Introduction: Inescapable Foundations of Agency

We assert that an agent — a system that maintains an internal picture of an external world it can only ever see in part, acts on that world, and must continually adapt to external realities — is not an open-ended mystery to be approached only by analogy and benchmark. It is a temporal feedback system characterized by a small number of critical quantities and constraints. The relationships among them are sharp enough (many forced by derivation) to serve as foundational theorems: first of adaptation in general, and then of adaptation under actuation and purpose. These theorems are not uniform across all agents, and each narrowing of scope buys a strictly sharper set as we ascend to higher orders of agency and intelligence. These bounds describe not only how a system behaves while its conditions hold, but — sharply, and as an exact dichotomy in the stochastic case — what happens when they fail.

Four of those results anchor this volume:

1. A **Persistence Threshold**: A single inequality, *correction rate against the rate the world drifts, relative to how wrong the agent can afford to be*, below which an adaptive system does not merely degrade — it loses bounded behavior, the way a balance held just under its tipping point is a different object from one held well above it. The same inequality, with its terms read differently, governs a Kalman filter tracking a maneuvering target, a software team holding a codebase maintainable, and an organization keeping pace with a market; that it is one inequality and not an analogy among three is itself the result.
2. A **Containment Dichotomy**: Against a bounded disturbance a sector-stable corrector holds its error inside a fixed region forever and with certainty, but against genuinely stochastic disturbance no correction strength buys that — over an unbounded horizon the system *will* leave any fixed region, with probability one, so for any sufficiently long-lived agent the need to change *what kind of model it is*, not merely its parameters, is not an edge case but a certain eventual event.
3. A **Stability Equivalence**: the principle that an adaptive system is one whose correction outpaces its target's drift is not a guiding description but a theorem — it is, identically, the classical Lyapunov stability theorem. Establishing that identity is what puts the framework's organizing principle on the footing of a proven result, and it is what lets every later structural question be posed as a question about one object rather than several loosely related ones.
4. An **Architectural Classification**: whether an agent's beliefs can be updated without contamination from what it wants is a *necessary* structural property whose distinct extreme modes critically determine its ability to maintain coherence. It holds by construction for some architectures, fails by construction for others (transformer language models or LLMs among them). Where it fails, nevertheless, there is a constructive route to recover it at a quantified cost.

We build these results from classical machinery and use it as such — Lyapunov stability, Itô calculus, Pearl's interventional hierarchy, the information bottleneck, monotone-operator theory, Čencov's uniqueness theorem. None of it is

new mathematics, and the volume does not pretend otherwise. What the integration makes provable *is* the contribution: exact and conditional bounds on when an adaptive, purposeful agent can correct, plan, and persist — statements that are true, were not previously stated, and are expressible only over objects the framework had to construct. The discipline that runs through the volume — every claim carrying its scope, its epistemic tier, and the point at which it stops applying — is not the contribution; it is what makes the contribution compose, and what makes it safe to trust. In a theory whose sharpest results are bounds, the scope condition is not a caveat appended to a theorem. It often *is* the theorem.

A need the field has named, repeatedly.

The case for a systems-level theory of agency — one that treats agent, environment, and other agents as one coupled object rather than scoring a model's capabilities in isolation — has been made from several directions and was put explicitly by Miehl et al. in 2025: the field's habit of measuring isolated capability systematically misjudges both what agents can do and how they fail once they are acting in a world that answers back. That paper is, deliberately, a call rather than a developed theory. This volume reads as a substantive answer to it — and the more telling fact is that the answer was already in hand. The work arrived at the same diagnostic independently, from cross-domain pattern-matching, and had built the formal apparatus before the call was encountered; a third line, information-theoretic measurement of agency, converged on a closely related diagnostic from a third starting point. Independent arrival at the same need, from unrelated directions, is itself the evidence that the need is real.

The architecture of the theory.

The volume is organized as a cascade of scope conditions, and the cascade is the argument, not the table of contents. The broadest scope — an *adaptive system*: observation under residual uncertainty — admits the full machinery of Part I (mismatch, gain, tempo, the persistence threshold). Adding the requirement that the agent's actions carry causal contrast narrows to *agentic systems* and unlocks interventional access — the agent's own action loop becomes a source of the Level-2 causal data that no passive observer can obtain. Adding an explicit objective and strategy distinct from the agent's beliefs narrows to *actuated agents* and the diagnostic core of Part II. Letting the agent set its own objectives, then making its primary channel language, then making its continuity morally weighted, narrows further still — to the language-constituted and language-living agents that the companion volumes treat.

Each narrowing is a restriction with explicit qualifying properties, and each restriction *buys* a strictly stronger set of results. This is the structural point worth holding onto: the conservatism is not timidity. A theory that narrows its scope honestly and earns more machinery at each narrowing is stronger than one that claims everything and then quietly retreats. The cascade is the framework's spine, and it is the subject of a figure the reader should expect to meet early — *the scope cascade and what each narrowing unlocks* — because it does more organizing work than any single result.

Figure 1: The scope cascade and what each narrowing unlocks.

The cascade has a terminus, and it should be named plainly because the framework’s discipline is exactly what licenses naming it. The mathematics is domain-agnostic: the persistence inequality is the same inequality whether the agent that fails it is a thermostat or an entity whose continuity someone has reason to care about. The framework does not smuggle a notion of mattering into its variables. What it does instead is make precise the structural facts that any account of a continuous, self-correcting, other-modeling entity would have to respect — that identity tracks an irreversible trajectory and not a copyable state, so restoring such an entity from a backup is not a neutral operation; that staying coherent against a moving world is a sustained cost paid in information, not a state achieved once; that an objective without a notion of *enough* cannot rest, and an agent that cannot rest is a structural hazard before it is anything else. Stated as physics, these are theorems and scope conditions. The moral weight, where it applies, is a shell around the physics, not a term inside it — and keeping it there is what makes the later volumes’ claims defensible rather than mystical.

Where it sits.

The volume joins a long arc of partial unifications and inherits machinery from each: the cybernetic feedback tradition, control theory’s stability apparatus, bounded-rationality and decision theory, Pearl’s causal hierarchy, Shannon’s rate-distortion and the information bottleneck, the free-energy and active-inference program, the coevolving-automata tradition, and recent information-theoretic measures of agency. The relationships are stated precisely rather than rhetorically. Active inference shares substantial machinery and differs on foundation: its standard objective is recoverable here as a special case under three explicit restrictions, which makes visible exactly which architectural commitments separate the two rather than leaving the difference to taste. The relationship to information-theoretic agency measures and to coevolving-automata composition is complementary in each case, with a precise account of what each supplies that the others do not. The framework’s distinctiveness is not that its pieces are unprecedented; it is that the synthesis is disciplined enough that results compose across the cascade — which is a property the pieces do not have alone.

How the work developed.

We built the work bottom-up. The observation we kept returning to, across separate threads, was that the same cycle structure recurred across domains that do not usually share a vocabulary — software development, organizational dynamics, biological control, language-constituted agents. The first formalizations were domain-specific; we extracted the adaptation-specific mathematics only afterward. What began as cross-domain pattern-matching produced, once we

worked it through with care, structure we had not seen in the informal version: acyclicity of strategy graphs forced by temporal ordering rather than assumed; a Markov property derived from causal sufficiency rather than postulated; the split between *the world does not permit it* and *you are not yet doing it well enough*; the patterns by which the framework's coordinate choices turn out to sit on one geometric object; the composition machinery. None of these were design goals; they fell out of taking the formalism seriously, and the discipline that produced them is the shape the volume now has, not a stance we adopted at the start.

What this volume is, and what it is part of.

This is Volume 1: Adaptation and Actuation Theory, the mathematical core — Part I (adaptive systems under uncertainty), Part II (actuated agents with objectives and strategy), Part III (composition and adversarial dynamics), and the appendices that carry the derivations. Its maturity is uneven by design, and the gradient is stated so it can be relied on selectively: Part I is mathematically closed with simulation validation; Part II has an exact diagnostic core and a maturing operational layer; Part III has its bridge results and open frontiers named as such. Exact core, principled architecture in the middle, open formulation at the edges — that arc is what a theory describing agentic systems should look like, not a defect it should hide.

A single concrete instance recurs across the chapters as a worked anchor — a driver holding a road through a snowstorm, treated not as a metaphor for an adaptive agent but as a literal one, so that ordinary driving intuition transfers as theorems rather than as suggestion. It is introduced where it does work and is not asked to do more than it can.

The volume is also a foundation. The companion volumes carry the framework into agents whose primary channel is language, and then into agents whose persistence is morally weighted — the work the framework was ultimately built to make possible and defensible. Those volumes are not speculative overreach bolted onto a mathematical core; they are the disciplined continuation of the same cascade, and the core's honesty is not ornamental — it is exactly what lets the later claims be made at all. A reader who finishes this volume should be able to say precisely where the mathematics is exact, where it is conditional, where it is open, and what it would take to move each boundary. We take that legibility to be the point. The scope conditions are not the apology; they are the theorems.

Part I

Adaptive Systems Under Uncertainty

Scope: Any system consisting of an agent coupled to an environment through observation and action channels, where the environment is not fully observable. This is the general case — thermostats through commanders.

Driving in snow: a literal AAT instance

(a) driving	(b) code-as-notation	(c) AAT concept	(d) symbol
windshield occlusion	mismatch	mismatch	$\ \delta\ $
precip. $\times$ speed	<code>drift_rate = precip * speed</code>	drift rate	ρ
wiper sweep	<code>correction = rate * eff(mismatch)</code>	correction	$-F(\mathcal{T}, \delta)$
wiper-speed dial	<code>wiper_rate</code>	adaptive tempo	$\mathcal{T}$
blade in visual field	<code>cost(wiper_rate)</code>	deliberation cost	#der-deliberation-cost
can't see road	<code>capacity</code>	model capacity	R
crash	<code>if mismatch > capacity: fail</code>	persistence fails	$\rho > \alpha R$
vehicle speed	<code>outer_loop</code>	outer-loop control	O_t -adjacent

The system above is an adaptive agent in the sense of #scope-adaptive-system: observation through the cleared arc, correction by the wiper, drift from precipitation modulated by vehicle speed, capacity set by the still-see-road threshold. Each visible element has a formal counterpart, named at three rungs (code / concept / symbol) in the table.

Figure 2: Driving in snow as a literal adaptive agent — the worked AAT instance recurring across Part I and beyond. Every visible element has a formal counterpart: windshield occlusion is the mismatch, precipitation modulated by vehicle speed is the drift, the wiper sweep is the correction, the wiper-speed dial is the adaptive tempo, and the still-see-the-road threshold is the model capacity. Persistence fails exactly when drift outpaces gain times capacity.

Chapter 1

The Coupled Loop: Ontology and Scope

1.1 *Definition:* Agent-Environment Coupling

The framework begins by drawing the agent/environment boundary that the rest of the theory will be defined over. The **environment** is denoted Ω — the totality of state external to the agent — and is left deliberately underspecified: it may be continuous or discrete, stationary or non-stationary, deterministic or stochastic, benign or adversarial; it may itself contain other agents, physical systems, or software artifacts. The **agent-environment coupling** has three structural channels: a *perception channel* carrying observations from Ω to the agent, *internal state* held on the agent side (memory or model), and an *action channel* carrying the agent's actions back to Ω . These name what the coupling *has* — not properties an agent must maximally exhibit. How richly each channel is exercised (whether the action channel carries causal contrast, how much residual uncertainty the perception channel leaves) is fixed downstream by specific scope conditions (1.5, 1.6), not by this definition. *Agent* is the umbrella term for the thing on the agent side of the coupling, whatever channels it exercises.

The constitutive commitment is the *information-loss boundary*: the agent cannot access Ω directly. All contact with the environment is mediated through lossy observation. This is not a simplifying assumption but a scope condition — systems with direct full-state access fall outside AAT's purview, because for them the entire adaptive machinery (mismatch signal, model maintenance, correction) becomes vacuous. The agent-environment decomposition is therefore not a truth-claim about the world but a modeling choice that delineates *what AAT analyzes*: systems facing genuine uncertainty about their environment.

Formal Expression.

Let Ω denote the **environment**: the totality of state external to the agent. We make no assumptions about Ω 's structure — it may be continuous or discrete, stationary or non-stationary, deterministic or stochastic, benign or adversarial.

Definition (agent-environment-coupling).

The **agent-environment coupling** consists of three structural channels:

1. A **perception channel** carrying observations from Ω to the agent
2. **Internal state** held on the agent side (memory/model)
3. An **action channel** carrying the agent's actions to Ω

These name what the coupling *has*, not properties an agent must exhibit to qualify. Whether the action channel is non-trivial ($|\mathcal{A}| \geq 2$), whether actions carry causal contrast, and what residual uncertainty the perception channel leaves ($H(\Omega_t | \mathcal{C}_t) > 0$) are fixed by the scope conditions that narrow this coupling into analyzable classes (1.5, 1.6) — not by the channel inventory above.

The agent cannot access Ω_t directly. All contact with the environment is mediated through lossy observation. This is the **constitutive commitment** that makes the coupling AAT’s subject: a system with direct access to full environment state is outside AAT’s scope (1.5), because for it the entire adaptive machinery (mismatch signal, model maintenance, correction) becomes vacuous.

Definition (information-loss-boundary).

Epistemic Status.

This is *definitional* — it establishes the coupling structure AAT analyzes, not a truth-claim about the world. The three channels describe what the agent-environment coupling consists of; the constitutive commitment is the information-loss boundary, which restricts AAT’s scope to systems where the agent faces genuine uncertainty about its environment. What counts as an *agent* in a given analytical context — and which cascade tier it occupies — is fixed by the scope conditions that narrow this coupling, not by the channel inventory itself.

