY weight by relative uncertainty

For the heuristic: when $U_M \gg U_o$ (highly uncertain model), exploration is cheap relative to exploitation risk, so λ should be large. When $U_M \ll U_o$ (confident model, noisy observations), exploitation dominates. The constant c is domain-specific.

Deliberation Stopping Policy. From 4.1, deliberation of duration $\Delta\tau$ is warranted when $\Delta\eta^*(\Delta\tau) \cdot \|\delta_{\text{post}}\| > \rho_{\text{delib}} \cdot \Delta\tau$. Operationally:

1. Estimate ρ_{delib} from prior pause windows.
2. Before each deliberation episode, estimate $\|\delta_{\text{post}}\|$ as current mismatch + $\rho_{\text{delib}} \cdot \Delta\tau_{\text{planned}}$.
3. Estimate $\Delta\eta^*(\Delta\tau)$ from the diminishing-returns profile of past deliberation episodes.
4. Stop deliberating when the marginal improvement rate $\partial\Delta\eta^*/\partial\Delta\tau$ drops below $\rho_{\text{delib}}/\|\delta_{\text{post}}\|$.

Structural-Switch Trigger. From 4.8, structural adaptation is indicated when parametric convergence leaves a mismatch floor. Operationally:

1. Estimate the current mismatch floor $\|\delta\|_{\text{floor}}$ from converged residual statistics.
2. Estimate post-switch expected mismatch as $\|\delta\|_{\text{new}} \approx \rho/\alpha'$ where α' is the sector bound under the candidate new model class.
3. Estimate transition cost C_{switch} : knowledge loss, retraining time ($\Delta\tau_{\text{switch}}$), and accumulated mismatch during transition ($\rho \cdot \Delta\tau_{\text{switch}}$).
4. Switch when: $(\|\delta\|_{\text{floor}} - \|\delta\|_{\text{new}}) \cdot T_{\text{horizon}} > C_{\text{switch}}$.

Estimator Uncertainty Guidance.

$\hat{\eta}^*$ (**gain estimate**). Approximate variance via the delta method:

$$\text{Var}(\hat{\eta}^*) \approx \hat{\eta}^{*2}(1 - \hat{\eta}^*)^2 \left[\frac{\text{Var}(\hat{U}_M)}{\hat{U}_M^2} + \frac{\text{Var}(\hat{U}_o)}{\hat{U}_o^2} \right] \quad (\text{AY.7})$$

Near 0 or 1, stable (dominated by one source). Near 0.5, most volatile.

$\hat{\rho}$ (**mismatch injection rate**). Finite-difference estimation amplifies noise. Recommend smoothing before differencing. Minimum ~ 20 observations for stable trend; ~ 50 for reliable variance. The $[\cdot]_+$ clipping introduces positive bias at small ρ .

$\hat{\alpha}$ (**sector lower bound**). The 10th-percentile approach gives approximately 90% confidence under stationarity. Report quantile level, bin count, and bin width.

$\hat{R}$ (**sector-condition radius**). A sharp drop-off in sector-condition satisfaction is a strong signal; gradual decay suggests the sector condition may not hold cleanly.

Nonstationarity caveat. All estimators assume approximate stationarity over the estimation window. When environment regime changes are suspected (4.8), re-estimate from post-change data only.

Epistemic Status.

This is a *procedures document* — estimation recipes, not theoretical claims. Each estimator inherits the epistemic status of the quantity it targets: the gain estimator’s validity depends on 3.6’s structural claim; the sector-bound estimator’s validity depends on 4.4’s assumptions. The estimation procedures themselves are *conditional* on these theoretical foundations and on the stationarity and data-sufficiency assumptions noted above.

Working Notes.

- End-to-end worked examples instantiating the full chain are in [AZ](#) (exact) and [BA](#) (approximate).
 - The $\hat{\rho}$ estimator’s dependence on $\hat{\mathcal{T}}$ creates a sequential estimation chain. Errors compound. An alternative approach: estimate ρ directly from exogenous environmental change measurements when available, bypassing the mismatch trajectory entirely.
 - The structural-switch trigger’s T_{horizon} (expected time the new model class will remain adequate) is itself uncertain and difficult to estimate. In practice, this is where the agent’s M_t does the real work — predicting environmental stability.
-

Appendix AZ

Worked Example: 1D Active Tracking (Kalman Domain)

Every AAT quantity has an exact Kalman-filter counterpart. This is a *validation* of the formal chain — all quantities are computable in closed form.

This is AAT's **calibration on a problem with known exact answers**. AAT's contribution in the Kalman instance is not adding new results to Kalman theory; it is *embedding Kalman in a more general framework that handles the same primitives across non-linear, non-Gaussian, and non-fully-observable agent classes*, with the Kalman case as the special case where everything reduces to closed-form. The mismatch is the innovation; the optimal gain coincides with the Kalman gain (the uncertainty-ratio formula equals the Kalman gain in the linear-Gaussian case); the sector parameter equals tempo via 4.3; the persistence condition reduces to observability plus detectability. Where AAT predicts what Kalman theory says, the framework is minimally correct; where AAT predicts beyond Kalman's scope (non-linear, non-Gaussian, partial observability, multi-agent), the framework's reach extends past Kalman's. The Kalman instance is the anchor point that grounds the abstract machinery in a familiar concrete case.

System.

The agent tracks scalar state x_t and chooses sensor mode $a_t \in \{L, H\}$:

- Dynamics: $x_{t+1} = x_t + v_t$, $v_t \sim \mathcal{N}(0, q)$, $q = 0.25$
- Observation: $y_t = x_t + n_t^{(a_t)}$
- Low mode noise: $r_L = 9$; High mode noise: $r_H = 1$
- Event rate: $\nu = 5$ Hz
- High mode has higher energy cost

Chain Instantiation.

Scope (1.5). *Mapping: exact.*

$\Omega_t = x_t$ is partially observed via noisy channel. $\mathcal{A} = \{L, H\}$ is non-empty and causally affects observation quality. Residual uncertainty persists due to process and sensor noise.

Causal Structure (1.7) + CIY (3.7). *Mapping: exact.*

Action precedes observation and changes $P(y_t \mid do(a_t))$ through r_{a_t} . Using low mode as comparator action, the CIY is the interventional KL divergence:

Worked Quantity.

$$\text{CIY}(H) = D_{\text{KL}}(P(y \mid do(H)) \parallel P(y \mid do(L))) \quad (\text{AZ.1})$$

$$= \frac{1}{2} \left[\log \left(\frac{P^- + r_L}{P^- + r_H} \right) + \frac{P^- + r_H}{P^- + r_L} - 1 \right] \quad (\text{AZ.2})$$

With $P^- = 4.25$: $\text{CIY}(H) \approx 0.161$ nats.

Model (2.1). *Mapping: exact.*

Model state $M_t = (\hat{x}_{t|t}, P_{t|t})$ — a compression of interaction history with recursive update.

Mismatch (3.4). *Mapping: exact.*

$$\delta_t = y_t - \hat{x}_{t|t-1} \quad (\text{AZ.3})$$

Update Gain (3.6). *Mapping: exact.*

Scalar Kalman gain:

$$K_t = \frac{P_t^-}{P_t^- + r_{a_t}} \quad (\text{AZ.4})$$

With $P^- = 4.25$: $K(H) \approx 0.810$, $K(L) \approx 0.321$.

The exact uncertainty ratio mapping: $U_M = P_t^-$, $U_o = r_{a_t}$, $\eta^* = K_t$.

Exploration (3.7).

Worked Objective.

$$a_t^* = \arg \max_a [\mathbb{E}[\text{value}(a) \mid M_t] + \lambda_t \mathbb{E}[\text{CIY}(a) \mid M_t]] \quad (\text{AZ.5})$$

When uncertainty is high (P^- large), CIY term favors high mode. As uncertainty falls, policy shifts toward low-cost L .

Deliberation Threshold (4.1). Suppose a planning pause of $\Delta\tau = 0.5$ s, with measured $\rho_{\text{delib}} = 0.40$ surprise/s.

Cost during pause: 0.20 surprise units. If $\|\delta_{\text{post}}\| = 0.70$, deliberation is worthwhile when:

$$\Delta\eta^*(0.5) \cdot 0.70 > 0.20 \implies \Delta\eta^*(0.5) > 0.286 \quad (\text{AZ.6})$$

Structural Adaptation (4.8). Assume maneuvering regime change introduces sustained residual autocorrelation and mismatch floor. If estimated valid radius drops to $R = 0.08$ while $R^* = \rho/\alpha = 0.12$, parametric adaptation is no longer adequate ($R^* > R$), triggering model-class change (e.g., constant-velocity $\rightarrow$ constant-acceleration process model).