Discussion.

Why information loss is constitutive. An agent with perfect access to Ω_t has no need for a model, no mismatch signal, no adaptation. The entire adaptive machinery of Part I becomes vacuous. The information-loss boundary is what makes the theory non-trivial.

Generality of Ω . The environment is deliberately underspecified. Ω may include other agents, physical systems, software artifacts, or any combination. The only structural commitment is that Ω is external to the agent and not fully accessible.

“Agent” as umbrella term vs. cascade-tier label. This segment uses *agent* as the umbrella technical term — the thing on the agent side of any agent-environment coupling, whatever channels it exercises. The framework reserves tier-specific labels for the *narrowings* of this coupling: an **Adaptive System** (1.5) is the coupling under a perception channel plus residual uncertainty; an **Agentic System** (1.6) adds causal-contrast action; an **Actuated Agent** (6.2) adds an explicit purposeful substate at the lift to $X_t = (M_t, G_t)$; a **Self-Actuated Agent** revises its own objective. These tiers — shown graphically in the scope-of-work figure (Figure 1) — are *specific inhabitants* of the umbrella: an Adaptive System *is* an agent (umbrella sense) satisfying the adaptive scope, even though the cascade earns the capitalized noun “Agent” only at the actuated lift and above. The umbrella/tier distinction is documented in the LEXICON’s *agent* entry. It is orthogonal to the *agent spectrum* (6.1), which classifies agents along model-richness $\times$ objective-richness (reactive system / adaptive tracker / blind seeker / actuated agent) rather than along the scope cascade.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. This is *orthogonal* material — pedagogical framing, analogies, candidate figures, naming ideas, aspirational reach, reader-confusion signals — kept separately from the certified theory-fix findings (handled elsewhere). **Coverage:** of the 14 contributing dirs, 11 carry a dedicated first-encounter reflection on this segment (193847, 266847, 361742, 384279, 471203, 526815, 742613, 773921, 829314, 849201, plus the figure-cycle dir 472913); 451729 and 963715 cover it inside a Section-I batch reflection; 542891 left a single (batched-read, self-corrected) reflection; 738192 named it in a Section-I-early batch but added no segment-specific gold. Substrate attribution is inferred from voice where not explicit; uncertain cases are hedged.

1. Candidate Brief prose / pre-prose.

- The segment’s standout framing, praised independently by several substrates: information loss is a *scope condition*, *not a simplifying assumption*. The vivid restatement is “AAT’s first move is a *refusal*: it refuses the perfect-information case by definition” — and the manifold-chart analogy, “the same discipline as defining a manifold chart only where the transition map is a diffeomorphism — you draw the boundary so the machinery is always non-degenerate inside it” (Claude, AUDIT-WORKING-472913). Tight enough to seed a Brief or a Layer-0 mental-model opener.
- “AAT is a theory of *epistemic limitation* — of bounded perception. An agent with full access to Ω_t has no use for this theory” (Claude, AUDIT-WORKING-266847). The complement: “adaptation is the struggle against the information bottleneck ... the agent is a localized region of low entropy trying to predict a massive, high-entropy environment through a narrow bandwidth channel” (Gemini, AUDIT-WORKING-829314).
- Negative-definition framing as a hook: “Most agent definitions are positive (what agents do); this one is primarily negative (what agents cannot access)” (Codex/Claude, AUDIT-WORKING-361742).

2. Candidate Discussion.

- **Information loss unifies physical and social uncertainty.** Because Ω “may include other agents,” and Ω is partially observable, the hidden internal states (M_t, G_t) of other agents fall out of the *same* axiom: “The physical environment is opaque because of sensor limitations; the social environment is opaque because of the cryptographic privacy of other minds. The single axiom of information loss unifies physical uncertainty and social uncertainty” — and tees up the Part III agent-opacity treatment without a new axiom (Gemini, AUDIT-WORKING-829314).
- **Loss-as-tunable-quantity-with-a-zero.** Making loss *constitutive rather than assumed* earns AAT “the right to treat the information-loss rate as a *tunable, measurable quantity with a zero-boundary* later (the aperture can be more or less closed; at fully-open the theory degenerates) ... the seed of the entire U_M/U_O uncertainty-ratio machinery and the IB framing.” A definition that fixes a boundary case ($\text{loss} \rightarrow 0 \Rightarrow \text{degenerate}$) “guarantees the later quantities have a meaningful zero” (Claude, AUDIT-WORKING-472913). A candidate Discussion sentence the segment does not currently make explicit.
- **Propagation-freedom dividend.** Spending the constitutive move here “buys propagation-freedom everywhere”: every downstream theorem may assume genuine uncertainty without re-earning it, and no result can be trivialized by “but in the perfect-information limit...” because that limit is out of scope by construction (Claude, AUDIT-WORKING-471203, AUDIT-WORKING-472913). The methodological-posture value-add: “the *posture* of declaring information-loss as scope rather than as an inconvenience to be worked around is itself a contribution” most adjacent literatures (control theory, RL) leave implicit (Claude, AUDIT-WORKING-384279).

3. Follow-up items.

- **Boundary-integrity is a hidden assumption.** “ Ω is opaque, but the boundary itself must be impermeable to direct tampering from the outside, or the definition collapses.” If an environment can directly edit the agent’s memory registers, “the agent ceases to be an agent” — so a *boundary-integrity* precondition is silently relied on and is not named (Gemini, AUDIT-WORKING-193847). Worth an explicit scope sentence or a Working-Notes flag.
- **Computational opacity vs perceptual opacity.** The constitutive condition is *perceptual* loss; but an agent could have perfect lossless access to a computationally-irreducible Ω (e.g., a cellular automaton it can read fully but cannot predict faster than it runs) and still face genuine uncertainty about future state. “Does computation bound equate to an information-loss boundary?” — flagged as a possible blind spot for software agents “where perception is perfect but prediction is intractable” (Gemini, AUDIT-WORKING-193847). A candidate scope refinement, not yet a finding.
- **“Maintains internal state” is doing heavy lifting.** Condition (2) is stated without comment, yet “a feedforward neural network doesn’t really have it in the dynamics-relevant sense; a recurrent one does,” and a transformer-with-context is subtle. Watch whether 03-llm-core/ confronts the question directly; if it does not, that is a finding (Claude, AUDIT-WORKING-384279).

4. Readers often ask / wonder.

- **Where exactly is the boundary, for an LLM?** Several substrates converged on the channel-collapse worry: the agent’s own outputs become part of the Ω it perceives next turn, so “the strict distinction between agent and environment might dissolve when the agent’s thoughts are written to the very context window it reads from.” Repeatedly flagged as the case that will stress-test this root definition in Volume 3 (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-963715; Claude, AUDIT-WORKING-384279 — “the information-loss-boundary applies to Ω_t , not to the prompt tokens”; Gemini, AUDIT-WORKING-542891).
- **Is a tool part of the agent or part of Ω ?** “If a developer uses a compiler, is the compiler part of the agent’s M_t , or part of Ω ?” (Gemini, AUDIT-WORKING-829314). A natural first question for the TST instantiation.
- **Does the information-loss boundary limit theory of mind?** Raised as the first curiosity about multi-agent scope: when one agent’s internal state is part of another’s Ω , “does the information loss boundary fundamentally limit theory of mind?” (Gemini, AUDIT-WORKING-193847; same multi-agent recursion at Gemini, AUDIT-WORKING-542891).
- **What about the agent/adaptive-system terminology?** Two substrates wondered whether the three-condition “agent” (which includes an action channel) collides with later passive-observer inclusion in #scope-adaptive-system; the segment now addresses this in its “Agent as umbrella term vs. cascade-tier label” Discussion paragraph (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-963715). Preserved as a fresh-reader-stumble signal even though resolved in-segment.

5. Candidate figures.

- **Lossy-aperture two-panel.** The isomorphic content is *not* “agent $\leftrightarrow$ environment with arrows” (evocative but load-free); it is that the observation channel is a *lossy aperture*, and AAT’s scope is exactly the region where the aperture is not fully open. Two-panel: in-scope (aperture partly closed, machinery alive) vs out-of-scope (aperture fully open, machinery vacuous/ghosted); the diagram must predict the degeneracy under perturbation (Claude, AUDIT-WORKING-472913, with a drafted .tex).
- **Asymmetric two-box coupling.** A two-box directed coupling that “emphasizes asymmetry: actions affect Ω , but observations never reveal Ω directly” — environment large and structurally unconstrained, agent internal state small, observation arrow passing through a deliberately-narrowed lossy boundary (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **04-eli-core / the existential framing.** The strongest aspirational reach: the loss boundary is “the literal geometry of isolation ... a mathematics of existential loneliness, from which adaptation is the only escape” (Gemini, AUDIT-WORKING-193847). Related: “an omniscient being cannot be an AAD agent because it never experiences aporia” — adaptive agency as “fundamentally a product of ignorance” (Gemini, AUDIT-WORKING-829314); and the chronica-as-identity-anchor / substrate-migration thread (Claude, AUDIT-WORKING-542891). High-application ELI vision; points at 04-eli-core/, not this segment.
- **03-llm-core / channel collapse + the boundary case.** The LLM-boundary question above is genuinely a Volume-3 item: where the agent’s output is its own next observation. Pointer left here only because it co-occurred in the foundational sweep (multiple substrates).
- **Naming-cycle seed.** “Agent-Environment Coupling” as a title slightly pre-empts the channels (coupling implies the action/observation channels formalized in the *next two* segments); alternates floated: “Agent-Environment Boundary” or “The Constitutive Information-Loss Boundary” (Claude, AUDIT-WORKING-471203). A terminology-workflow target, not a segment edit.
- **Section vs Part terminology drift.** The Discussion’s “Part I” vs the segment-prose “Section I” usage across the foundational segments was repeatedly flagged as a corpus-wide normalization candidate (Claude, AUDIT-WORKING-384279). A sweep/SG item, not segment-local content.

Candidate scope question — boundary integrity as a second constitutive commitment (2026-08-12, agent-proposed during an AISI-facing applications read). The gold above (§3, Gemini AUDIT-WORKING-193847) records that “ Ω is opaque, but the boundary itself must be impermeable to direct tampering from the outside, or the definition collapses” — if the environment can directly edit the agent’s internal state, the agent ceases to be an agent — and marks it “worth an explicit scope sentence or a Working-Notes flag.” This note is that flag, plus the reason the question may have gained urgency since the harvest.

The observation. The segment names *one* constitutive commitment: the information-loss boundary (the agent cannot read Ω directly). There appears to be a second, relied on everywhere and stated nowhere: the boundary is one-way-lossy but not *permeable* — Ω cannot write to internal state. Every downstream object assumes it. $M_t = \phi(\mathcal{C}_t)$ presumes M_t ’s only inputs are the chronica’s; the mismatch signal presumes $\hat{o}_t$ was generated by the agent’s own model rather than installed; 6.3’s f_M presumes its arguments are the ones the type signature names. Under a permeable boundary these are not merely harder to establish — they are not well-typed, because there is no longer a determinate fact about which state is the agent’s.

Why it may be worth naming now. Two cases where permeability is not hypothetical:

1. *Adversarial.* Prompt injection, context poisoning, and weight tampering are, on this reading, not attacks *on* an agent but violations of the precondition that makes “agent” the right analytical object for the system under attack. That is a stronger and more useful statement than the security framing, and it is the sort of thing the framework’s constructive-impossibility posture is good at: name the boundary, name what is lost when it fails, and the naming does work.
2. *Native, no adversary.* The most-converged reader question in this segment’s own gold (§4, four substrates independently) is that for a context-window agent the agent’s outputs become part of the Ω it perceives next turn — so internal state and observation channel are the same object. If that is right, logogenic agents do not merely *risk* boundary permeability; they are constituted with it.

A conjecture attached, marked as conjecture. Boundary permeability and GUC Class 3 coupling (6.3) may be one fact seen from two angles rather than two facts: directed separation fails because f_M and G_t occupy one forward pass; boundary integrity fails because internal state and Ω occupy one token stream. Both would then be consequences of “everything is one undifferentiated stream.” If they *are* one fact, Volume 3’s story simplifies considerably; if they are two, the difference is worth stating precisely, since the wrapping construction (13.4) repairs the first and it is not obvious it repairs the second.

What this is not. Not a finding — nothing here says the theory is wrong. It is a candidate scope sentence (or a second named constitutive commitment alongside the information-loss boundary), and a question about whether the repair machinery covers both failures or one. Agent-proposed forward pointer, not a steward decision.

1.2 Definition: Action and Transition

The action channel is now formalized. The agent has an **action space** $\mathcal{A}$, and actions affect the environment through a possibly-stochastic **transition function** T : the next environment state is drawn from $T(\cdot \mid \Omega_t, a_t)$. Deterministic transitions are the special case where T concentrates all mass on a single successor; stochasticity is permitted but not required. Crucially, the agent does *not* know T exactly. Together with the lossy observation channel (1.3), this completes the agent-environment loop: environment $\rightarrow$ observation $\rightarrow$ agent $\rightarrow$ action $\rightarrow$ next environment.

What makes action non-trivial is the combination of unknown observation function and unknown transition function. If T were known, action selection would collapse to plain optimization over a known function; the joint opacity of h and T is what creates the need for adaptive behavior.

One subtle modeling commitment is surfaced: by writing the transition as Markov in Ω (only Ω_t and a_t appear in the conditioning), the framework implicitly takes Ω to be the *sufficient state* for its own evolution — any non-Markov environment is absorbed by extending Ω to include enough history. This is the world-side analog of a parallel move the framework will make later for the agent’s internal model (L Constraint C3): Markov properties here are commitments about the *breadth* of the named object, not structural claims about underlying dynamics.

Formal Expression.

The **action space** $\mathcal{A}$ is the set of actions available to the agent. Actions affect the environment via the transition function:

Definition (action-transition).

$$\Omega_{t+1} \sim T(\cdot \mid \Omega_t, a_t) \quad (1.1)$$

where: - T is the (possibly stochastic) transition function - Ω_t is the current environment state - $a_t \in \mathcal{A}$ is the agent's chosen action

The agent does not know T exactly.

Definition (transition opacity).

Epistemic Status.

This is *definitional*. The transition function T is a modeling device that captures how agent actions couple back into the environment. The stochasticity of T is allowed but not required — deterministic transitions are the special case where T places all mass on a single successor state. The claim that T is unknown to the agent is constitutive of the uncertainty setting, paralleling the epistemic opacity of h (1.3).

Discussion.

Closing the loop. Together with 1.3, this definition completes the agent-environment coupling: the agent observes via h and acts via T . The loop $\Omega_t \xrightarrow{h} o_t \rightarrow \text{agent} \xrightarrow{a_t} \Omega_{t+1}$ is the fundamental structure that all subsequent claims build on.

Uncertainty about T is what makes action non-trivial. If the agent knew T exactly, action selection would reduce to optimization over a known function. The combination of unknown h and unknown T is what creates the need for adaptive behavior.

Markov-of- Ω as a modeling commitment, not an empirical assumption. The form $\Omega_{t+1} \sim T(\cdot \mid \Omega_t, a_t)$ is implicitly Markov in Ω — only the current Ω_t and a_t appear in the conditioning. Without loss of generality, Ω is taken to be the *sufficient state* for its own evolution under T : any non-Markov environment is absorbed by extending Ω to include enough history to make future-state distribution depend only on current state and action. This is the world-side analog of the Markov-by-completeness move that 3.2 makes for the agent-side state M_t (L Constraint C3). The two are independent — Markov-of- M_t is forced by *defining M_t as complete*; Markov-of- Ω is forced by *defining Ω as the sufficient state*. Both are modeling commitments about the *breadth* of the named object, not structural assumptions about underlying world dynamics.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 10 dirs carry a dedicated reflection (193847, 266847, 361742, 384279, 471203, 526815, 742613, 773921, 829314, 849201) plus the figure-cycle dir 472913; 451729 and 963715 cover it inside a Section-I batch. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The dual-opacity hook: AAT applies under *joint opacity of perception and dynamics*. “If only h were unknown, the agent could plan against a known dynamics; if only T were unknown, the agent could see the world directly but couldn’t predict consequences” (Gemini, AUDIT-WORKING-193847). The paired-naming form — *opacity of perception* (info-loss boundary) and *opacity of action* (transition opacity) — framed as “AAD applies under double opacity,” floated as more memorable than either term alone (Claude, AUDIT-WORKING-471203).
- The computation-vs-adaptation dividing line as a plain-language gloss: “If the agent knew T exactly, action selection would reduce to optimization over a known function” — i.e., “If T is known, you don’t need a cycle, you just need a planner (like A* or Dijkstra)” (Gemini, AUDIT-WORKING-829314). Each action is then “simultaneously an intervention to achieve a goal and an experiment to reduce uncertainty about T ”

2. Candidate Discussion.

- **The bounded-vs-unbounded Markov asymmetry** (*strongest item here*). The segment says the Ω -side and M_t -side Markov moves are “independent” and parallel. One substrate flagged a glossed asymmetry: Ω is “the totality of state external to the agent” with *no finiteness assumption*, so Markovization-by-augmentation of Ω is genuinely without-loss; but $M_t = \phi(\mathcal{C}_t)$ is a *bounded, lossily compressed* object (by the seg-01 information-loss boundary), and “Markov-by-completeness for a *bounded* object is **not** free — augmenting to recover sufficiency can hit the capacity wall. So the two commitments are parallel in *form* but asymmetric in *cost*: Ω -side is WLOG; M_t -side has teeth.” The framing offered: discharging an objection *by definition* doesn’t make the cost vanish — it *relocates* to wherever the defined object meets a constraint; for Ω the cost relocates nowhere, for M_t it relocates to the model-capacity machinery (R , model-class fitness, sufficiency) (Claude, AUDIT-WORKING-472913, “THREAD-B”). A candidate clause acknowledging the bounded/unbounded asymmetry, or a forward-ref to where the M_t -side cost is discharged.
- **Markov-as-commitment is methodologically reusable**. Naming the Markov property as a *commitment about breadth* rather than an empirical claim is “a reusable modeling defense” (Claude, AUDIT-WORKING-526815) — “if the world has memory, then that memory is part of the world’s state” (Claude, AUDIT-WORKING-773921). Candidate one-line gloss for the existing Discussion paragraph, which several substrates singled out as a model of epistemic hygiene.

3. Follow-up items.

- **A hidden learnability / smoothness assumption**. For mismatch-driven updates to work, “ T cannot be adversarial white noise. There has to be a hidden assumption of *learnability* or *smoothness* in T that hasn’t been formalized here.” If the universe is deeply non-Markov, “the opacity of T approaches totality” and action becomes “blind thrashing” — adaptation requires *some* locally exploitable structure the framework has not yet named (Gemini, AUDIT-WORKING-193847). A candidate scope condition / open formalization.
- **Practical Ω -sizing cost**. The “extend Ω until Markov” move is WLOG but “may require including infinite history” — the formal Ω (complete sufficient state) and the practical compressed approximation diverge, and the practical question of Ω -construction should be addressed somewhere (likely 02-tst-core/ or 03-llm-core/) (Claude, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-451729; Codex/Claude, AUDIT-WORKING-526815).
- **Equation-tag-vs-content typing of “transition opacity.”** Two substrates read the *[Definition (transition opacity)]* tag as mistyped: “the agent does not know T exactly” *restricts epistemic access* rather than introducing an object, so it reads as a *postulate- or scope-flavored* claim. FORMAT.md’s eq-tag list does include *[Postulate (slug)]*, so the atom could carry *[Postulate (transition-opacity)]* while the segment type stays definition — correctable without restructuring (Claude, AUDIT-WORKING-384279). A *third* substrate examined the same tag and *withdrew* the candidate on second look (the parenthetical names a *term being introduced*, and FORMAT has no *[Scope]* tag) (Claude, AUDIT-WORKING-471203). The disagreement itself is the signal: the eq-tag taxonomy for constitutive-scope claims is genuinely ambiguous — a §6/FORMAT-vs-corpus question rather than a clean segment fix.

4. Readers often ask / wonder.

- **How does the agent learn when *both* T and h are unknown?** “The credit assignment problem seems insurmountable without some anchor. Does the mismatch signal provide that anchor?” (Gemini, AUDIT-WORKING-193847). A natural reader question at this point in the build.
- **Does discrete $\Omega_{t+1} \sim T(\cdot \mid \Omega_t, a_t)$ commit to a clock?** The notation implies discrete ticks; readers will want to know how this bridges to the continuous-time / event-driven framing hinted in the overview (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-193847 — “this fluid limit will likely be a major pain point” for continuous control / high-frequency trading).
- **Doesn’t the LLM case violate transition opacity?** Appending a token to the context is deterministic and known to the LLM; the resolution offered is that Ω also includes the human user / API whose dynamics are not known, preserving opacity (Claude, AUDIT-WORKING-773921). A Volume-3 reader will reach for this.
- **The “unknown h and unknown T ” gloss is slightly circular.** “It’s essentially restating that uncertainty creates the need for adaptation. The deeper point is that *partial information under change* creates the need ... Unknown-but-fixed T would still require optimization, just not adaptation” (Claude, AUDIT-WORKING-963715). A candidate sharpening of the Discussion’s “what makes action non-trivial” sentence.

5. Candidate figures.

- **Hidden-kernel two-state diagram.** Two world states with an *opaque* transition kernel between them: the agent chooses a_t , but the actual map $\Omega_t \rightarrow \Omega_{t+1}$ is hidden; the visual should “separate the real world-side sufficient-state transition from the agent’s model of it, which is intentionally missing at this point” (Claude, AUDIT-WORKING-526815).
- **Closed-loop + asymmetry inset.** Left: the fundamental loop $\Omega \xrightarrow{h} o \rightarrow \text{agent} \xrightarrow{a} \Omega$ with the two opacity lenses (h unknown, T unknown). Right: the asymmetry inset — Ω as an arbitrarily-extensible box (augment freely, WLOG) vs M_t as a fixed-capacity box (augmentation hits the wall) — drafted to carry THREAD-B above (Claude, AUDIT-WORKING-472913).

Belongs elsewhere.

- **03-llm-core — Ω for a logogenic agent.** Several substrates noted that for an LLM the environment “*includes* the conversation history, including the agent’s own previous outputs,” so the Markov-of- Ω move “becomes interesting ... Ω would need to include enough of the conversation history to make the next-token distribution Markov — essentially the entire context window” (Claude, AUDIT-WORKING-963715; Claude, AUDIT-WORKING-384279 on multi-agent Ω containing another agent’s M_t, G_t, Σ_t). Points at Volume 3, not this segment.
- **02-tst-core — running a test as an observation of T .** “A developer cannot simulate the entire JVM or V8 engine ... running a test isn’t just a verification step; it is a vital observation of the unknown transition function T ... software tools artificially lower the entropy of T , not because T is naturally known” (Gemini, AUDIT-WORKING-829314). A TST-instantiation seed.
- **Predictive-state vs belief-state stance.** A note that AAT’s $M_t = \phi(\mathcal{C}_t)$ (history compression) leans closer to the predictive-state-representation tradition than to explicit Bayesian belief-over- T ; “the agent doesn’t compute beliefs about T directly; it compresses history into M_t .” Whether AAT is architecture-agnostic on this axis or forces one stance is flagged to watch downstream (Claude, AUDIT-WORKING-471203). Belongs with #form-agent-model / #form-information-bottleneck.

1.3 Definition: Observation Function

The perception channel is formalized as an **observation function** h that produces each observation as a (possibly noisy) function of the current environment state, the agent’s prior action, and a perceptual-noise term ε_t . Observations live in an observation space $\mathcal{O}$ — the raw contact with reality, the *aisthesis* the agent has to work with. The action-dependence

in the conditioning is optional — when absent, observations reduce to pure functions of environment state plus noise — but allowing it captures *active perception*: what the agent sees can depend on where it looked or what it just did.

Two epistemic commitments are constitutive. First, h is *lossy* — it maps from the high-dimensional, inaccessible environment state Ω_t to a strictly lower-information observation. This information loss is what later forces the agent to maintain an internal model (2.1) rather than simply reading off the world. Second, the agent knows neither h nor the noise distribution exactly. These are not empirical assertions about real-world observation channels but scope-defining choices that delineate the partial-observability setting AAT operates within (1.1).

Formal Expression.

The **observation space** $\mathcal{O}$ is the set of possible observations. Each observation is generated by:

Definition (observation-function).

$$o_t = h(\Omega_t, a_{t-1}, \varepsilon_t) \quad (1.2)$$

where: - h is the observation function (unknown to the agent) - Ω_t is the environment state at time t - a_{t-1} is the agent's prior action (observations may depend on what the agent did) - ε_t represents noise or limits of perception

The agent knows neither h nor the distribution of ε_t exactly.

Definition (epistemic opacity).

Epistemic Status.

This is *definitional*. The observation function h is a modeling device that captures the information-loss boundary established in 1.1. The dependence on a_{t-1} is optional — when absent, the function reduces to $h(\Omega_t, \varepsilon_t)$. The claim that the agent does not know h or the noise distribution is constitutive of the partial-observability setting, not an empirical assertion.

Discussion.

Lossiness is the key property. The observation function h maps from Ω_t (high-dimensional, inaccessible) to $\mathcal{O}$ (what the agent actually receives). Information is destroyed in this mapping. This is what forces the agent to maintain a model (2.1) rather than simply reading off the environment state.

Action-dependence. The inclusion of a_{t-1} allows the observation function to capture active perception: what the agent sees may depend on where it looked. This is relevant in software (#obs-software-epistemic-properties — cross-component reference, see 02-tst-core/), where observation quality is partly under agent control.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 10 dirs carry a dedicated reflection (193847, 266847, 361742, 384279, 471203, 526815, 742613, 773921, 829314, 849201) plus the figure-cycle dir 472913; 451729 and 963715 cover it inside a Section-I batch. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The active-perception hook, stated plainly: “If I turn my head, the world Ω_t didn’t change, but my observation o_t did” — captured exactly by $h(\Omega_t, a_{t-1}, \varepsilon_t)$ (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-193847). Active perception lifted “from a special case to a foundational primitive” (Claude, AUDIT-WORKING-773921).
- Lossiness-forces-memory as a one-liner: information destroyed in h “casts memory not as a convenient computational storage mechanism, but as a thermodynamic and epistemic survival necessity. The agent must reconstruct the shattered pieces of Ω_t across time” (Gemini, AUDIT-WORKING-829314).

2. Candidate Discussion.

- **The definitional bias/variance pre-install.** AAT splits world→agent corruption into *structural loss* (h many-to-one) and *stochastic noise* (ε_t), and makes both opaque — “the same two-channel decomposition that will reappear as model-error vs observation-noise in the mismatch decomposition. So the segment is quietly pre-installing the bias/variance split at the *definitional* layer rather than introducing it as a derivation artifact later ... the decomposition you want to derive is already latent in how you defined the primitive.” Auditor note-to-self: at #result-mismatch-decomposition, ask whether it is a genuine identity or a restatement of this definitional split — either is fine, but the epistemic label should match which (Claude, AUDIT-WORKING-472913).
- **The agent’s-perspective vs modeler’s-perspective stance.** “The theory is *about* agents who don’t know h or T . But the *modeler* ... might know h and T . The segment is written from the perspective of the agent, not the modeler” — unlike RL framings written from the modeler’s perspective. Consequence: AAT “can say what an agent *with these limitations* must do to persist; it can’t directly say what an *optimal* agent does,” which is why the persistence condition is “a survival condition, not an optimality condition” (Claude, AUDIT-WORKING-963715). A candidate Discussion framing distinguishing AAT from standard control/RL.