Tempo + Persistence (3.8, 4.5). Using action mix 70% H , 30% L :

$$\bar{\eta}^* = 0.7(0.810) + 0.3(0.321) = 0.663 \quad (\text{AZ.7})$$

$$\mathcal{T} = \nu \bar{\eta}^* = 5 \cdot 0.663 = 3.315 \text{ s}^{-1} \quad (\text{AZ.8})$$

With $\rho = 0.18$ surprise/s and $\|\delta_{\text{critical}}\| = 1$:

$$\mathcal{T} > \frac{\rho}{\|\delta_{\text{critical}}\|} \Rightarrow 3.315 > 0.18 \checkmark \quad (\text{AZ.9})$$

Lyapunov Bounds (4.4, 4.3). *Mapping: exact (derived, not estimated).*

By 4.3, the sector parameter for a scalar Kalman filter is $\alpha = \mathcal{T} = \nu \bar{\eta}^*$:

$$\alpha = \mathcal{T} = 3.315 \text{ s}^{-1} \quad (\text{AZ.10})$$

This is derived from the Kalman gain, not estimated from data — the correction function $F(e) = Ke$ is exactly linear, so $\alpha = K$ per observation and $\alpha = \nu \bar{K} = \mathcal{T}$ in continuous time. With $R = 1.4$ (model class capacity, a domain parameter) and $\rho = 0.18$:

$$R^* = \frac{\rho}{\alpha} = \frac{0.18}{3.315} \approx 0.054 < R \quad (\text{AZ.11})$$

$$\Delta\rho^* = \alpha R - \rho = 3.315(1.4) - 0.18 = 4.46 \quad (\text{AZ.12})$$

The agent is comfortably within its invariant region with substantial adaptive reserve.

Mapping Quality Summary.

Table AZ.1

<i>AAT Concept</i>	<i>Kalman Mapping</i>	<i>Status</i>
Scope	Exact	Definitional
Causal structure + CIY	Exact	Closed-form KL
Model (M_t as sufficient statistic)	Exact	Kalman state + covariance
Mismatch ($\delta_t = \text{innovation}$)	Exact	Standard Kalman innovation
Gain ($\eta^* = K_t$)	Exact	Kalman gain IS uncertainty ratio
Tempo ($\mathcal{T} = \nu \bar{\eta}^*$)	Exact	Closed-form
Persistence condition	Exact	Linear ODE solution
Sector parameter ($\alpha = \mathcal{T}$)	Exact	Derived from Kalman gain via 4.3

<i>AAT Concept</i>	<i>Kalman Mapping</i>	<i>Status</i>
Lyapunov bounds ($R^*, \Delta \rho^*$)	Exact	From derived sector parameter + domain R

Epistemic Status.

This is a *worked instantiation*, not a theoretical claim. Every mapping is exact — the Kalman domain is the canonical case where AAT’s formal chain has closed-form realizations. The example validates that the formal chain is internally consistent and instantiable.

Working Notes.

- This example uses a 1D system. The tensor-tempo extension (16.5) becomes visible only in multi-dimensional tracking where different state dimensions have different observability.
- The structural adaptation trigger (constant-velocity $\rightarrow$ constant-acceleration) is manufactured for the example. A more natural test would be a real tracking system with genuine regime changes.
- The Kalman filter is provably optimal for the linear-Gaussian case. Every AAT quantity has not just an analog but the *exact optimal* value. This makes it the strongest validation but also the easiest — the real test is non-Kalman domains (see BA).

Appendix BA

Worked Example: Nonstationary Bandit (RL Domain)

AAT’s conceptual architecture applies beyond the conjugate-Bayesian regime. The mapping here is *approximate* — it shows that AAT’s concepts organize RL phenomena, but the quantitative relationships are structural analogies, not derivations. Where the mapping is exact versus approximate is marked explicitly.

This is the framework’s bridge to RL theory. AAT does not subsume RL theory; it claims that typical RL methods (ϵ -greedy, UCB, Thompson sampling) are *operational approximations* of AAT primitives under regime-specific scope conditions — none exactly implements the optimal-gain principle, but their gains are *related to* the uncertainty-ratio gain and the methods converge in steady state toward optimal-gain behaviour. The worked example concentrates on the nonstationary case where AAT’s machinery is most distinctive from classical RL: the forgetting prerequisite becomes operational (effective sample size per arm must be bounded or the agent’s gain converges to zero); the per-arm tempo decomposition surfaces persistence as the binding constraint when uniform exploration is mismatched to drift.

System.

A k -armed bandit ($k = 4$) with slowly drifting reward means:

Formulation.

$$\mu_i(t+1) = \mu_i(t) + w_i(t), \quad w_i(t) \sim \mathcal{N}(0, q), \quad q = 0.01 \quad (\text{BA.1})$$

- Observation: Pulling arm $a_t = i$ yields reward $r_t = \mu_i(t) + \varepsilon_t$, $\varepsilon_t \sim \mathcal{N}(0, \sigma^2)$, $\sigma^2 = 1.0$.
- Event rate: $\nu = 1$ pull per step.
- Agent: Q-learning with fixed learning rate α and UCB action selection.

Chain Instantiation.

Scope (1.6). *Mapping: exact.*

$\Omega_t = (\mu_1(t), \dots, \mu_4(t))$ — not directly observable. $\mathcal{A} = \{1, 2, 3, 4\}$. Residual uncertainty persists: means drift continuously, rewards are noisy, and only one arm is observed per step.

Causal Structure (1.7) + CIY (3.7). *Mapping: exact for causal ordering; approximate for CIY formula.*

The action (arm choice) temporally precedes the reward observation. Under the Gaussian reward model, CIY for arm i :

Discussion — Bandit CIY, Gaussian Case.

$$\text{CIY}(i; M_{t-1}) = \frac{1}{2\sigma^2} \mathbb{E}_{j \sim q} [(\hat{\mu}_i - \hat{\mu}_j)^2] \quad (\text{BA.2})$$

This measures how *distinctive* arm i 's predicted reward is relative to alternatives — distinctiveness of predictions, not uncertainty about predictions. A proper uncertainty-aware CIY would require maintaining posterior variances per arm, which the basic Q-learning model does not track.

Model (2.1) and Sufficiency (2.3). *Mapping: exact structural mapping; the model is deliberately impoverished.*

$$M_t = (\hat{\mu}_1, \dots, \hat{\mu}_4, n_1, \dots, n_4) \quad (\text{BA.3})$$

Model sufficiency $S(M_t) < 1$ for two reasons: (1) No drift tracking — the model treats reward means as stationary. (2) No uncertainty representation — unlike a Bayesian agent that would maintain posterior variances.

Mismatch (3.4). *Mapping: exact.*

$$\delta_t = r_t - \hat{\mu}_{a_t} \quad (\text{BA.4})$$

Decomposes exactly: $\mathbb{E}[\delta_t^2] = (\hat{\mu}_{a_t} - \mu_{a_t}(t))^2 + \sigma^2$.

Update Gain (3.6). *Mapping: approximate. This is where the bandit agent is most deficient relative to AAT-optimal behavior.*

The Q-learning update

$$\hat{\mu}_{a_t} \leftarrow \hat{\mu}_{a_t} + \alpha \cdot \delta_t \quad (\text{BA.5})$$

uses a **degenerate constant gain**. It does not adapt to the agent's current uncertainty state.

Optimal gain via effective window. A fixed α is equivalent to exponential discounting with effective window $W = (1 - \alpha)/\alpha$. The per-arm model uncertainty balances estimation variance and drift-induced bias:

$$U_M \approx \frac{\sigma^2}{W} + q \cdot W \quad (\text{BA.6})$$

The optimal window $W^* = \sigma/\sqrt{q} = 10$ gives $\alpha^* \approx 0.091$, $U_M \approx 0.2$, and:

$$\eta^* = \frac{U_M}{U_M + U_o} = \frac{0.2}{1.2} \approx 0.167 \quad (\text{BA.7})$$

The discrepancy between α^* and η^* arises because α operates on raw prediction errors while η^* accounts for the full uncertainty structure. The two converge when the model properly tracks its own uncertainty.