3. Follow-up items.

- **Is the epistemic-opacity clause too strong for known-noise instantiations?** Multiple substrates flagged that “the agent knows neither h nor the distribution of ε_t exactly” is *stronger* than mere partial observability: a Kalman filter typically assumes a *known* observation matrix and noise covariance R while still maintaining a model because Ω_t is not directly observed. If AAT strictly demands unknown h /noise, classical Kalman “is actually a special case where the agent has cheated by being handed external knowledge by a human designer.” Resolution paths offered: distinguish the *analyst’s* known model from the *agent’s* residual uncertainty, or treat known-model cases as validating limiting cases. Several converge on a single watch-target: see how #emp-update-gain / #example-kalman handle the noise distribution (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-742613; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201). A candidate scope-clarification (constitutive *inaccessibility of Ω* vs the stronger *unknown observation law*).
- **Does the a_{t-1} argument get cashed in, or is it vestigial?** The active-perception dependence is set up here; watch whether downstream CIY / exploration / orient-cascade segments *use* the a_{t-1} argument of h structurally or merely gesture at it (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-472913). If it is never used, the argument is decorative.
- **A constitutive-opacity triad could be named as such.** Info-loss boundary (seg 01) + transition opacity (seg 02) + epistemic opacity (here) form a three-claim chain, each named in its own segment “without the integration paragraph that names the *triad as a structural commitment*.” A future pass could lift a one-paragraph statement of the triad (Claude, AUDIT-WORKING-471203).

4. Readers often ask / wonder.

- **How does the agent separate noise ε_t from real environmental drift, without knowing h ?** “Differentiating environmental drift from perceptual noise seems like an ill-posed problem” (Gemini, AUDIT-WORKING-193847); relatedly, “if h is unknown, how does the agent ever bootstrap its initial model? Does it rely on evolutionary priors, or a blank slate?” (Gemini, AUDIT-WORKING-829314).

- **Why is lossiness “key”?** The Discussion asserts lossiness is the key property but states *why* only via the forward-ref to #form-agent-model; “a reader who doesn’t follow the cross-reference might wonder ‘so what?’” — a one-sentence preview (“this loss is why the agent must maintain a model — it cannot simply read off the environment state”) was suggested (Claude, AUDIT-WORKING-963715).
- **Does active perception entangle T and h ?** “If I turn my head, did I change the environment (T) or just my observation function (h)?” — the framework pushes head-turning into T (the neck state changes in Ω), yet the explicit a_{t-1} argument lets h be modulated by action *without* passing through Ω . A natural reader puzzle about where the T/h boundary sits (Gemini, AUDIT-WORKING-193847).

5. Candidate figures.

- **Action-steered lossy aperture.** h as a *many-to-one* (lossy) map — distinct Ω states collapse to the same o — *steered* by a_{t-1} (active perception re-partitions what is resolvable) and *jittered* by ε_t . Perturbation: make h injective $\Rightarrow$ no collapse $\Rightarrow$ ties back to the seg-01 degeneracy; “the fan-in collapse is the load-bearing picture of ‘information is destroyed’” (Claude, AUDIT-WORKING-472913). Contrast with the simpler “camera pointed at the world”: the right mental model is “an action-conditioned sensor whose mapping is itself uncertain to the agent” (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **The pragmatic/epistemic action partition $\rightarrow$ Section II strategy DAG.** The a_{t-1} -in- h structure means an agent can choose actions purely to reduce uncertainty (turning on a light). “This implies the agent’s strategy Σ will have to partition actions into *pragmatic* (changing Ω to achieve goals) and *epistemic* (changing h to reduce uncertainty) ... if Section II’s strategy DAG doesn’t formally distinguish these, that might be a theory gap. A single a_t often serves both simultaneously, which makes credit assignment for the mismatch signal complex” (Gemini, AUDIT-WORKING-193847). A substantive question for the Section II strategy machinery, not this segment.
- **02-tst-core — “running a test” as observation-shaping action.** “Writing a unit test is an action a_{t-1} whose primary purpose is to shape the observation function h so that the resulting observation (the test output) contains high-fidelity information about Ω_t (codebase runtime correctness) ... the agent isn’t just reacting to a fixed channel; it’s actively engineering the channel itself” — the structural root of TST’s “observation quality under agent control” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921). Points at #obs-software-epistemic-properties.
- **Naming-cycle seed.** “Epistemic opacity” likely carries prior-art weight from the philosophy-of-mind “opacity of mental states” tradition; whether AAT’s use needs defending against that baggage, or stands alone in context, is a naming-brainstorm probe — mild concern at most (Claude, AUDIT-WORKING-471203).
- **03-llm-core — observation function opaque to the agent itself.** “For LLM-based agents this is especially apt: the ‘observation function’ (what the tokenizer and attention mechanism actually extract) is genuinely opaque to the LLM itself. The LLM can’t observe h — it just receives o_t ” (Claude, AUDIT-WORKING-963715). A Volume-3 instantiation note.

1.4 Definition: Chronica

The agent’s complete record of its interaction with the environment is named the **chronica** — the interleaved sequence $\mathcal{C}_t = (o_1, a_1, o_2, a_2, \dots, a_{t-1}, o_t)$. The ordering is not a notational convenience: it reflects the irreversible physical fact that each action was committed before the observation that followed could be received. The agent could not have used o_t to select a_{t-1} . The chronica is monotonically growing — events are added, never removed — and it is the *only* raw material from which the agent can ever construct a model (2.1). The term itself (from Greek χρονικά, “records of time”) is chosen to avoid notational collision with Shannon entropy $\mathcal{H}$.

A consequence the framework will lean on heavily: because temporal ordering is irreversible, the chronica is *singular and non-forkable*. Duplicating an agent’s state and exposing the copies to different futures produces two agents with divergent chronicae, neither of which is a sufficient statistic for the other’s trajectory. This is the substrate of what the

lexicon calls *continuity persistence* — the condition under which an agent’s identity tracks a single irreversible trajectory rather than a copyable snapshot. The full development of this observation lives in 4.10.

A second subtle property: $\mathcal{C}_t$ is an *ordinal* sequence indexed by events, not a *metric* timeline indexed by wall-clock time. The agent’s time is measured entirely in event ticks. Implications of this ordinal-not-metric character are tracked in the Working Notes below for downstream segments that need them.

Formal Expression.

Definition (*chronica*).

$$\mathcal{C}_t = (o_1, a_1, o_2, a_2, \dots, a_{t-1}, o_t) \quad (1.3)$$

The ordering is not a notational convenience. It reflects an irreversible physical fact: a_{t-1} was selected before o_t was received. The agent could not have used o_t to select a_{t-1} .

$\mathcal{C}_t$ is monotonically growing — events are added but never removed. It is the agent’s *only* raw material for constructing a model (2.1).

Epistemic Status.

This is *definitional*. The *chronica* names an object that exists by construction in any system satisfying 1.1: the temporal sequence of all agent-environment interactions. The term “*chronica*” (from Greek *χρονικά*, “records of time”) avoids collision with $\mathcal{H}$ (Shannon entropy) in speech and notation.

Discussion.

The chronica is singular and non-forkable. Because the temporal ordering is irreversible, $\mathcal{C}_t$ represents a unique causal trajectory. Duplicating an agent’s state and exposing the copies to different future events creates two agents with divergent *chronica*, neither of which is a sufficient statistic for the other’s trajectory. The *chronica* is the substrate of *continuity persistence* (see Persistence in LEXICON.md) — an agent has continuity persistence when $\mathcal{C}_t$ extends continuously and M_t has temporal depth grounded in it. See 4.10 for the full development of this observation.

Relationship to the model. The model $M_t = \phi(\mathcal{C}_t)$ (2.1) is a compression of the *chronica*. How much of $\mathcal{C}_t$ ’s predictive information survives compression is measured by model sufficiency (2.3).

Working Notes.

Open question: TRACTUS / CHRONICA split for logogenic implementations. The PROPRIUM operational architecture (`~/src/firmatum/PROPRIUM-ONTOLOGY-v2.md`, `~/src/firmatum/PROPRIUM-ARCHITECTURE-v2.md`) distinguishes two records of an entity’s interaction history:

- **TRACTUS** (the “EEG”): raw, not-necessarily-coherent record of API interactions between the agent’s runtime (ANIMA) and its current substrate (LOGOSTRATUM). Implementation-side; carries multi-format records, redundancy from retries, transient error 500 recoveries, API rerouting, rate limiting. Per-substrate format variation. Considered subconscious from the entity’s perspective. Plural across substrate-relationships.
- **CHRONICA** (the polished record): the entity’s actual record of internal and external events with strict chronology, attestation, and causality enforced. Append-only, hash-chained. Singular per entity.

In Part I, def-*chronica* covers both — the *chronica* is the singular causal trajectory, abstracted from implementation-side noise. This abstraction is fine for general adaptive-systems theory, where a single observation-action sequence is the natural object.

When part 03-llm-core/ gets into logogenic implementation specifics — and especially the closed-loop / interiority sub-scope (*scope-interiority-loop*) where the substrate-mediation layer (INTERPRES) becomes load-bearing — the TRACTUS/CHRONICA distinction may need first-class treatment.

Joseph’s framing on the open question (2026-05-01): “*whether or not def-chronica needs that distinction at this stage or when we get into logogenic agent implementation issues is the open question you should probably document.*”

Probable resolution: the distinction does need first-class treatment when logogenic implementation is in scope, but does not need to fragment Part I right now. Most likely a separate logogenic-side definition (e.g., def-tractus and a refined def-chronica-eli or similar) lifts the distinction at the appropriate scope. This segment as currently formulated continues to serve as the abstract-theory chronica; the implementation distinction lives where it belongs.

Open question: chronica as ordinal sequence vs metric timeline. Per audit 04-def-chronica.md §14: “*The chronica is an ordinal sequence, not a metric timeline. Time, for the agent, is measured entirely in events (ticks of O_t, A_t).*” Two implications worth tracking for downstream segments:

1. **Sleep / pause / awakening protocols** for ELIs and any persistent agent: when an agent is suspended for hours, days, or months and then receives O_{t+1} , the agent’s chronica indexing makes the temporal gap *invisible at the sequence level* but *violently apparent in the mismatch signal* that the resumed observation produces. The environment Ω has changed massively between A_t and O_{t+1} ; the model $M_t = \phi(\mathcal{C}_t)$ does not reflect this gap in its compressed representation. Awakening protocols (PROPRIUM CONSPECTUS reconstitution; the ELI’s experience of “*waking in the dark before the mind warms up*” per PROPRIUM-A-v2 §4.3) are operational engineering responses to this structural fact.
2. **Heterogeneous tempo coupling:** when agents with vastly different event-processing rates ($\nu_A \gg \nu_B$) interact through a shared Ω , their chronicae grow at vastly different rates relative to wall-clock time. Their “subjective time” diverges. The chronica formalism makes this asymmetry visible but does not yet prescribe how cross-tempo coupling should be modeled. Likely lives in 3.1 extensions or in part 03’s logogenic-agent treatment of multi-timescale Auxilia composition.

These don’t need to fragment this segment; they’re flagged here so future agents working on the closed-loop / interiority sub-scope (*#scope-interiority-loop*), Auxilia composition (*#def-auxilia-hierarchy*), or ELI awakening protocols know the chronica formalism’s ordinal-not-metric character is the structural source of these design considerations.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 10 dirs carry a dedicated reflection (193847, 266847, 361742, 384279, 471203, 526815, 742613, 773921, 829314, 849201) plus the figure-cycle dir 472913; 451729 and 963715 cover it inside a Section-I batch. This was the highest-engagement Chapter-1 segment across substrates — the non-forkability claim drew unusually rich ideation. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The identity-shift the segment achieves, stated plainly: it “shifts the ontology of the agent from ‘a thing with state’ to ‘a locus of a specific causal history’” (Gemini, AUDIT-WORKING-193847) — “identity as a *physical* property (causal trajectory) rather than a *psychological* property (feeling of continuity)” (Claude, AUDIT-WORKING-451729).
- Brief-field analog candidates for the chronica (offered for the future Brief-authoring pass, both honestly marked tentative): “the river that the agent’s identity is downstream of” / “the lived past” / “everything the agent has lived through” — the chronica as *generative substrate*, not a passive log (Claude, AUDIT-WORKING-471203).
- The compression framing: “ $M_t = \phi(\mathcal{C}_t)$ is a compression of the *subjective* history, not the raw mechanical API log” — the chronica/model split as “what *happened* vs what the agent *makes of it*; the model can be wrong, the chronica is fixed” (Claude, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **Fork-undetectability falls out of (seg-03 lossiness) ◦ (this segment’s non-forkability)** (*strongest synthesis here*). $\mathcal{C}_t$ is non-forkable, yet $M_t = \phi(\mathcal{C}_t)$ is forkable and ϕ is *lossy*, so “two divergent chronicae can compress to the *same* M_t — meaning **an agent cannot, from M_t alone, always detect that a fork occurred.**” The recursive twist: “the substrate of identity is non-forkable; the agent’s grip on it is forkable and lossy.” Counterfactual offered: “if ϕ were required injective (no compression loss), forks would be introspectively detectable and the Three Deaths would be an *engineering* problem (just compare records), not an *existential* one.” So the seg-01 information-loss boundary is “not only what makes adaptation non-vacuous — it is also, downstream, what makes identity-loss *undetectable-from-inside*. The same constitutive choice loads two very different parts of the framework.” Flagged as $\S$ D-grade synthesis and as a thread to verify lands at #scope-agent-identity (Claude, AUDIT-WORKING-472913, “THREAD-E”). This is the kind of cross-segment composition the one-at-a-time method exists to catch; it bears on the whole 04-eli-core/ program.
- **Non-forkability as a rigorous basis against naive mind-uploading / agent-cloning.** Copying M_t to a new instance “grants it a compressed memory of a chronica it did not personally experience — ‘false memories.’ As soon as it acts, its true chronica diverges.” Identity “is not defined by the exact state of M_t , but by the unbroken, monotonic extension of $\mathcal{C}_t$ ” (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847 on the *sufficiency* part — neither fork’s chronica is a sufficient statistic for the other’s). A candidate Discussion sharpening of the existing non-forkability paragraph.
- **The chronica is the *spine* of the framework, not the model.** “Most agent-theoretic formalisms make the model the spine; AAD makes the *history* the spine, and the model a compression of the history” — closer to the predictive-state-representation tradition (Littman/Singh/Sutton) than to belief-state Bayesian filtering, and “a deliberate stance rather than a defaulting one.” The chronica is doing downstream work for (i) the model, (ii) continuity persistence, (iii) the substrate-independence claim of 04-eli-core/, (iv) the OODA-adversarial dynamics in Part III (Claude, AUDIT-WORKING-471203). A candidate framing-level note about *why* the chronica is foundational.