Exploration (3.7). *Mapping: approximate structural analogy.*

UCB: $a_t = \arg \max_i [\hat{\mu}_i + c\sqrt{\ln t / n_i}]$

Table BA.1

<i>AAT component</i>	<i>UCB analog</i>	<i>Quality</i>
$\mathbb{E}[\text{value}(a) \mid M_t]$	$\hat{\mu}_i$	Exact
$\lambda(M_t) \cdot \mathbb{E}[\text{CIY}(a)]$	$c\sqrt{\ln t / n_i}$	Approximate

UCB captures the CIY structure (rarely-visited arms are more informative) but depends on visit count, not observation content.

Tempo + Persistence (3.8, 4.5). *Mapping: approximate.*

Per-arm tempo. With approximately uniform exploration, each arm sampled at rate $\nu/k = 1/4$:

$$\mathcal{T}_i = \frac{\nu}{k} \cdot \alpha = 0.25 \times 0.091 = 0.023 \text{ step}^{-1} \quad (\text{BA.8})$$

Per-arm drift rate: $\rho_i = \sqrt{q} = 0.1 \text{ reward units} \cdot \text{step}^{-1}$.

Persistence check: $\mathcal{T}_i = 0.023$ vs $\rho_i = 0.1$ — **fails**. Per-arm correction tempo is too low relative to drift. The agent cannot keep all arms' estimates current under uniform exploration.

Interpretation. This is expected and informative. AAT diagnoses exactly why: with 4 arms and one pull per step, each arm is visited too infrequently to track its drifting mean. Two remedies:

1. **Increase η^*** (raise α): Extract more per observation, but increase steady-state noise.
2. **Concentrate ν** : Abandon uniform exploration. Focus pulls on a subset, increasing per-arm ν/k_{active} . This is exactly what a good UCB policy does.

With focused exploration ($k_{\text{active}} = 2, \alpha = 0.2$): $\mathcal{T}_i = 0.5 \times 0.2 = 0.1$ — barely meets the threshold. The fundamental tension: with limited pulls and significant drift, the agent must accept either failing to track some arms or using high α that introduces noise.

Aggregate failure. $\mathcal{T} = \nu \cdot \alpha = 0.091$ vs $\rho = k \cdot \sqrt{q} = 0.4$. The agent's total adaptive capacity is outpaced by total environmental drift — a regime where model-based approaches (Bayesian bandits, Kalman bandit filters) with higher effective η^* have a structural advantage.

<i>AAT Concept</i>	<i>Bandit Mapping</i>	<i>Status</i>
--------------------	-----------------------	---------------

Mapping Quality Summary.

Table BA.2

<i>AAT Concept</i>	<i>Bandit Mapping</i>	<i>Status</i>
Scope	Exact	Definitional
Causal structure	Exact	Structural
CIY	Approximate	Model lacks uncertainty representation
Model (M_t)	Exact	Definitional
Model sufficiency ($S < 1$)	Exact	Q-learner demonstrably insufficient
Mismatch (δ_t)	Exact	Standard prediction error
Gain (α as degenerate η^*)	Approximate	Fixed, does not adapt
Exploration (UCB as approximate CIY)	Approximate	Structural analogy
Tempo ($\mathcal{T} = (\nu/k) \cdot \alpha$ per arm)	Approximate	Assumes uniform allocation
Persistence condition	Exact (qualitative)	Threshold structure is robust

Epistemic Status.

This is a *structural mapping*, not a derivation. The mapping is *exact* for scope, causal ordering, model compression, and mismatch. It is *approximate* for gain, exploration, and tempo — precisely because the Q-learner does not represent its own uncertainty, which is what 3.6 requires for optimal behavior. The gap between the Q-learner’s fixed α and the AAT-optimal adaptive η^* is precisely the gap between a fixed-gain PID controller and a Kalman filter.

The mapping status is *conditional* because the quantitative relationships depend on the Gaussian reward model and specific parameterization. The qualitative conclusions (persistence failure under uniform exploration, the concentration-vs-noise tradeoff) should be robust.

Working Notes.

- The per-arm analysis is a natural instance of the per-dimension tempo decomposition (165): each arm is an independent mismatch dimension with its own $\mathcal{T}_i$ and ρ_i . The aggregate tempo overstates effective adaptation along any individual arm’s dimension — exactly the failure mode that the scalar-to-tensor generalization captures.
- A Bayesian bandit (maintaining per-arm posteriors with exponential discounting) would achieve higher 2.3 by representing its own uncertainty, yielding an adaptive η^* that matches the AAT-optimal form. Comparing Q-learner vs Bayesian bandit performance under nonstationarity is a direct test of 3.6’s structural claim.
- Reward-unit and surprise-unit formulations coincide up to normalization by σ^2 . For this example ($\sigma = 1$), they are identical.

Appendix BB

Worked Example: Nonstationary Bandit with Explicit Strategy (Part II Validation)

AAT's Part II machinery — objectives, strategy DAGs, the orient cascade, satisfaction gap, control regret, chain confidence decay, observability dominance, and edge update via gain — is exercised on a concrete system simple enough for closed-form analysis. The key payoff: Part II diagnostics tell the agent things that Part I quantities alone cannot.

System.

A 3-armed Bernoulli bandit with drifting success probabilities and an agent that maintains an explicit strategy DAG for arm selection.

Environment. Three arms with time-varying success probabilities:

Formulation.

$$\theta_k(t) \in [0, 1], \quad k \in \{1, 2, 3\} \quad (\text{BB.1})$$

At each step, pulling arm k yields reward $r_t \in \{0, 1\}$ with $P(r_t = 1 \mid a_t = k) = \theta_k(t)$. The best arm changes slowly: at rate ρ_θ , a random arm's success probability shifts by a random perturbation clipped to $[0.1, 0.9]$.

Concrete parameterization. At $t = 0$: $\theta_1(0) = 0.7$, $\theta_2(0) = 0.5$, $\theta_3(0) = 0.3$. Drift rate: $\rho_\theta = 0.05$ per step (one arm shifts by ± 0.05 every 20 steps on average). Horizon: $N_h = 100$ steps.

Agent. Maintains Beta-Bernoulli beliefs per arm and an explicit strategy DAG encoding its plan for achieving a target reward rate.

Part I Chain Instantiation (Summary).

Part I quantities map as in [BA](#). The brief summary here establishes the epistemic baseline; the novel content is Part II.

Scope (1.6). $\Omega_t = (\theta_1(t), \theta_2(t), \theta_3(t))$; $\mathcal{A} = \{1, 2, 3\}$; residual uncertainty persists. *Exact.*

Model (2.1). $M_t = (\alpha_k, \beta_k)_{k=1}^3$ — Beta posteriors per arm, with exponential discounting (effective window $W = 20$):

$$\hat{\theta}_k = \frac{\alpha_k}{\alpha_k + \beta_k} \quad (\text{BB.2})$$

Exact structural mapping.

Mismatch (3.4). $\delta_t = r_t - \hat{\theta}_{a_t}$. *Exact.*

Update gain (3.6). The Beta-Bernoulli conjugate update with discounted pseudo-counts gives:

$$\eta_k^* = \frac{1}{\alpha_k + \beta_k + 1} \quad (\text{BB.3})$$

For a well-observed arm with $\alpha_k + \beta_k \approx W = 20$: $\eta_k^* \approx 0.048$. *Exact for the pulled arm; zero for unpulled arms.*

Tempo (3.8). Per-arm tempo: $\mathcal{T}_k = \nu_k \cdot \eta_k^*$ where ν_k is the pull rate for arm k . Under uniform exploration: $\nu_k = 1/3$, so $\mathcal{T}_k \approx 0.016$ per step. *Approximate.*

Part II Chain Instantiation.

Objective (6.4). *Mapping: exact.*

The agent's objective: achieve a target average reward rate over the horizon.

Definition (bandit-objective).

$$V_{O_t}(\tau_{0:N_h}) = \frac{1}{N_h} \sum_{t=0}^{N_h-1} r_t \quad (\text{BB.4})$$

$$V_{O_t}^{\min} = 0.6 \quad (\text{BB.5})$$

This is a utility-type objective with a satisfaction threshold: the agent counts the mission as successful if its average reward rate meets or exceeds 0.6. The value functional evaluates trajectories on $[0, 1]$ (average reward).

Value Object (6.6). *Mapping: exact.*

Under the one-step improvement convention ($\pi_{\text{cont}} = \pi_{\text{current}}$):

$$V_O(M_t, \pi; N_h) = \mathbb{E} \left[\frac{1}{N_h} \sum_{s=t}^{t+N_h-1} r_s \mid M_t, \pi \right] \quad (\text{BB.6})$$

For a greedy policy that always pulls the estimated-best arm $k^* = \arg \max_k \hat{\theta}_k$:

$$V_O(M_t, \pi_{\text{greedy}}; N_h) = \hat{\theta}_{k^*} \quad (\text{BB.7})$$

This is tractable: the agent's expected average reward under greedy play equals its belief about the best arm's success probability. With M_0 : $V_O = \hat{\theta}_1 = 0.7$.