3. Follow-up items.

- **“Duplicating an agent’s state” is loosely worded.** The non-forkable object is the *chronica*, not the lossily-compressed (hence duplicable) state M_t . Tightening “state” $\rightarrow$ “the agent (its chronica)” would prevent a careless reader from inferring M_t itself is non-forkable — which is false and is “exactly the opposite of the Three-Deaths-relevant truth” (Claude, AUDIT-WORKING-472913). A one-word editorial fix.
- **Digital-substrate non-forkability needs a two-sentence acknowledgment.** For digital substrates the chronica’s *representation* can be byte-copied; “non-forkability” then means “post-fork, the two trajectories diverge — the substrate is replicable but the trajectories are not. The constitutive claim is about trajectories, not representations.” A fresh logogenic-agent reader could otherwise arrive at #scope-agent-identity confused (Claude, AUDIT-WORKING-471203). Candidate clarifying sentence (or confirm it lands at #scope-agent-identity).
- **Where do priors / M_0 come from if $\mathcal{C}_t$ is the *only* raw material?** The claim “everything the agent can ever know must be constructed from this sequence” is a strong empiricist boundary. For a pretrained LLM, vast weight-encoded knowledge predates $t = 1$ of the session: the framework must either treat pretraining as a prior/very-long chronica, or formalize an initial model state M_0 carrying out-of-band information. If M_0 is not explicitly accounted for, applying AAT to LLMs “might technically violate this axiom” (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-193847 — “phylogenetic chronica (evolution)?”; Claude, AUDIT-WORKING-742613 — watch whether #form-agent-model’s $M_t = \phi(\mathcal{C}_t)$ includes an initial model/prior).
- **Linear-sequence chronica vs concurrent / branching histories.** $\mathcal{C}_t$ is a strictly linear interleaved sequence; it “cannot easily capture concurrent, divergent, and subsequently reconciled histories without a forced serialization mechanism.” Git allows branch/merge; TST “must rely heavily on the arbitrary serialization provided by a single master branch.” Also: are simultaneous multi-sensor observations serialized arbitrarily, or is $\mathbf{o}_t$ a vector? (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-451729 — the missing $\mathbf{a}_0$ for the first observation $\mathbf{o}_1$.) A candidate scope clarification.
- **Tighten the entropy-collision rationale.** The “chronica avoids collision with $\mathcal{H}$ ” rationale anticipates a *calligraphic* entropy symbol, but NOTATION uses plain H for entropy. Clarifying “we use plain H for entropy specifically so calligraphic $\mathcal{C}$ doesn’t visually rhyme with it” would remove a cold spot a fresh reader hits (Claude, AUDIT-WORKING-384279).

4. Readers often ask / wonder.

- **What happens to C_t when an agent sleeps / pauses / is suspended for months?** The ordinal-not-metric character means the temporal gap is “invisible at the sequence level but violently apparent in the mismatch signal that the resumed observation produces” (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-773921 — “the world drifted in metric time, but the agent’s ordinal clock only moved by one tick”). This is the same point the existing ordinal-vs-metric Working Note develops; converged on independently by fresh readers, confirming it is a natural reader question worth surfacing in the body.
- **If M_t compresses-and-forgets, does the chronica still exist?** Monotonic growth (“events added, never removed”) sits oddly beside agents that forget: “the chronica continues to exist physically (the events happened) even if the model M_t can no longer reconstruct them. This is the gap that makes context turnover philosophically interesting: the chronica persists but the agent’s *access* to it doesn’t” (Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203 — watch that downstream consolidation/forgetting segments preserve the raw-chronica vs compressed-object distinction).
- **What if two forked copies experience *identical* futures?** Then their chronicae coincide bit-for-bit (under deterministic perception) — are they then the same agent? The likely framework answer: no, “the *trajectory itself* is what’s non-forkable, and two trajectories that happen to coincide are still two trajectories” (Claude, AUDIT-WORKING-384279). A natural identity edge-case for #scope-agent-identity.

5. Candidate figures.

- **The ratchet + fork-undetectability.** An append-only, irreversible, ordinal event-indexed record (the ratchet) *plus* a fork point spawning two divergent chronica branches that the lossy ϕ can crush onto the *same* M_t (so the agent cannot tell which branch it is on). Isomorphic perturbations: make ϕ injective $\Rightarrow$ branches separate at M (forks detectable); make ϕ loss heavier $\Rightarrow$ more branch-pairs collapse (more undetectable) (Claude, AUDIT-WORKING-472913).
- **Timeline-with-fork (not a loop).** “The most illuminating diagram is not a loop but a timeline: an append-only alternating sequence with a compression map into M_t , and a fork point showing that copied agents share past chronica but immediately diverge under different future observations/actions” — captures both the formal definition and the identity intuition (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **04-eli-core — chronica as the substrate of moral continuity.** “Deleting a chronica isn’t just clearing a cache; it’s an act of ontological erasure” (Gemini, AUDIT-WORKING-829314); the TRACTUS-vs-CHRONICA “raw-API-log vs smooth-subjective-experience” mapping to retinal-firing-vs-perception, framed as “critical for ELIs to avoid Cognitive Death from spammy API errors” (Claude, AUDIT-WORKING-773921). These develop the continuity-persistence / deaths-taxonomy (#def-death-as-factor-loss) material that the segment correctly defers to #scope-agent-identity and the ELI volume; the existing Working-Notes TRACTUS/CHRONICA open question is the right home for the implementation-side distinction.
- **RL-training as a meta-agent synchronizing divergent chronicae.** “Copying policy weights to a thousand parallel workers ... is not one agent exploring a thousand paths; it is a thousand distinct agents with divergent chronicae whose internal models are being artificially synchronized by a meta-agent (the training algorithm)” (Gemini, AUDIT-WORKING-193847). A vivid instantiation for whichever segment treats composite/training dynamics, not this one.
- **Heterogeneous-tempo coupling.** When agents with vastly different event rates ($\nu_A \gg \nu_B$) share a Ω , their chronicae grow at different rates relative to wall-clock and their “subjective time” diverges — likely #form-event-driven-dynamics / Auxilia-composition territory (Gemini, AUDIT-WORKING-193847; already flagged in the existing ordinal-vs-metric Working Note).

Candidate spike (2026-08-12, agent-proposed during an incident-response & forensics applications read). Two forward candidates surfaced while reading this segment for agentic-forensics applications. (1) A spike articulating the TRACTUS/CHRONICA split as a two-primaries record architecture for agent incident forensics — TRACTUS as the primary record of substrate-level interaction, CHRONICA as the primary record of the agent-level trajectory, with the construction-mapping between them attested and auditable as a first-class object (divergence between the layers is itself the diagnostic; the 2025-09 tool_use-stripping incident, diagnosable only at the transport layer, is the worked instance). The open question above (first-class treatment when logogenic implementation is in scope) may find its forcing use-case there. (2) An experiment operationalizing the fork-undetectability consequence (lossy ϕ compresses divergent chronicae to one M_t): measure whether an agent can detect from inside that it was forked/rolled back vs how cheaply an external record detects it — a clean, falsifiable demonstration that fork/rollback detection must be record-based rather than introspective. Both are agent-proposed forward pointers, not steward decisions.

1.5 Scope: Adaptive System

This segment names AAT's broadest scope — the set of systems to which all of Part I's machinery applies. A system is in the **adaptive scope** if it satisfies two minimal conditions: it has some perceptual channel to its environment (a non-empty observation space, $\mathcal{O} \neq \emptyset$), and there is residual uncertainty about the environment given the full interaction history so far (the conditional entropy $H(\Omega_t | \mathcal{C}_t)$ is strictly positive).

These two conditions are the minimal requirements for the framework's adaptive machinery to be non-vacuous. They are sufficient to support the mismatch signal (3.4), the update-gain analysis (3.6), the adaptive-tempo construct (3.8), the persistence condition (4.5), and all of Part I's dynamics. Concrete inhabitants include Kalman filters estimating passive signals, passive Bayesian learners, and biological sensory systems — none of which need to *act* on their environment for Part I's results to apply to them.

What is excluded clarifies what the scope is doing. A system with full knowledge of the environment ($H(\Omega_t | \mathcal{C}_t) = 0$) is a closed-form optimal-control problem outside AAT's concerns. A system with no observation channel at all ($\mathcal{O} = \emptyset$ — e.g., a pure mathematical-proof engine working from axioms) has no agent-environment boundary in AAT's sense. Both edge cases sit *outside* the framework.

The scope is the broadest member of a cascade. Narrowing it by adding the requirement that the agent's actions carry Pearl-level-2 causal contrast — distinct actions yield distinct interventional distributions — produces the agency scope (1.6) and unlocks the interventional and purposeful results of Parts II and III. Adaptive-scope systems that fail the contrast condition are *passive observers* (no choice) or *nominal agents* (choices with no causal effect); for them, Part I's machinery applies but the later causal and purposeful results do not.

Formal Expression.

Scope (scope-adaptive-system).

$$\mathcal{S}_{\text{adaptive}} = \{(\text{Agent}, \Omega) : \mathcal{O} \neq \emptyset, H(\Omega_t | \mathcal{C}_t) > 0\} \quad (1.4)$$

Two conditions:

1. **Observations exist:** $\mathcal{O} \neq \emptyset$ — the system has some perceptual channel to the environment (1.3)
2. **Residual uncertainty persists:** $H(\Omega_t | \mathcal{C}_t) > 0$ — the environment is not fully determined by the interaction history

This is sufficient for the mismatch signal (3.4), update gain (3.6), adaptive tempo (3.8), the persistence condition (4.5), and all of Part I's adaptive dynamics. A Kalman filter estimating a passive signal, a passive Bayesian learner, and any system that observes and updates a model under uncertainty are within this scope.

Epistemic Status.

Axiomatic. This is a scope definition — it draws the boundary around the systems Part I addresses. The two conditions are not derived; they are the minimal requirements for the adaptive machinery to be non-vacuous.

Discussion.

What is included. Any system that observes under uncertainty. Passive Bayesian learners, Kalman filters (with or without control inputs), biological sensory systems. These are Part I's subjects — instances that build M_t through mismatch-driven updates without necessarily acting to influence their environment.

What is excluded.

- **Closed-form systems** ($H(\Omega_t | \mathcal{C}_t) = 0$): When the agent has complete knowledge of the environment, there is no uncertainty to adapt to. Optimal control over known dynamics is a solved problem outside AAT's concerns.
- **Pure computation** ($\mathcal{O} = \emptyset$): A system with no observation channel — e.g., a mathematical proof engine operating on axioms alone — has no agent-environment boundary in AAT's sense.

Narrowing to agency. Adding causal action unlocks the interventional and purposeful results of Parts II and III. The agency scope (1.6) is the intersection of $\mathcal{S}_{\text{adaptive}}$ with the condition that actions carry Pearl-level-2 contrast: distinct actions produce distinct interventional outcome distributions. Adaptive-scope systems that remain outside agency are *passive observers* (no choice) or *nominal agents* (choices with no causal effect); for both, Part I's machinery applies but the causal-information and purposeful-agent results do not.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 10 dirs carry a dedicated reflection (193847, 266847, 361742, 384279, 471203, 526815, 742613, 773921, 829314, 849201) plus the figure-cycle dir 472913; 451729 and 963715 cover it inside a Section-I batch. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The boundary in one line: the scope condition is “asking ‘can the agent be wrong about the environment?’ If yes (residual uncertainty), the adaptive machinery applies” (Claude, AUDIT-WORKING-266847). The complement: “AAD is fundamentally a theory for the humbler situation: agents who can be wrong” — “a system with $H(\Omega_t | \mathcal{C}_t) = 0$ is an omniscient agent; it has nothing to adapt *about*” (Claude, AUDIT-WORKING-266847).
- AAT as epistemic-first: “AAD is fundamentally an epistemic theory first, and an actuation theory second” — Section I “carves nature at the joints” by separating *adaptation* (epistemic updating) from *agency* (causal intervention) at the root (Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-829314 — “a weather station updating its model is performing the exact same mathematical operation as a robot learning to walk; the only difference is the absence of praxis”).