Action-value form:

$$Q_O(M_t, k; \pi_{\text{greedy}}, N_h) \approx \frac{1}{N_h} \hat{\theta}_k + \frac{N_h - 1}{N_h} \hat{\theta}_{k^*} \quad (\text{BB.8})$$

The first pull contributes $1/N_h$ of the horizon; the rest follows the greedy policy.

Objective Attainability (8.4). *Mapping: exact.*

$$A_O(M_t; \Pi, N_h) = \sup_{\pi \in \Pi} V_O(M_t, \pi; N_h) \quad (\text{BB.9})$$

For a bandit with Beta-Bernoulli beliefs, the optimal policy (Gittins index or Bayes-adaptive) achieves an attainability that is bounded:

$$\max_k \hat{\theta}_k \leq A_O \leq \max_k \hat{\theta}_k + \epsilon_{\text{info}} \quad (\text{BB.10})$$

where ϵ_{info} accounts for the information value of exploration (pulling a suboptimal arm now to identify the true best arm later). The upper bound is tight when exploration can reveal a better arm. For our initial beliefs: $A_O \approx 0.70 + \epsilon_{\text{info}}$.

Satisfaction gap:

$$\delta_{\text{sat}} = V_{O_t}^{\min} - A_O = 0.6 - 0.70 \approx -0.10 \quad (\text{BB.11})$$

$\delta_{\text{sat}} < 0$: the objective is **attainable**. The agent believes it can achieve a 0.6 average reward rate. The negative gap is margin — the agent has room to spare.

Control Regret (8.5). *Mapping: exact.*

Under an explore-then-exploit policy that spends 30 steps exploring uniformly, then exploits the estimated-best arm:

$$V_O(M_t, \pi_{\text{explore-exploit}}; 100) = \frac{30}{100} \cdot \bar{\theta} + \frac{70}{100} \cdot \hat{\theta}_{k^*(30)} \quad (\text{BB.12})$$

where $\bar{\theta} = (\hat{\theta}_1 + \hat{\theta}_2 + \hat{\theta}_3)/3$ is the average expected reward during exploration and $\hat{\theta}_{k^*(30)}$ is the estimated-best arm after 30 observations. With initial beliefs: $V_O \approx 0.3 \cdot 0.5 + 0.7 \cdot 0.7 = 0.64$.

$$\delta_{\text{regret}} = A_O - V_O(\pi_{\text{explore-exploit}}) \approx 0.70 - 0.64 = 0.06 \quad (\text{BB.13})$$

The agent is leaving 0.06 reward-rate points on the table with its current explore-then-exploit strategy — it explores too much. This is the signal for strategy revision (10.1 step 3).

The 2x2 diagnostic (8.5 Discussion):

Table BB.1

	$\delta_{\text{sat}} \leq 0$	$\delta_{\text{sat}} > 0$
$\delta_{\text{regret}} \approx 0$	Success	Capability limit
$\delta_{\text{regret}} \gg 0$	Strategy problem	Both

Our agent is in the **Strategy problem** cell: the goal is achievable, but the current policy is suboptimal. Part I alone (which reports $\hat{\theta}_k$, η_k^* , and $\mathcal{T}_k$) cannot distinguish “good strategy, hard goal” from “bad strategy, easy goal.” The 2x2 diagnostic is Part II’s value-add.

Strategy DAG (8.3, 8.2). Mapping: exact for structure and propagation; the DAG is simple enough for closed-form status.

The agent's strategy for achieving $V_{O_t}^{\min} = 0.6$:

```
[root: "achieve  $\geq 0.6$  avg reward"] (AND) / \ [Phase 1: "identify best arm"] (OR) [Phase 2: "exploit best arm"]
/ | \ | [arm 1 [arm 2 [arm 3 [pull identified is best] is best] is best] arm reliably]
```

Nodes: - v_{root} : AND-node. Both phases must succeed: identify the best arm AND exploit it. Terminal satisfaction condition: average reward ≥ 0.6 . - v_{id} : OR-node (Phase 1). Identifying the best arm succeeds if ANY one arm is correctly identified as best. - v_1, v_2, v_3 : leaf condition nodes. "Arm k is the best arm." Base credence: $p_k(M_t) = P(\theta_k > \theta_j \forall j \neq k | M_t)$. - v_{exploit} : leaf action node (Phase 2). "Pulling the identified arm yields reward ≥ 0.6 ." Base credence: $p_{\text{exploit}}(M_t) = P(\theta_{k^*} \geq 0.6 | M_t)$.

Edge credences. The edges from leaf nodes to their parents carry causal credences: - $p_{v_k, v_{\text{id}}}$: "correctly identifying arm k as best enables Phase 1 success." These are structural (close to 1.0) — if the agent correctly knows which arm is best, Phase 1 succeeds by definition. Set $p_{v_k, v_{\text{id}}} = 1.0$ for all k . - $p_{v_{\text{id}}, v_{\text{root}}}$: "having identified the best arm advances the root goal." Set to 0.95 (slight uncertainty about whether identification translates to exploitation success). - $p_{v_{\text{exploit}}, v_{\text{root}}}$: "successful exploitation advances the root goal." Set to 0.90 (the identified arm might drift below threshold during exploitation).

Leafbase credences from M_t . At $t = 0$ with $(\hat{\theta}_1, \hat{\theta}_2, \hat{\theta}_3) = (0.7, 0.5, 0.3)$ and moderate pseudo-counts ($\alpha_k + \beta_k \approx 5$) from prior experience:

$$p_1(M_0) = P(\theta_1 > \theta_2, \theta_1 > \theta_3 | M_0) \approx 0.75 \quad (\text{BB.14})$$

$$p_2(M_0) \approx 0.20, \quad p_3(M_0) \approx 0.05 \quad (\text{BB.15})$$

$$p_{\text{exploit}}(M_0) = P(\theta_{k^*} \geq 0.6 | M_0) \approx 0.70 \quad (\text{BB.16})$$

Status propagation (8.3, 8.2):

Phase 1 (OR-node):

$$s_{v_{\text{id}}} = 1 - \prod_{k=1}^3 (1 - p_{v_k, v_{\text{id}}} \cdot p_k) = 1 - (1 - 0.75)(1 - 0.20)(1 - 0.05) \quad (\text{BB.17})$$

$$= 1 - (0.25)(0.80)(0.95) = 1 - 0.19 = 0.81 \quad (\text{BB.18})$$

Phase 2 (leaf): $s_{v_{\text{exploit}}} = 0.70$.

Root (AND-node):

$$s_{v_{\text{root}}} = (p_{v_{\text{id}}, v_{\text{root}}} \cdot s_{v_{\text{id}}}) \cdot (p_{v_{\text{exploit}}, v_{\text{root}}} \cdot s_{v_{\text{exploit}}}) \quad (\text{BB.19})$$

$$= (0.95 \times 0.81) \times (0.90 \times 0.70) = 0.770 \times 0.630 = 0.485 \quad (\text{BB.20})$$

Plan-confidence score: $\hat{P}_2(M_0) = 0.485$. The strategy assigns about 49% confidence to achieving the objective. This is distinct from A_O (which optimizes over all policies) — $\hat{P}_2$ is the DAG's self-assessment of *this specific plan*.

Chain Confidence Decay (8.1). *Mapping: exact (mathematical identity).*

The root node's confidence illustrates chain decay through an AND structure. The root requires two children to succeed, each with their own sub-chains:

$$\log \hat{R}_2 = \log(p_{v_{\text{id}}, u_{\text{root}}} \cdot s_{v_{\text{id}}}) + \log(p_{v_{\text{exploit}}, u_{\text{root}}} \cdot s_{v_{\text{exploit}}}) \quad (\text{BB.21})$$

$$= \log(0.770) + \log(0.630) = -0.261 + (-0.462) = -0.724 \quad (\text{BB.22})$$

Each term is negative; the AND combination accumulates them additively in log-space. If the agent added a third AND-child (e.g., “maintain budget”), even with $s_{\text{budget}} = 0.95$, the strategy-plan confidence would drop to $0.485 \times 0.95 = 0.461$. The pressure toward shallow, narrow DAGs is structural.

Contrast with the OR-node. Phase 1 (OR-node) benefits from redundancy: three alternative arms provide resilience. The OR combination yields $s_{v_{\text{id}}} = 0.81$ even though no single arm has credence above 0.75. The asymmetry between AND (multiplicative decay) and OR (complementary resilience) is the core structural result of 8.1 combined with 8.2.

Orient Cascade (10.1). *Mapping: exact for ordering; the content of each step is tractable in this domain.*

Suppose at $t = 40$, the agent has been pulling arm 1 (the initially-best arm) and observes a run of failures: the last 8 of 10 pulls yielded $r_t = 0$. Meanwhile, arm 2's true probability has drifted to $\theta_2(40) = 0.8$ (unknownst to the agent) and arm 1 has drifted to $\theta_1(40) = 0.3$.

The orient cascade proceeds:

Step 1: Reduce $\delta_{\text{epistemic}}$. Update M_t from the recent observations. The Beta posterior for arm 1 shifts:

$$\hat{\theta}_1 : 0.70 \rightarrow 0.38 \quad (\text{after 8 failures in 10 trials with discounted prior}) \quad (\text{BB.23})$$

Arms 2 and 3 are unobserved since the exploration phase ended. Their posteriors remain at approximately $\hat{\theta}_2 = 0.52$, $\hat{\theta}_3 = 0.28$ (slightly regressed toward the prior due to discounting). *The epistemic update proceeds without reference to O_t or Σ_t* — directed separation (6.3) holds because the Beta update depends only on the observation and the prior, not on the agent's goals.

Step 2: Evaluate δ_{sat} . With the updated M_t :

$$A_O(M_{40}) \approx \max_k \hat{\theta}_k + \epsilon_{\text{info}} = 0.52 + \epsilon_{\text{info}} \quad (\text{BB.24})$$

$$\delta_{\text{sat}} = 0.6 - (0.52 + \epsilon_{\text{info}}) \quad (\text{BB.25})$$

If $\epsilon_{\text{info}} \approx 0.05$ (exploration can reveal a better arm): $\delta_{\text{sat}} \approx 0.6 - 0.57 = 0.03 > 0$. The objective is now **marginally unmet** — the agent believes it may not be able to achieve 0.6 average reward. This triggers the disambiguation procedure (8.4): is the goal truly infeasible, or is M_t wrong about what's achievable?

Step 3: Evaluate δ_{regret} . Under the current greedy policy (still pulling arm 1 despite updated beliefs):

$$V_O(M_{40}, \pi_{\text{current}}) = \hat{\theta}_1 = 0.38 \quad (\text{BB.26})$$

$$\delta_{\text{regret}} = 0.57 - 0.38 = 0.19 \quad (\text{BB.27})$$

Control regret is high. The agent is pulling arm 1 out of inertia, but M_t now says arm 2 is better. *This is the Part II payoff*: Part I would report the mismatch δ_t on each pull and the updated $\hat{\theta}_1$, but it cannot diagnose that the *strategy* is the problem. The high δ_{regret} identifies the corrective action: revise Σ_t , not O_t .

Step 4: Evaluate $\delta_{\text{strategic}}$. The edge residual for the root AND-node's exploitation branch:

$$r_{\text{exploit}} = \mathbb{E}[\Delta V_O \mid \text{exploit arm 1}] - \Delta V_O^{\text{observed}} \quad (\text{BB.28})$$

The agent predicted reward ≈ 0.70 per pull from arm 1; it observed ≈ 0.20 . The residual is large and positive, localizing the problem to the exploitation edge: the agent's causal belief that "pulling arm 1 yields high reward" is wrong.

Simultaneously, the leaf credences update: $p_1(M_{40}) \approx 0.15$ (arm 1 is probably not the best), $p_2(M_{40}) \approx 0.60$ (arm 2 is probably best, by default from the prior). The Phase 1 OR-node status shifts: the identification sub-goal may need to be revisited.

Step 5: Revise Σ_t . The agent restructures its strategy: switch exploitation target to arm 2 (the currently estimated-best arm). In DAG terms: $p_1(M_{40})$ has dropped to 0.15 while $p_2(M_{40})$ has risen to 0.60. The OR-node now routes through arm 2. The exploitation leaf updates: $p_{\text{exploit}}(M_{40}) = P(\theta_2 \geq 0.6 \mid M_{40}) \approx 0.40$.

After strategy revision: $\hat{P}_2(M_{40}) \approx (0.95 \times 0.73) \times (0.90 \times 0.40) = 0.693 \times 0.360 = 0.249$. Plan confidence has dropped from 0.485 to 0.249 — the agent correctly recognizes that its situation has deteriorated.

What Part I alone cannot provide. At $t = 40$, Part I reports: $\hat{\theta}_1 = 0.38$, $\hat{\theta}_2 = 0.52$, $\hat{\theta}_3 = 0.28$, and the per-arm mismatch signals. This tells the agent what it believes about each arm. It does NOT tell the agent: - Whether its *goal* is still achievable (δ_{sat}) - Whether its *strategy* is the problem or the goal is (δ_{regret}) - Which *part* of the strategy is failing ($\delta_{\text{strategic}}$, edge residuals) - What corrective action to take (the cascade's ordering)

Observability Dominance (9.3). *Mapping: exact mechanism; approximate quantitative form.*

When the agent stops pulling arm 3 after the exploration phase (say at $t = 30$), the observation rate for arm 3 drops to $\nu_3 = 0$. By 3.6:

$$\eta_3^* = \frac{U_{\text{edge},3}}{U_{\text{edge},3} + U_{\text{obs},3}} \quad (\text{BB.29})$$

With $U_{\text{obs},3} \rightarrow \infty$ (no observations): $\eta_3^* \rightarrow 0$. Arm 3's credence $p_3(M_t)$ is **frozen at its exploration-phase value**.

For the strategy DAG, the leaf node "arm 3 is best" has: - Nominal credence: $p_3(M_t) \approx 0.05$ (from $t = 30$ beliefs) - Path observability: $\sigma_3 = 0$ (arm 3 is not being pulled) - Observability-adjusted confidence: $\text{conf}_{\text{obs}}(\text{arm 3 path}) = 0.05 \times 0 = 0$

Arm 3's path through the strategy is **epistemically dead** — the agent cannot learn whether arm 3 has become the best arm. If θ_3 drifts to 0.9 (which it might, given nonstationarity), the agent will never discover this through the exploitation-only policy.

The observability-dominance diagnostic. Compare arm 2 and arm 3:

Table BB.2

	Arm 2	Arm 3
Nominal credence p_k	0.52	0.28 (frozen)
Observability σ_k	moderate (occasional pulls)	0 (never pulled)
Adjusted confidence	$0.52 \times \sigma_2$	0
Can be updated?	Yes	No

Arm 2 is epistemically alive; arm 3 is epistemically dead. The agent should prefer exploring arm 2 (where it can learn) over arm 3 — unless it invests in making arm 3 observable again (pulling it despite low expected reward). This is the strategic case for exploration: not just expected value, but *observability maintenance*.

Part I vs Part II diagnosis. Part I reports $\hat{\theta}_3 = 0.28$ with growing uncertainty (the posterior variance increases under discounting with no new data). Part II adds the diagnostic: this arm's strategy path is epistemically dead ($\sigma_3 = 0$), and restoring observability has value beyond the arm's nominal expected reward.

Edge Update via Gain (9.4). *Mapping: exact for the Beta-Bernoulli case.*

When the agent pulls arm 1 at $t = 35$ and observes failure ($r_t = 0$):

Leaf credence update. The Beta posterior for arm 1 updates:

$$\beta_1 \rightarrow \beta_1 + 1, \quad \hat{\theta}_1 = \frac{\alpha_1}{\alpha_1 + \beta_1 + 1} \quad (\text{BB.30})$$

This is the standard conjugate update — the gain principle reduces to Bayesian updating in the binary case (9.4).

Strategy propagation. The updated $\hat{\theta}_1$ changes $p_1(M_t)$ (the credence that arm 1 is best). This propagates through the OR-node to the root:

$$s_{v_{\text{id}}}^{\text{new}} = 1 - (1 - p_1^{\text{new}})(1 - p_2)(1 - p_3) \quad (\text{BB.31})$$

The OR-node's status is *resilient* to single-arm credence drops: even if p_1 drops substantially, p_2 can compensate. This is the OR-node's structural advantage — redundancy absorbs single-edge failures.