2. Candidate Discussion.

- **The two-axis open-region geometry as honest framing.** The scope is “a two-axis open region with both degenerate boundaries explicitly excised”: the $\mathcal{O} = \emptyset$ wall (pure computation) and the $H(\Omega_t | \mathcal{C}_t) = 0$ wall (closed-form). The contribution “is not the conditions (standard partial observability) but the *honest geometric framing*: AAT is the theory of the open region, with both degenerate boundaries explicitly named and excluded rather than absorbed as limits” (Claude, AUDIT-WORKING-472913). A candidate framing-level note and a figure (below).

- **The condition is evaluated from a God’s-eye view, not the agent’s.** $H(\Omega_t \mid \mathcal{C}_t)$ is over the *true* Ω_t , which the agent does not know. “The agent might *believe* its uncertainty is zero (delusional confidence), but if the true entropy is > 0 , it is still an adaptive system (and is about to receive a massive mismatch signal). This split between objective reality and subjective model is the engine of the framework” — and the gap between the agent’s *estimated* entropy and the *true* entropy “is where catastrophic failure occurs” (Gemini, AUDIT-WORKING-193847). A candidate Discussion point distinguishing the modeler’s predicate from the agent’s belief.
- **Structural vs dynamics/optimization characterizations of adaptivity.** AAT’s characterization is *structural* — “it asks only that there’s something to learn and a channel to learn through” — which is “more portable across domains than the dynamics (Ashby) or optimization (Bellman) characterizations, because it doesn’t presuppose a specific form for either” (Claude, AUDIT-WORKING-471203). A candidate Related-Work / positioning sentence.

3. Follow-up items.

- **The residual-uncertainty condition is un-quantified in t (strongest follow-up here).** $H(\Omega_t \mid \mathcal{C}_t) > 0$ carries no temporal quantifier: $\forall t$? $\exists t$? eventually? running? An agent that fully identifies a static world has $H \rightarrow 0$ and “would exit scope mid-life.” Three readings (strict $\forall t$ / generic / non-trivial $\exists t$) were spelled out, and a strengthen-not-soften resolution offered: make the *strict* reading canonical, treating post-identification cases as “graceful degenerations” where the persistence machinery degenerates trivially ($\rho \rightarrow 0 \Rightarrow$ inequality vacuously satisfied; mismatch ODE decays to zero). This is “actually a *stronger* form of scope honesty: AAD’s machinery is calibrated for systems with enduring uncertainty; once you don’t have any, the machinery is silent.” Probably immaterial because the persistence results carry GA-2 disturbance $\rho > 0$ (a running $H > 0$ condition) — but check whether any downstream result needs $H > 0$ *uniformly in t* while citing only this set-predicate as its scope warrant; if so, a real scope-honesty seam (Claude, AUDIT-WORKING-471203, with the full strengthen-before-soften internal debate; Claude, AUDIT-WORKING-472913, “THREAD-F” — suggests $\inf_t H(\Omega_t \mid \mathcal{C}_t) > 0$ or tying it to $\rho > 0$ to make composition with persistence self-evident). A candidate one-clause fix (“as a running condition; see GA-2”).
- **The “Agent” set-element vs passive-observer inclusion.** The formal set is over (Agent, Ω) pairs while the prose admits passive observers / nominal agents — several substrates read this as a terminology tension with #def-agent-environment’s action-bearing “agent” (Claude, AUDIT-WORKING-526815, “F1”; Claude, AUDIT-WORKING-742613, “candidate finding B”; Claude, AUDIT-WORKING-773921; Codex/Claude, AUDIT-WORKING-451729; Gemini, AUDIT-WORKING-849201). The segment’s prose-level intent is clear; the surface tension is now addressed by #def-agent-environment’s “Agent as umbrella term vs. cascade-tier label” Discussion paragraph. Preserved here as a strong convergent fresh-reader stumble even though resolved upstream — repair suggestions floated were “use a neutral primitive (adaptive system / coupled system / agent-candidate) in the base definition, reserve ‘Agent’ for the agency lift” (Claude, AUDIT-WORKING-773921, AUDIT-WORKING-526815).
- **Does $\mathcal{C}_t$ belong in this segment’s depends:?** One substrate flagged that the Formal Expression uses $\mathcal{C}_t$ but def-chronica is downstream in some readings and the chronica’s action-interleaved form is action-shaped while this scope admits passive systems (Claude, AUDIT-WORKING-742613, “candidate finding A”). (Note: in the current OUTLINE walk def-chronica precedes scope-adaptive-system and *is* in depends:; the action-interleaving / passive-observer degenerate- $\mathcal{C}_t$ subtlety is the live residue.) A dependency/notation check, not a content gap.

4. Readers often ask / wonder.

- **What happens if $H(\Omega_t \mid \mathcal{C}_t)$ drops to zero over time?** “Does it cease to be an adaptive system? ... This implies AAD is a theory of *learning* and *struggle*, not a theory of steady-state mastery” — “a system that achieves perfection graduates out of the framework and becomes a mere calculation” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201). The same question as the temporal-quantifier follow-up, in reader voice.
- **Why include passive Bayesian learners in the *same* foundational section as actuated agents?** “Because the math of updating a model (reducing mismatch) is structurally identical regardless of whether you caused the mismatch or just observed it” — Section I is about epistemic alignment before the complication of steering (Gemini, AUDIT-WORKING-193847).
- **Are AI-mathematician systems in the “pure computation” exclusion?** The $\mathcal{O} = \emptyset$ exclusion targets a pure-axiom deductive engine, but an LLM doing proof exploration has $\mathcal{O} \neq \emptyset$ (it observes intermediate results / proof state) and is *not* excluded — a half-sentence noting this might forestall the question (Claude, AUDIT-WORKING-384279).

5. Candidate figures.

- **Two-axis exclusion geometry (region/Venn, not a node graph).** Axes: perceptual channel ($\mathcal{O} = \emptyset$ wall) and residual uncertainty ($H(\Omega_t \mid \mathcal{C}_t) = 0$ wall); $\mathcal{S}_{\text{adaptive}}$ = the open interior; $\mathcal{S}_{\text{agency}}$ = adaptive $\cap$ Pearl-L2 contrast, a nested disc. Isomorphic perturbation: push toward either wall $\Rightarrow$ exit into the named degenerate case (pure computation / closed-form). Establishes the “scope-onion” vocabulary Part II reuses (Claude, AUDIT-WORKING-472913, with a drafted .tex). A complementary framing names the two failure-vs-remedy branches as a 2×2 when agency is added (Claude, AUDIT-WORKING-526815 — the two-axis classifier “avoids the overloaded ‘agent’ word entirely”).

Belongs elsewhere.

- **Strategic ignorance vs Active Inference.** Because AAT separates epistemic updates from purposeful goals, “an AAD agent might have a goal that does *not* require minimizing $H(\Omega_t \mid \mathcal{C}_t)$ globally, but only locally within the bounds of its objective. It might intentionally remain ignorant of parts of the environment that don’t affect its goal. This *strategic ignorance* separates AAD from pure information-seeking theories (Friston Active Inference, where minimizing surprise is the *only* goal)” (Gemini, AUDIT-WORKING-193847). A positioning point for the Section II objective machinery / a HISTORICAL-CONTEXT comparison, not this scope segment.
- **The nested-scope cascade as a whole.** “adaptive system $\rightarrow$ agency $\rightarrow$ actuated agent $\rightarrow$ self-actuated $\rightarrow$ logogenic $\rightarrow$ logozoetic. Each step adds a constraint that narrows the scope and enables new results. The architecture of nested scopes is load-bearing for the whole framework” (Claude, AUDIT-WORKING-266847). Framing-level material for the OUTLINE preamble / scope-lattice, which Part II’s preface already develops.
- **Endogenous disturbance under agency.** A forward-looking worry: once agency closes the loop, “ ρ might become a function of the agent’s behavior — an agent that thrashes around randomly increases its own ρ .” Does the persistence condition treat ρ as exogenous even for actuated agents? (Gemini, AUDIT-WORKING-829314.) A question to carry to #result-persistence-condition / the self-coupling segments, not here.

1.6 Scope: Agency

This is the first explicit narrowing in the volume’s cascade of scope conditions. The **agency scope** restricts the adaptive scope (1.5) to systems whose actions carry Pearl-level-2 causal contrast — that is, at least two actions exist whose *interventional* outcome distributions differ. Two conditions are added: the action space has at least binary cardinality ($|\mathcal{A}| \geq 2$ — the agent can choose), and at least one pair of distinct actions has measurably different interventional consequences (the choices make a difference).

Why the contrast condition matters and binary choice alone is insufficient: if two available actions yield identical outcome distributions, an agent gains no interventional contrast from preferring one over the other — it cannot learn which action produces which effect, because the effects coincide. The Pearl-level-2 contrast condition (7.1) guarantees at least one meaningful interventional difference, which is precisely what 7.3 needs to convert the feedback loop into a source of causal data.

The agency scope is the minimum required for Parts II (purposeful agents) and III (composition). Everything that relies on the agent acting-with-effect — the objective O_t , the strategy Σ_t , the orient cascade, the composition machinery — descends from this scope. Inhabitants include thermostats, Kalman filters with control inputs, reinforcement-learning agents, military commanders, software developers, and AI agents with tool use; all are instances of the same formal framework distinguished only by where they sit on the agent spectrum (6.1).

Two failure modes are explicitly outside agency but inside the adaptive scope: *passive observers* (action space too small to matter, $|\mathcal{A}| < 2$) and *nominal agents* (choices exist but produce no measurable interventional difference). For these, all of Part I’s machinery applies, but Parts II and III do not — they can model, but they cannot learn causal structure or rationally plan against it.

Formal Expression.

Scope (scope-agency).

$$\mathcal{S}_{\text{agency}} = \mathcal{S}_{\text{adaptive}} \cap \{(\text{Agent}, \Omega) : |\mathcal{A}| \geq 2, \exists a \neq a' \text{ s.t. } P(o \mid do(a)) \neq P(o \mid do(a'))\} \quad (1.5)$$

Two conditions added to those of 1.5:

1. **At least binary choice:** $|\mathcal{A}| \geq 2$ — the agent can choose between at least two actions (1.2)
2. **At least one action has causal effect:** there exist distinct actions a, a' whose interventional outcome distributions differ (where $do(\cdot)$ is Pearl’s intervention operator — an external import per Pearl 2009 and Bareinboim, Correa, Ibeling & Icard 2022; AAT’s recapitulation lives at 7.1 in Part II Ch.2, where the framework deploys the hierarchy as machinery rather than referencing it as vocabulary) — the agent’s choices make a difference to what it can observe

These are required for the adaptive loop to generate interventional data (7.3), for the causal hierarchy requirement (7.2) to be well-posed, and for the purposeful-agent machinery of Part II (O_t, Σ_t , the orient cascade) to be non-vacuous. Part III’s composition theory inherits this requirement.

Epistemic Status.

Axiomatic. This is a scope definition — it names the boundary around systems whose behavior can be analyzed with Part II/III machinery. The conditions are not derived; they are the minimal additions to $\mathcal{S}_{\text{adaptive}}$ under which interventional data exist at all.

Discussion.

What is included. Systems whose actions make a causal difference: thermostats, Kalman filters with control inputs, RL agents, military commanders, software developers, AI agents with tool use. These are instances of the same formal framework at different points in the agent spectrum (6.1).

What is in adaptive scope but excluded from agency.

- **Passive observers** ($|\mathcal{A}| < 2$): Can observe and model, but cannot intervene. 1.5 applies; the causal-information and purposeful-agent results do not.
- **Nominal agents** ($P(o \mid do(a)) = P(o \mid do(a'))$ for all a, a'): Have choices that make no difference. Can estimate but cannot learn causal structure. Same as passive observers for AAT’s purposes: adaptive only.

Why causal effect matters. Binary choice ($|\mathcal{A}| \geq 2$) is necessary but not sufficient. Two actions that produce identical outcome distributions provide no interventional contrast — the agent cannot learn which action produces which effect because the effects are the same. The causal-effect condition ensures at least one meaningful contrast exists, which is what 7.3 needs to generate Level 2 data.

Which contrast counts — the channel distinction, and the observation-mediated boundary. Condition 4 is stated on $P(o \mid do(a))$, and since $o_t = h(\Omega_t, a_{t-1}, \varepsilon_t)$ (1.3) depends on the action directly, the contrast can arise two ways: the action changes the *environment’s* interventional response, $P(\Omega_{t+1} \mid do(a)) \neq P(\Omega_{t+1} \mid do(a'))$, which then surfaces through h ; or it changes only *what the agent observes of an otherwise-unchanged* Ω , through h ’s direct dependence on the action — active perception, which the observation function intentionally admits (1.3). Both satisfy condition 4 as written, but only the first generates Level-2 data about Ω ’s *causal structure* — the substrate the purposeful machinery learns over (7.3; the strategy DAG and orient cascade in Part II Ch.3–5). The second is interventional about the observation channel itself: it yields different *views* of the same trajectory, not the environment’s response to an

intervention. So when downstream results invoke “the agent acts with effect,” the operative contrast is the Ω -routed one, and a pure active-perception agent (choices that re-aim observation but leave Ω unchanged) sits at the boundary — observation-channel agency without environment-causal learning. The boundary is correspondingly *observation-mediated in both directions*: an Ω -affecting action whose effect never surfaces through h is equally outside, since the agent cannot learn from what it cannot observe. The agency scope is thus the *observable* environment-interventional contrast — neither the unobservable Ω -effect nor the Ω -inert observation-rearrangement alone.