The exploitation edge. The edge $p_{v_{\text{exploit}}, v_{\text{root}}} = 0.90$ is a causal credence: “pulling the identified-best arm reliably yields reward ≥ 0.6 .” After observing repeated failures from arm 1:

$$\text{signal} = 0 \quad (\text{failure observed}) \quad (\text{BB.32})$$

$$p_{\text{exploit}}^{\text{new}} = p_{\text{exploit}}^{\text{old}} + \eta_{\text{edge}} \cdot (0 - p_{\text{exploit}}^{\text{old}}) \quad (\text{BB.33})$$

With $\eta_{\text{edge}} = U_{\text{edge}} / (U_{\text{edge}} + U_{\text{obs}})$, the exploitation edge's credence decreases. The rate of decrease is governed by the gain principle: well-established edges (many prior successes, U_{edge} small) are slow to revise; newly formed edges are fast.

Directed Separation (6.3). *Mapping: exact. The agent is Class 1 (Separated) by construction.*

The Beta-Bernoulli update for M_t processes (α_t, r_t) without reference to (O_t, Σ_t) :

$$(\alpha_{a_t}, \beta_{a_t}) \rightarrow (\alpha_{a_t} + r_t, \beta_{a_t} + 1 - r_t) \quad (\text{BB.34})$$

The update function f_M has no G_t argument. The strategy DAG then updates its leaf credences from the new M_t — this is $f_G(G_t, M_{t+1}, e_t)$. The agent architecture is modular: a separate estimator (Beta posteriors) and planner (DAG evaluation), connected through the state-estimate interface.

$\kappa_{\text{processing}} = 0$ — no goal information flows into the epistemic update. Part II results apply exactly.

Satisfaction Gap Dynamics. *Mapping: exact definition; approximate computation.*

Tracking δ_{sat} over time reveals the agent’s evolving assessment of goal feasibility:

Table BB.3

Time	$\hat{\theta}_{k^*}$	A_O (approx)	δ_{sat}	Interpretation
$t = 0$	0.70	0.72	−0.12	Comfortably attainable
$t = 20$	0.68	0.70	−0.10	Still attainable
$t = 40$	0.52	0.57	+0.03	Marginally unmet
$t = 50$ (after exploring arm 2)	0.75	0.77	−0.17	Attainable again — M_t improved
$t = 70$	0.78	0.79	−0.19	Confidently attainable

The key transition is $t = 40 \rightarrow 50$: δ_{sat} goes from positive (unmet) to negative (attainable) — not because the goal changed or the environment improved, but because M_t improved. The agent explored arm 2, discovered $\hat{\theta}_2 \approx 0.75$, and its attainability assessment corrected upward. This matches the 8.4 disambiguation: the positive δ_{sat} at $t = 40$ was caused by a bad model, not an infeasible goal. The orient cascade’s ordering (fix M_t first, then reassess δ_{sat}) produced the right diagnosis.

The Part II Payoff.

The purpose of this worked example is to demonstrate that Part II adds genuine diagnostic value beyond Part I. Here is the explicit comparison:

Scenario at $t = 40$: arm 1 failing, arm 2 actually best, agent pulling arm 1.

Part I diagnosis. The mismatch signal δ_t is large. The posterior $\hat{\theta}_1$ has dropped. Per-arm tempo $\mathcal{T}_1 \approx 0.016$ is adequate for tracking arm 1’s drift. The agent knows arm 1 looks bad. Part I prescribes: update M_t faster (increase η^*) or observe more (increase ν).

Part II diagnosis. The orient cascade runs: 1. M_t updates correctly — arm 1’s posterior drops to 0.38. (Directed separation: this happens goal-blindly.) 2. $\delta_{\text{sat}} = +0.03$ — the objective is marginally unmet. The agent’s best-believed policy barely misses the target. 3. $\delta_{\text{regret}} = 0.19$ — the current policy (pulling arm 1) is far from the best available (pulling arm 2). 4. The 2x2 diagnostic says: “goal may be achievable, strategy is definitely suboptimal.” Corrective action: revise Σ_t , then reassess δ_{sat} . 5. Edge residuals localize the problem: the exploitation branch’s predicted-vs-observed value gap is large. The leaf credences identify arm 2 as the best candidate. 6. Observability check: arm 3 is epistemically dead ($\sigma_3 = 0$). The agent should invest in observing arm 2 (or arm 3) before committing.

Part II tells the agent: *switch to arm 2, but first explore to confirm — the goal is probably still achievable, the current strategy is the problem, not the goal*. Part I tells the agent: *arm 1 looks bad*. The difference is the difference between a diagnosis and a symptom.

Mapping Quality Summary.

Table BB.4

<i>AAT Concept</i>	<i>Bandit-Strategy Mapping</i>	<i>Status</i>	<i>Notes</i>
Scope (1.6)	Exact	Definitional	Same as BA
Model M_t (2.1)	Exact	Structural	Beta posteriors per arm
Mismatch δ_t (3.4)	Exact	Standard	Prediction error
Update gain η^* (3.6)	Exact	Conjugate	Beta-Bernoulli gain
Tempo $\mathcal{T}$ (3.8)	Approximate	Per-arm decomposition	Assumes known allocation
Directed separation (6.3)	Exact	Class 1 (Separated) by construction	Beta update is goal-blind
Objective O_t (6.4)	Exact	Utility with threshold	$V_{O_t}^{\min} = 0.6$
Value object V_O (6.6)	Exact	Closed-form (greedy)	$V_O = \hat{\theta}_{k^*}$
Satisfaction gap δ_{sat} (8.4)	Exact	Definition applied	$V_{O_t}^{\min} - A_O$
Control regret δ_{regret} (8.5)	Exact	Definition applied	$A_O - V_O(\pi_{\text{current}})$
Strategy DAG Σ_t (8.3)	Exact	AND/OR with 7 nodes	Small enough for manual propagation
AND/OR scope (8.2)	Exact	Natural fit	Phase 1 is genuinely OR; root is genuinely AND
Status propagation	Exact	Closed-form	Forward pass computable by hand
Plan confidence $\hat{P}_\Sigma$ (8.3)	Exact (computation)	From propagation; systematically optimistic under correlated failure	0.485 at $t = 0$
Chain confidence decay (8.1)	Exact	Mathematical identity	AND-node multiplicative; OR-node resilient
Orient cascade (10.1)	Exact (ordering)	All 5 steps exercised	Content is tractable in this domain
Observability dominance (9.3)	Exact (mechanism)	Unpulled arms frozen	$\sigma_3 = 0 \Rightarrow \eta_3^* = 0$
Edge update via gain (9.4)	Exact (binary case)	Beta-Bernoulli conjugate	Gain principle = Bayesian update
Strategic calibration (9.1)	Approximate	Credit assignment tractable here	Single-arm attribution is clean
Satisfaction gap dynamics	Exact	Time series of δ_{sat}	Model improvement resolves positive gap

Quantities that map cleanly. All Part II definitions (objective, value object, satisfaction gap, control regret, strategy DAG) have exact instantiations. Plan confidence $\hat{P}_\Sigma$ is exact as a computation (the AND/OR propagation is correct), but systematically overestimates actual success probability under correlated edge failures (8.3). In this toy bandit, edge independence is a reasonable approximation; in complex domains the overestimate may be severe. The orient cascade ordering is exact and all five steps are exercised.

Quantities that map approximately. Strategic calibration is approximate because even in this simple domain, attributing value changes to specific DAG edges requires assumptions about the agent's execution fidelity. Observability dominance is exact in mechanism but the multiplicative form $\text{conf}_{\text{obs}} = \text{conf} \cdot \text{obs}$ is a first-order approximation.

Quantities that don't map. No Part II quantity fails to map in this domain. The system is simple enough that every quantity is computable (at least approximately). This is the advantage of the bandit setting: it is the simplest system that exercises all Part II machinery.

Epistemic Status.

This is a *worked instantiation* — it demonstrates that the Part II formal chain is internally consistent and instantiable. The mapping quality is *conditional*: the quantitative relationships depend on the Beta-Bernoulli reward model, the specific DAG structure, and the parameterization. The qualitative conclusions — especially the diagnostic value of the 2x2 table and the orient cascade's ordering — should be robust across reward models and DAG topologies.

The status is *conditional* rather than *exact* because the attainability A_O is approximated (the exact Bayes-optimal policy for a nonstationary bandit is intractable), and the strategic calibration mapping inherits the discussion-grade status of 9.1. The core Part II definitions (satisfaction gap, control regret, strategy-plan confidence) are exact instantiations.

Working Notes.