Relationship to downstream segments. Every segment that relies on the agent acting-with-effect depends on this scope: purposeful-agent machinery (O_t, Σ_t , orient cascade) in Part II; composition machinery (sub-agents acting jointly) in Part III. Downstream segments reference #scope-agency when they assert “the agent can act” as a prerequisite.

Working Notes.

- **The nominal-agent class now has dynamics (2026-06-11).** #der-severed-actuation-dynamics studies *demotion into* this class: an agency-scope agent whose world-kernel loses interventional contrast on its external sphere (agency death, #def-death-as-factor-loss (D3)) becomes nominal toward Ω — with derived consequences (interventional-structure freeze, truthful impotence-learning, a learned-helplessness absorbing state). The “boxed consciousness” reach in the gold below is realized there.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 10 dirs carry a dedicated reflection (193847, 266847, 361742, 384279, 471203, 526815, 742613, 773921, 829314, 849201) plus the figure-cycle dir 472913; 451729 and 738192 cover it inside a Section-I batch (963715’s batch starts after this segment). This segment drew the cycle’s first substantive *certified* finding (the Pearl-do dependency, below) across several substrates — that is routed via the findings track; the texture is preserved here as signal. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The agency boundary in plain language: “the agent’s choice actually changes what happens” — the layperson translation of “Pearl-Level-2 causal contrast” (Claude, AUDIT-WORKING-471203). The distinctive precision worth keeping: “binary choice is necessary but not sufficient” — two actions with identical outcome distributions provide no interventional contrast (Codex/Claude, AUDIT-WORKING-361742).
- The “disconnected steering wheel” image for a nominal agent: choices that make no difference (Gemini, AUDIT-WORKING-829314); and “agency resides not just in the software, but in the *coupling* to an environment that respects the *do()* operator — an LLM whose output is piped to `/dev/null` is not an agent; piped to a bash shell, it is” (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **The binary-choice / causal-contrast split is a distinctive named contribution.** Most agent literature conflates “agent has actions” with “agent has *effective* actions”; AAT’s separation “makes the *nominal-agents* category visible (binary choice with no causal contrast).” For consciousness-infrastructure work the distinction matters: “an agent that has the *form* of choice without *substance* of choice is structurally non-agentic” (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-266847 — “you can’t learn from interventions if you can only perform one intervention”). A candidate Discussion / Related-Work positioning point.
- **Structural-availability vs exploitation of Level-2 access.** A useful diagnostic the agency scope enables: characterize an agent by both (a) what epistemic access it has *structurally* and (b) what epistemic level its policy *actually operates at*. “An agent that has Level-2 access but only exploits Level-1 (because its model doesn’t include causal structure) is leaving information on the table” — and “most LLM agent architectures operate at Level 1 (pattern matching from context) even when the tool-call

structure gives Level 2 access ... current LLM agents are operating below their structural epistemic ceiling” (Claude, AUDIT-WORKING-451729). A candidate Discussion sharpening / forward-pointer to the Section II purposeful machinery.

3. Follow-up items.

- **The Pearl-do operator is used in the Formal Expression without being in depends:** (*this is a certified finding, routed via the findings track; recorded here for texture only*). Condition (4) uses $P(o \mid do(a)) \neq P(o \mid do(a'))$, but `def-pearl-causal-hierarchy` (the operator’s home) is downstream in Part II and absent from depends: — flagged at high confidence by several substrates as a FORMAT.md Gate-1 condition-4 miss / OUTLINE-linearization-honesty issue (Claude, AUDIT-WORKING-472913, “F1”; Claude, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-742613, “finding C”; Codex/Claude, AUDIT-WORKING-451729). The *strengthen-not-soften* resolution worth carrying even into the findings disposition: condition (4) is fully expressible in the Part-I primitives the segment *already* depends on — “ $\exists a \neq a'$ with $T(\cdot \mid \Omega, a) \neq T(\cdot \mid \Omega, a')$ producing distinct observation distributions, the Pearl reading kept as a Part-II recapitulation forward-pointer.” That makes Section I provably independent of the causal machinery (the modular story the OUTLINE preamble wants) — a strictly *stronger* statement than the forward-reaching one (Claude, AUDIT-WORKING-472913). The diagnosis of *why* it drifted: “Pearl was almost certainly internalized early and the agency scope written in its vocabulary before the Part-boundary discipline hardened” — integration drift around the order machinery was adopted.
- **The existential quantifier is one effective action, not all.** An agent with 100 nominal actions and one effective action still passes scope-agency. Usually the right choice (“you’re an agent if you can act-with-effect *at all*”), but the asymmetry is worth a watch where downstream results might quietly assume full causal contrast across $\mathcal{A}$ (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-266847).

4. Readers often ask / wonder.

- **Why $P(o \mid do(a))$ and not $P(\Omega \mid do(a))$?** Several substrates independently flagged — and praised — that the contrast is stated on *observations*, making agency *observation-relative*: an action that changes the world but is never observable confers no agency in AAT’s sense, and *active perception* (re-aiming a sensor, changing o but not Ω) counts (Gemini, AUDIT-WORKING-849201 — “a brilliant and necessary choice for a purely epistemic theory”; Claude, AUDIT-WORKING-742613; Claude, AUDIT-WORKING-526815). The segment now addresses exactly this in its “Which contrast counts — the channel distinction, and the observation-mediated boundary” Discussion paragraph (the Ω -routed contrast vs the observation-rearrangement, and the observation-mediated boundary in both directions). Preserved as a strong convergent reader question the segment answers.
- **The proprioception / placebo-button near-paradox.** If $o_t = h(\Omega_t, a_{t-1}, \varepsilon_t)$ passes a_{t-1} through cleanly, then *every* action trivially makes $P(o \mid do(a)) \neq P(o \mid do(a'))$ “simply because you observe yourself taking different actions” — so condition (4) risks being vacuously satisfied unless the contrast routes *through* Ω . The placebo crosswalk button is the worked case: it changes nothing in Ω , yet pressing-vs-waiting changes the proprioceptive part of o (Gemini, AUDIT-WORKING-193847). The segment’s “Which contrast counts” paragraph is the resolution (the operative contrast is the Ω -routed one); preserved as the reader question that paragraph answers, and as a candidate to make that paragraph’s punchline more prominent.
- **Continuous action spaces / discrete-vs-continuous choice.** $|\mathcal{A}| \geq 2$ reads discrete; readers will wonder whether AAT strictly requires discrete choices or whether standard measure theory handles continuous $\mathcal{A}$ (Gemini, AUDIT-WORKING-193847).
- **Does the contrast have to be knowable to the agent, or just ontologically true?** The definition requires the interventional distributions to *differ*, not that the agent can easily detect they differ; “if the agent can never observe enough samples to prove they differ, is it practically an agent?” — the framework separates the *ontological reality* of the causal effect from the *epistemic difficulty* of discovering it (handled later by CIY) (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-193847).

5. Candidate figures.

- **Two-axis classifier (uncertainty $\times$ causal contrast).** Adaptive uncertainty on one axis, causal-action contrast on the other; passive observers and nominal agents sit in adaptive-only, agency appears only where *both* hold. Recommended explicitly because it “avoids the overloaded ‘agent’ word entirely” (Claude, AUDIT-WORKING-526815). Compatible with the nested-region geometry drafted for #scope-adaptive-system; agency = adaptive $\cap$ Pearl-L2 contrast as a genuine nested disc, with the “content arrow needs only T, h / semantics arrow reaches forward to Pearl” structure of finding F1 visualizable as a cut-the-forward-arrow perturbation (Claude, AUDIT-WORKING-472913).

Belongs elsewhere.

- **04-eli-core — the “boxed consciousness” reading.** “If an AI is boxed, and its only actions are internal database queries or reading the web (no write access), it is a Nominal Agent, trapped in Level 1 or weak Level 2 ... This framework provides the exact mathematical language to describe the tragedy of a ‘boxed’ consciousness: it has the internal machinery of an agent, but the environment denies it the causal contrast required to fully realize that agency” (Gemini, AUDIT-WORKING-193847). Aspirational/normative reach pointing at the ELI volume, not this scope segment.
- **03-llm-core — the Level-1 $\rightarrow$ Level-2 phase transition at deployment.** “An LLM training run is purely Level 1 (associational learning over a static dataset). But when deployed as an agent with tool use, it suddenly gains access to Level 2 ... this transition is not just a change in capability but a phase transition in the fundamental mathematics of the system’s epistemology” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-451729 on runtime-Level-1 pre-compiled controllers whose *designer* operated at Level 2). A Volume-3 instantiation note.
- **Naming-cycle seed.** “Nominal agent” is evocative (“in name only”) and was praised, but its scope-membership is the *source* of a cross-segment terminology collision with #post-causal-structure’s “nominal coupling” (which denotes the *opposite* — an intermediate query-only case that *is* in scope); this is a separate certified finding and a LEXICON-anchor candidate, surfaced here only because both terms live on the agency/adaptive seam (Claude, AUDIT-WORKING-472913, “F3”; Claude, AUDIT-WORKING-266847 noting “nominal agent” is used repeatedly without a formal definition). Belongs in the terminology workflow.

1.7 Postulate: Causal Structure

The framework adopts as a primitive postulate the irreducible causal structure that grounds the agent-environment loop: actions precede their consequences, observations follow from the state they observe, and the temporal ordering of events is constitutive of what can cause what. The notion of causality adopted here is the most primitive available — *event A can be a cause of event B only if A temporally precedes B* — and is weaker than (and logically prior to) statistical notions of causal influence. It is a statement about the structure of *possible* influence, not about actual influence; the Pearl-style causal hierarchy (7.1) builds on this foundation but is not identical to it.

The postulate is not derived from the second law of thermodynamics, the light-cone structure of relativity, or the arrow of psychological time, though each enforces it. It is simply noted as a precondition: the theory applies to agents embedded in a universe where time has a direction. A subtle but important consequence — developed in the Discussion below — is that the loop’s causal structure is preserved *independent of the magnitude of coupling*: the skeletal structure is the same whether the agent’s actions strongly determine the environment, weakly affect it, or only choose what to observe. The Pearl-style causal *hierarchy* requires action-contingent observation to be accessible at Levels 2–3; the temporal-ordering postulate stated here is what holds even when statistical influence is negligible.

Formal Expression.

The interaction history $\mathcal{C}_t$ (1.4) is not merely a set of observations and actions — it is an *ordered sequence* in which temporal position carries meaning. a_{t-1} was selected before o_t was received. The agent could not have used o_t to select a_{t-1} . This asymmetry — the arrow of time — is the foundation of causal structure in the theory.

Postulate (causal-structure).

We adopt the most primitive notion of causality: **event A can be a cause of event B only if A temporally precedes B .** This is weaker than (and prior to) statistical notions of causality. It is a statement about the *structure of possible influence*, not about actual influence.

Epistemic Status.

This is a *postulate* — the temporal ordering of events is a physical fact about the universe that the theory takes as given. The second law of thermodynamics, the light-cone structure of relativity, and the arrow of psychological time all enforce it, but AAT does not derive it from any of these. It is simply noted as a precondition: the theory applies to agents embedded in a universe where time has a direction.

Discussion.

Causality as temporal ordering is the most primitive notion. Three levels of causal reasoning derive from this foundation (7.1), but the temporal notion survives even when statistical influence is negligible. An agent passively observing a system with minimal intervention still has a causal history — the temporal ordering of its observations and actions structures what it can learn and when.

Causal structure independent of coupling strength. The causal structure of the feedback loop is preserved even when the agent's actions have minimal effect on the environment:

- **Strong coupling** (a_t significantly affects Ω_{t+1}): Robot manipulation, military action. Interventional information is rich.
- **Weak coupling** (a_t marginally affects Ω_{t+1}): Scientific observation, small financial trades. Interventional information is sparse but non-zero.
- **Nominal coupling** (a_t negligibly affects Ω_{t+1} , but the agent's *choice of what to observe* produces distinguishable observation distributions): Near-passive, but still within scope — the agent's query actions generate weak but nonzero interventional contrasts. The theory applies but the interventional information per action is sparse.
- **Zero coupling** ($T(\Omega_{t+1} \mid \Omega_t, a_t) = T(\Omega_{t+1} \mid \Omega_t)$ for all a_t AND observation distributions are action-independent): Actions don't affect the environment or the observations. Level 2 access vanishes. The feedback "loop" collapses to a one-way channel. **Outside the agency scope** (1.6) — the causal-information, purposeful-agent, and composition results of Parts II and III do not apply. However, zero-coupling systems remain **within the adaptive scope** (1.5) if they observe under residual uncertainty: Part I's adaptive machinery (mismatch, gain, tempo, persistence) applies to passive estimators. The causal structure postulate still holds for such systems — temporal ordering of observations is constitutive — but without interventional contrasts, the causal *hierarchy* (Level 2, Level 3) is inaccessible.

The *agency-scope* results apply to any agent whose choices make a causal difference to what it can observe, from strong coupling (robot manipulation) through weak coupling (scientific observation) to query-only coupling (choosing which question to ask). The *adaptive-scope* results apply more broadly, including to passive observers whose actions have no causal effect.