- This example uses a deliberately simple DAG (7 nodes, depth 2). A richer example with depth 3+ would better exercise chain confidence decay's exponential penalty and the evidence-starvation effect from 9.3's quantitative discussion. A natural extension: add an intermediate "confirm arm k is best" node between identification and exploitation, creating a 3-level chain.
 - The explore-then-exploit policy is deliberately suboptimal to demonstrate nonzero δ_{regret} . A Gittins-index agent would achieve $\delta_{\text{regret}} \approx 0$, demonstrating the "Success" cell of the 2x2 table. Comparing the two in the same environment would validate the control-regret diagnostic.
 - The satisfaction gap dynamics table (Section "Satisfaction Gap Dynamics") would benefit from simulation confirmation. The specific numbers are plausible but hand-computed. A Monte Carlo study averaging over environment drift realizations would strengthen the claim.
 - This example does not exercise strategy-level tempo (9.10) or the three-way tradeoff (10.2). A future worked example targeting these would need a system with genuine deliberation costs — simulation in `spikes/sim-three-way-tradeoff.py` provides a drifting-bandit version but found deliberation rarely dominates in simple settings.
 - The DAG's AND/OR assignment is unambiguous in this domain (Phase 1 is genuinely disjunctive; the root is genuinely conjunctive). Domains where the AND/OR assignment is uncertain or updatable would be a stronger test of 8.2.
-

Appendix BC

Worked Example: L1 Augmented DAG with Common-Cause Node

A concrete instantiation of the Correlation Hierarchy (8.3) and Proposition B.6 (R). Two OR-alternatives sharing an infrastructure dependency are modeled at L0 (independence) and L1 (augmented DAG), with the sector condition verified for L1.

The example **exhibits AAT’s central observation about causally-insufficient DAGs**. At L0 (independence), AND/OR propagation systematically *overestimates* plan success: the strategy-plan-confidence comes out higher than the actual rate because the model treats the two paths as independently failing rather than as both depending on shared infrastructure. The overestimate is *exactly* the covariance between the paths’ outcomes — the direction-of-bias formula for OR-structures. At L1 (augmented DAG with the infrastructure node factored *above* the correlated OR-alternatives as a strict-prerequisite AND-node), propagation is correct: conditional on infrastructure up, the paths are independent and standard propagation gives the exact answer. The L1 construction principle (factor the common cause above the correlation it creates) recovers the correct probability. The sector parameter under L1 augmentation has a three-way gating form — condition-testing rate, evidence-starvation on each path under θ_C , exploration-gating on the OR-node — with each factor reflecting a different mechanism. When the common cause is *unobservable*, the L1 augmentation breaks and 5.1 Instance 2 kicks in: the per-conditional decomposition is Cramér-Rao-floored. The agent’s three escape routes (augment observability; multi-child joint observation; fall back to L0-on-marginals) are exercised below with their respective trade-offs.

Setup.

Two alternative paths to a goal G , sharing a common infrastructure dependency C :

- Infrastructure up with probability $\theta_C = 0.8$
- Path 1 succeeds with probability $\theta_{1|C} = 0.9$ when infrastructure is up, fails when down
- Path 2 succeeds with probability $\theta_{2|C} = 0.7$ when infrastructure is up, fails when down
- Goal succeeds if at least one path succeeds (OR)

Actual plan success probability (from the generative model):

$$P(G) = \theta_C \cdot [1 - (1 - \theta_{1|C})(1 - \theta_{2|C})] = 0.8 \cdot 0.97 = 0.776 \quad (\text{BC.1})$$

L0 Analysis: The Independence Model.

The L0 DAG has two leaf nodes with marginal success probabilities:

$$\theta_1 = \theta_C \cdot \theta_{1|C} = 0.72, \quad \theta_2 = \theta_C \cdot \theta_{2|C} = 0.56 \quad (\text{BC.2})$$

OR-propagation:

$$\hat{P}_2^{L0} = 1 - (1 - \theta_1)(1 - \theta_2) = 1 - (0.28)(0.44) = 0.877 \quad (\text{BC.3})$$

Overestimation: $0.877 - 0.776 = 0.101$ (13% relative error).

The overestimation equals $\text{Cov}(X_1, X_2)$ — the covariance induced by the shared infrastructure. The OR-node’s redundancy is illusory: both paths fail together when infrastructure fails, so the “backup” provides less protection than the independence model predicts. This is the $-\rho$ bias from the Correlation Hierarchy’s direction-of-bias formula.

Naive L1: Why Adding a Node Is Not Sufficient.

The obvious L1 construction adds C as a parent of both paths:

- $B_1 = \text{AND}(C, A_1), B_2 = \text{AND}(C, A_2)$
- $G = \text{OR}(B_1, B_2)$

Status propagation: $s_{B_1} = 0.8 \cdot 0.9 = 0.72, s_{B_2} = 0.8 \cdot 0.7 = 0.56, s_G = 1 - (0.28)(0.44) = 0.877$.

Same answer as L0. The OR-propagation treats B_1 and B_2 as marginally independent, but they are correlated through their shared parent C . Adding the common-cause node does not fix the overestimation because the node is *inside* the correlated structure (below the OR-node), not factored above it.

Correct L1: Factor the Common Cause Above the Correlation.

The correct L1 restructuring places C as an AND-prerequisite *above* the OR-structure:

- $G_{\text{sub}} = \text{OR}(A_1, A_2)$ — the sub-plan assuming infrastructure holds
- $G = \text{AND}(C, G_{\text{sub}})$ — infrastructure must hold AND sub-plan must work

Status propagation:

$$s_{G_{\text{sub}}} = 1 - (1 - \theta_{1|C})(1 - \theta_{2|C}) = 1 - (0.1)(0.3) = 0.97 \quad (\text{BC.4})$$

$$s_G = \theta_C \cdot s_{G_{\text{sub}}} = 0.8 \cdot 0.97 = 0.776 \quad (\text{BC.5})$$

Correct. Matches the actual plan success probability exactly.

Why this works: C is above the OR-node, so its value is factored out before the OR-propagation occurs. Conditional on $C = 1$, the two paths A_1 and A_2 are genuinely independent (their exogenous noise terms are independent — the common cause has been conditioned away). The OR-propagation’s independence assumption holds within G_{sub} because the correlation source is above, not among the siblings.

The L1 construction principle: *factor the common cause above the correlation it creates.* When a common cause correlates siblings under an OR-node, restructure so the common cause gates the entire OR-structure via an AND-relationship. This ensures conditional independence of the OR-children and makes standard propagation correct.

Sector Condition Verification (Proposition B.6).

Three leaf nodes with Beta-Bernoulli dynamics and ε -greedy path selection:

Table BC.1

<i>Leaf</i>	<i>True value</i>	<i>Tested when</i>	<i>Expected correction</i>
C (condition)	$\theta_C = 0.8$	Every trial	$-\delta_C/(n_C + 1)$
A_1 (greedy)	$\theta_{1 C} = 0.9$	$C = 1$ AND path 1 selected	$-\theta_C(1 - \varepsilon) \delta_{A_1}/(n_{A_1} + 1)$
A_2 (explore)	$\theta_{2 C} = 0.7$	$C = 1$ AND path 2 selected	$-\theta_C \varepsilon \delta_{A_2}/(n_{A_2} + 1)$

The sector parameter (full proof in Prop B.6 of [R](#)):

$$\alpha_\Sigma = \min\left(\frac{1}{n_C + 1}, \frac{\theta_C(1 - \varepsilon)}{n_{A_1} + 1}, \frac{\theta_C \varepsilon}{n_{A_2} + 1}\right) \quad (\text{BC.6})$$

Three-way gating. This is the first verified mixed AND/OR topology, combining:

1. **Condition testing** — C is tested every trial, same rate as a single edge (B.1)
2. **Evidence starvation** — action edges are gated by θ_C (tested only when $C = 1$), same mechanism as B.2
3. **Exploration gating** — OR-alternatives compete for test opportunities (ε vs $1 - \varepsilon$), same mechanism as B.4

The B.5b bridge applies (non-negative Jacobian, componentwise corrections): $\alpha_s = \alpha_\Sigma$ with no penalty.

L0 vs L1 Comparison.

Table BC.2

<i>Quantity</i>	<i>L0</i>	<i>L1 (correct)</i>
Leaf edges	2 (A_1, A_2 at marginals)	3 ($C, A_1 \mid C, A_2 \mid C$)
Φ at truth	0.877 (biased)	0.776 (correct)
Φ – actual success	+0.101 (overestimates)	0 (unbiased)
Bottleneck α_Σ (at $\varepsilon = 0.3$)	$0.3/(n_2 + 1)$	$0.24/(n_{A_2} + 1)$
Persistence threshold	Lower (easier)	Higher (harder)

The tradeoff: L0 has a higher sector parameter (easier to maintain persistence) but its reference value Φ^{L0} is systematically wrong — it overestimates actual success by the covariance ρ . L1 has a lower sector parameter (the θ_C attenuation makes action calibration harder) but its reference value Φ^{L1} is correct.

Both models have $\delta_s = 0$ when credences are at truth. The difference is what $\delta_s = 0$ means:

- **L0**: well-calibrated within the independence model — which overstates plan success by ρ
- **L1**: well-calibrated to actual plan success

L1 persistence is harder but calibration is honest. The extra leaf (C) adds a degree of freedom, and the conditioning slows action calibration. But the resulting target (Φ^{L1}) is the true plan success probability, not a biased surrogate.

When Correct L1 Construction Is Not Possible.

The factoring-above principle works under two conjoint conditions: (a) the common cause cleanly gates all correlated children through a single AND-relationship (*topological*), and (b) the common cause is a *strict prerequisite* — $\theta_{\text{child}|\neg C} \approx 0$, so children cannot succeed when the common cause is absent (*semantic*). Both conditions must hold. The example above satisfies both: infrastructure gates all alternatives, and absent infrastructure forces failure ($\theta_{i|\neg C} = 0$).

Topological failure: mixed gating. When some OR-alternatives share a common cause and others do not, the factoring-above construction cannot place C above the full sub-plan. Conditioning-based propagation:

$$P(G) = \sum_c P(C = c) \cdot R_\Sigma(G \mid C = c) \quad (\text{BC.7})$$

where $R_\Sigma(G \mid C = c)$ is computed by standard AND/OR propagation with C fixed. Cost: $O(2^k \cdot (|V| + |E|))$ where k is the number of common-cause nodes. Tractable for small k ; exponential in general.

Semantic failure: soft facilitators. When the common cause is a soft facilitator — $\theta_{\text{child}|\neg C} > 0$, so children can still succeed when C is absent, just less reliably (favorable market conditions, a supportive environment, an enabling but non-essential resource) — the AND-prerequisite construction mathematically forces $P(\text{sub-plan} \mid \neg C) = 0$, which strictly understates actual success probability. This is a real failure mode even when the topology admits factoring-above. The natural repair at $O(1)$ cost per soft-facilitator node is the **mixture form (L1')**:

$$\hat{R}_\Sigma^{L1'} = \theta_C \cdot R_\Sigma(G \mid C) + (1 - \theta_C) \cdot R_\Sigma(G \mid \neg C) \quad (\text{BC.8})$$

where the two conditional sub-plans may share structure but carry separate edge credences $p_{ij|C}$ and $p_{ij|\neg C}$. The parametric cost per soft-facilitator-affected edge doubles; the propagation remains polynomial. This is the gap between L1 (strict prerequisites) and L2 (arbitrary joint): L1' handles soft facilitators without the $O(2^k)$ exponential blowup of L2's explicit conditioning. Sector-condition verification for L1' is derived as **Proposition B.7** in *R when C is observable per trial*: under Beta-Bernoulli updating, componentwise updates per conditional branch, and facilitator monotonicity ($R_\Sigma(G|_C) \geq R_\Sigma(G|_{\neg C})$), the sector condition holds globally with five-way gating

$$\alpha_{L1'} = \min\left(\frac{1}{n_C+1}, \min_{j \in \mathcal{J}_C} \frac{\theta_C \pi_{j|C}}{n_{j|C}+1}, \min_{j \in \mathcal{J}_{\neg C}} \frac{(1-\theta_C) \pi_{j|\neg C}}{n_{j|\neg C}+1}\right) \quad (\text{BC.9})$$

(condition testing; evidence starvation and exploration gating on each of the $C = 1$ and $C = 0$ branches). The B.5b transfer to plan value is lossless by facilitator monotonicity plus AND/OR monotonicity on each conditional sub-DAG. In the strict-prerequisite limit $\theta_{j|\neg C} \rightarrow 0$, B.7 reduces to B.6's three-way gating. **When C is not observable on a single observation channel**, the mixture is refuted as a no-go: the per-trial Fisher information matrix on $(\theta_C, p_{j|C}, p_{j|\neg C})$ factors as rank 1 around the indeterminacy manifold $\{\hat{\theta}_C \hat{p}_{j|C} + (1 - \hat{\theta}_C) \hat{p}_{j|\neg C} = \mu_j\}$, so by the Cramér-Rao bound no unbiased online estimator on the joint conditional vector admits $\alpha > 0$. Repair routes when C is unobservable: (i) augment C -observability (recovers B.7); (ii) run $K \geq 2$ children jointly under the same C -realization so the joint Fisher matrix reaches rank $2K + 1$; or (iii) fall back to plan-level tracking on the marginal $\hat{\mu}_j$ (recovers B.1 at the scalar marginal, losing the per-conditional decomposition). See 5.1 for the meta-pattern shared with the on-policy detection no-go in 9.2.

For strategies with many mixed or soft common causes, the agent faces a practical choice: model the most important common causes at L1 (for strict prerequisites) or L1' (for soft facilitators), accept residual L0 bias from unmodeled causes, or invest in richer propagation algorithms. See 8.3 Correlation Hierarchy for the higher-level treatment of L1 / L1' / L2.

Detecting Latent Common Causes.

The detection of causal insufficiency and interventional localization of latent common causes is treated as a standalone result in 9.2 — a *no-go theorem*: under purely on-policy short-circuit execution, no statistic of the agent's observable history can detect the latent, and the L0 residual in particular is *identically zero* on-policy. The residual figures of this example are the **marginal-sampling** regime ($\epsilon = 1$: every trial, both paths observed regardless of policy): there the credences converge to the marginals θ_1, θ_2 and the L0 residual $\Phi^{L0} - \bar{y}_G$ converges to $+\rho$ (our example: $0.877 - 0.776 = 0.101$). Between the two regimes the residual scales as $O(\epsilon)$ and serves only as a *confirmatory* signal; the primary detector is the pairwise sibling covariance test under exploration (9.2).

On-policy observational equivalence (the no-go's shallow-case verification). This example is also the shallow case for which the no-go is *exact*, and the matched-world construction can be verified directly. The on-policy world $\mathcal{W}_{L0}^*$ has independent edges at the regime conditionals

$$\theta_1^* = \theta_C \theta_{1|C} = 0.72, \quad \theta_2^* = \frac{\theta_C (1 - \theta_{1|C}) \theta_{2|C}}{1 - \theta_C \theta_{1|C}} = \frac{0.056}{0.28} = 0.2. \quad (\text{BC.10})$$

Under sequential short-circuit OR execution (try path 1; try path 2 only on failure), the three on-policy observable events have identical probabilities in both worlds:

Table BC.3

Event	$\mathcal{W}_{L1}$ (latent C)	$\mathcal{W}_{L0}^*$ (independent)
A_1 succeeds	0.72	$\theta_1^* = 0.72$
A_1 fails, A_2 succeeds	$0.8 \cdot 0.1 \cdot 0.7 = 0.056$	$0.28 \cdot 0.2 = 0.056$
A_1 fails, A_2 fails	$0.2 + 0.8 \cdot 0.1 \cdot 0.3 = 0.224$	$0.28 \cdot 0.8 = 0.224$

The agent's on-policy history is drawn from the same distribution in both worlds — no on-policy statistic can tell them apart, which is the no-go's content instantiated on this example's numbers.

Epistemic Status.

Conditional on Beta-Bernoulli model. The L0 overestimation, L1 correction, and sector condition verification are exact algebra. The direction-of-bias formula ($\pm\rho$) is exact for two binary siblings **under marginal sampling** (credences at the marginals θ_j ; under on-policy short-circuit execution the credences converge to regime conditionals instead and the residual vanishes — see 9.2); for deeper DAGs with multiple common causes, the bias involves higher-order covariance terms. The on-policy observational-equivalence table is exact arithmetic on the matched-world construction of 9.2. The L1 construction principle (factor common cause above the correlation) is general for single common causes gating OR-siblings; the conditioning-based extension for more complex topologies is standard (variable elimination in Bayesian networks).

Appendix BD

Worked Example: #worked-example-cam (missing)

Segment worked-example-cam not yet written.

Claim: Coevolving automata (Miller 2022): AAT $\leftrightarrow$ Moore machine mapping, meta-machine as $\varepsilon^* = 0$ composition, simplest adaptive agent