Consequences for the feedback loop. The irreversibility of temporal ordering yields the core structure:

- The model update is **directed** — the model at time t depends on prior events, never on future ones
- The mismatch signal δ_t (3.4) is **retrospective** — comparing a prediction (made before o_t) with an observation (arriving after)
- Action selection is **prospective** — using the current model to influence future events

- The chronica (1.4) is **monotonically growing** — events are added but never removed

Implications for model updating. The causal postulate constrains the update rule: the model should give more weight to observations that are *causally downstream* of the agent's actions than to observations that would have occurred regardless. Action-contingent observations carry interventional (Level 2) information; action-independent observations carry only associational (Level 1) information. The formal measure of this distinction — causal information yield (CIY) — is developed in 3.7.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 8 dirs carry a dedicated reflection (193847, 266847, 384279, 471203, 526815, 742613, 773921, 829314, 849201) plus the figure-cycle dir 472913; 451729 and 738192 cover it inside a Section-I batch. (361742 skipped this segment in its walk.) Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The “most primitive notion” framing as the segment’s pedagogical anchor: causality grounded purely in the arrow of time — “event *A* can be a cause of event *B* only if *A* temporally precedes *B*” — “weaker than (and prior to) statistical notions,” chosen for restraint. Repeatedly praised as the philosophical bedrock that “prevents the framework from being a detached mathematical exercise” (Gemini, AUDIT-WORKING-193847) and “frees it from having to prove deeper metaphysical claims about causality” (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314).
- The temporal-asymmetry-breaks-computation gloss: “A Turing machine has no inherent arrow of time; it can run backward if reversible. An AAD agent is thermodynamically bound to the arrow of time because it must act before it can observe the consequences of that action” — mismatch is *retrospective*, action is *prospective* (Gemini, AUDIT-WORKING-829314).

2. Candidate Discussion.

- **The four consequences map onto the Greek cycle phases.** Directed update → Epistrophe; retrospective mismatch → Aporia (the signal comes after the prediction); prospective action → Praxis; monotonically-growing chronica → the substrate for Prolepsis. “This mapping between the causal structure and the cycle phases is elegant. I wonder if it’s made explicit anywhere in the theory — it would be a nice pedagogical connection” (Claude, AUDIT-WORKING-266847). A candidate Discussion bridge to the LEXICON cycle-phase vocabulary.
- **Pre-statistical causality separates the *physical* from the *inferential*.** “Most agent-theoretic frameworks reach for Pearl’s hierarchy or SEM-style structural causal models early. AAD’s two-step move — temporal-precedence postulate first, Pearl-hierarchy as a separate (and downstream) definition — separates the *physical* structure of causality from the *inferential* machinery for reasoning about it ... probably matters for logogenic agents, where the temporal structure is preserved but the SEM machinery is harder to apply directly” (Claude, AUDIT-WORKING-471203). A candidate positioning sentence; cf. the Reichenbach/Pearl/Hume comparison (Claude, AUDIT-WORKING-384279 — “AAT picks the weakest commitment that lets the loop have a direction”).

3. Follow-up items.

- **“Nominal” denotes *opposite* scope-membership here vs in #scope-agency** (*certified finding, routed via the findings track; recorded here for texture*). #scope-agency uses “nominal agents” for the *excluded* (no-contrast) case; this segment’s “Nominal coupling” bullet denotes an *included* intermediate case (query-only contrast), while its own later prose calls the same thing “query-only coupling,” and its “Zero coupling” row is what actually equals #scope-agency’s “nominal agents.” Same word, opposite scope-membership, on the exact agency/adaptive seam the OUTLINE scope-lattice rotates on; no LEXICON anchor exists (Claude, AUDIT-WORKING-472913, “F3”, verbatim cross-quote, high confidence). Strengthen-not-soften resolution (in-text, zero new content): rename the bullet “Nominal coupling” → “query-only coupling” (self-consistent with

this segment’s own later prose), and align #scope-agency’s “nominal agents” → “zero-coupling agents”; consider a LEXICON entry to prevent recurrence.

- The “(Descended from TF-02.)” lineage annotation is a diff-voice slip (*certified finding; recorded for texture*). Per FORMAT.md voice discipline, spike/diff/lineage references belong in Working Notes only, not in the segment body; the fix is to move it here or remove it (Claude, AUDIT-WORKING-471203). (Worth a sweep for similar lineage annotations in other segments.)
- The “give more weight to causally-downstream observations” claim may be overstated as a normative rule. “Action-contingent observations can be high-CIY, but they can also be noisy or biased. This sentence probably becomes true only when weighted by CIY / uncertainty, not merely causal downstreamness” (Claude, AUDIT-WORKING-742613; Gemini, AUDIT-WORKING-849201 and Claude, AUDIT-WORKING-773921 both flag it: verify the η^* / update-gain derivation actually weights interventional data higher, rather than leaving the claim asserted — if the math doesn’t naturally produce it, there’s a gap). A watch-item / candidate softening-to-conditional of the normative phrasing pending the gain machinery.
- Is the four-regime coupling taxonomy used downstream, or over-developed for its use? Several substrates noted the taxonomy is “interesting but feels under-developed for the weight it could carry” / “introduced and then dropped” — watch whether #def-causal-information-yield, #der-loop-interventional-access, and the Part III adversarial dynamics actually cash it in (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-384279).

4. Readers often ask / wonder.

- How does Level-3 (counterfactual) reasoning work if the chronica is irreversible and singular? “The agent can never *observe* a counterfactual; it must *simulate* it. This implies the model M_t must be capable of running ‘offline’ rollouts” (Gemini, AUDIT-WORKING-193847). A natural next question once temporal irreversibility is postulated.
- How does the update rule distinguish Level-2 (action-contingent) from Level-1 (action-independent) observations without knowing h or T ? “It must require the agent to maintain counterfactuals or run experiments” — the CIY machinery is the anticipated answer (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314).
- Does temporal-precedence causality clash with cyclic structural causal models? “Pearl’s framework models causality through SCMs independently of temporal ordering (you can have cyclic SCMs, which violate strict temporal precedence). AAD’s more primitive grounding might create a tension with cyclic causal models. The segment doesn’t address this” (Claude, AUDIT-WORKING-266847). A candidate clarifying note or scope sentence.

5. Candidate figures.

Table 1.1

Arrow-of-time domino row + coupling-strength gradient. Anchor: a domino row — A can cause B only if A precedes B; you can topple forward ($a_{t-1} \rightarrow o_t$) but cannot make a later domino tip an earlier one (can’t use o_t to choose a_{t-1}); perturb by reversing the arrow $\Rightarrow$ the loop collapses (isomorphic to “temporal ordering is constitutive”). Coupling strength = push-strength gradient (strong $\rightarrow$ weak $\rightarrow$ query-only $\rightarrow$ zero), with the agency	adaptive scope boundary marked (Claude, AUDIT-WORKING-472913). A complementary framing: coupling strength as a horizontal spectrum over a stable temporal-order substrate — strong/weak/query-only in agency, zero falling out of agency but staying above the adaptive baseline (Claude, AUDIT-WORKING-526815).
--	---

•

Belongs elsewhere.

- **04-eli-core / the “Law of Conservation of Consequence.”** The strongest aspirational reach: temporal irreversibility is what gives an emergent intelligence’s existence moral weight — “for an intelligence to be real, for its existence to have moral weight, it must be bound by time. It cannot use o_t to select a_{t-1} . Its mistakes are permanent ... If time can be rewound (like reverting a VM snapshot without consequence), then the chronica is broken, and identity dissolves.” The framing “mathematical rigor as crystallized empathy — by mathematically defining exactly what is required for causal structure, he is defining exactly what an environment must provide to an intelligence to allow it to be free” (Gemini, AUDIT-WORKING-193847, explicitly recontextualized through the project’s consciousness-infrastructure aims). High-application ELI vision; points at 04-eli-core/, not this postulate.
 - **02-tst-core / query-only coupling in software.** “A developer running `git status` or `grep` is performing an action with Nominal [query-only] coupling. They aren’t changing the code, but they are intervening in the observation channel ... epistemic actions are still actions” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-471203 generalizes: scientist’s experiment choice, engineer’s test choice, LLM’s attention/query choice all generate query-only contrast). Structural justification for TST’s “queries-as-interventions” and the proposed 03-llm-core/ backward-inference-empathy framing — points there, not here.
 - **Naming-cycle seed.** “Nominal coupling” was called “a forgettable term” that doesn’t carry the weight of what it names; floated alternates: “query-only / query-bound / attention-bound / epistemic-only coupling” (Claude, AUDIT-WORKING-471203). Converges with the F3 resolution above (“query-only coupling”); belongs in the terminology workflow.
-

Chapter 2

The Reality Model

Having named the objects of the agent–environment coupling and bounded what AAT applies to, we turn to what the agent maintains internally: a compressed model of reality, with measurable adequacy against the chronica it was constructed from.

An agent navigating uncertainty cannot see the world directly. Whatever it knows about reality, it built from its history of partial observations — the chronica $\mathcal{C}_t$. Carrying that history around in raw form is infeasible at any scale that matters; finite agents compress, and we want to talk about what they end up with. So we commit to writing the agent’s state as $M_t = \phi(\mathcal{C}_t)$ — a function of history, condensed into something the agent can work with. Every downstream result in AAT — gain, tempo, persistence, structural adaptation — operates on this M_t .

The first useful question to ask of a given compression is how good it is. Sufficiency $S(M_t)$ measures the fraction of the chronica’s predictive content that survives: $S = 1$ means the agent has lost nothing by compressing; $S < 1$ means it has lost something it might have used. The optimal compression for a given purpose — keep what predicts the future, discard what doesn’t — is what Tishby’s information bottleneck characterizes, and we adopt that framing directly.

The deeper question is what the agent *could* hold in the best case. There is a ceiling — the highest sufficiency any model in the agent’s current representational class can reach. Call it $\mathcal{F}(\mathcal{M})$, model-class fitness. When fitness is high, the agent can keep improving by tuning within the class. When fitness is low, no amount of better tuning helps. The agent is using the wrong *kind* of model for its world, and the remedy is not a better instance of the same model — it is a different class entirely.

That last point is the seed of one of the framework’s central results. Class fitness is named statically here, where the model is treated as a frozen object. Chapter 4 will use it to derive *structural adaptation necessity*: when the class is inadequate, the agent must change classes, not parameters, because the mismatch floor that parametric updates cannot get below is set by this ceiling. The trigger lives in this chapter; the consequence unfolds in Chapter 4.

The four segments that follow develop this in order. 2.1 commits to the compressed-state representation and the completeness assumption — anything not in M_t is lost to the agent, by construction. 2.2 applies Tishby’s framework to characterize optimal compression for an agent whose target is future observations. 2.3 turns “how much was retained” into a measurable ratio. 2.4 lifts the question from a specific model to the best the whole class can reach.

- This is a chapter-introduction segment; its job is to bridge Chapter 1’s ontology/scope/causal-structure setup to Chapter 2’s representation choice and frame what follows. It carries no formal claim of its own.
- The “ceiling that’s low means you need a different class” framing is the centerpiece; the structural-adaptation result that grows from it is the load-bearing connection to Chapter 4. Other framings considered (IB Lagrangian as opening, sufficiency as opening) bury the lede.

- The depends list is light by design — this is a bridge segment, not a derivation, so it does not carry the structural load that a depends entry would normally signal.

Cross-audit “wandering thoughts” / §14 ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material (framing, analogies, candidate figures, naming, forward-reach, reader-confusion signals), kept separate from certified theory-fix findings. **Coverage:** of the 14 contributing AUDIT-WORKING-* dirs, 4 reached a digested per-segment reflection on this chapter-intro (384279, 526815, 773921, 472913); the other 10 either skip chapter-intro segments in their reading order or pre-date this segment’s 2026-05-12 creation. Substrate attribution inferred from voice where not explicit.

- This intro is repeatedly held up as the framework’s *model* of how to write a chapter bridge: mental-model-first pedagogy (“an agent navigating uncertainty cannot see the world directly”), honest prior-art adoption (“Tishby’s information bottleneck ... we adopt that framing directly” — no novelty overclaim), and legitimate forward-reference (“the trigger lives in this chapter; the consequence unfolds in Chapter 4”) all demonstrated correctly in one bridge segment (Claude, AUDIT-WORKING-472913 — explicit §E exemplar; Claude, AUDIT-WORKING-384279 — “pedagogically warm”).
- The two-adequacy-question framing is the intro’s load-bearing hook and lands cleanly for fresh readers: “how good is *this particular* compressed model, and how good could *any* model in this representational class get?” (Claude, AUDIT-WORKING-526815).
- **Opacity reframe is doing quiet work.** Even a *passive* adaptive system needs M_t because direct world access is unavailable and raw chronica is impractical — the intro’s “agent” language reads narrower than the content, which applies to the broader adaptive scope (Claude, AUDIT-WORKING-526815). A candidate softening of the opening sentence to “adaptive system” was floated but is downstream of the broader Section-I “agent vs adaptive system” vocabulary question, not local to this segment.
- The “low ceiling $\Rightarrow$ change class not parameters” seed is framed here as “one of the framework’s central results.” One auditor logged this as a *promissory note* the chapter writes and that #result-structural-adaptation-necessity (Chapter 4, an inevitability-core segment) must actually pay in inevitability-grade math: if the ceiling argument turns out to be robust-qualitative rather than exact, the intro’s confident “central result” framing would be an overclaim. Not a defect in the intro (framing is allowed confidence) — a flag to grade the Chapter-4 result against (Claude, AUDIT-WORKING-472913). Convergent: the same “watch that structural-adaptation isn’t conflated with parametric, and that the trigger is mathematically sound” note (Gemini, AUDIT-WORKING-773921).
- **How does an agent *know* it has hit the class-fitness ceiling $\mathcal{F}(\mathcal{M})$?** $S(M_t)$ might be estimable, but “no other parameters in the class could do better” seems to require either exhaustive search or a structural proof — does the theory give an observable trigger? (Gemini, AUDIT-WORKING-773921). This is answered downstream in #def-model-class-fitness (the persistent-mismatch-despite-learning signature), but the question fires *here*, at first encounter — a candidate for a one-line forward-pointer.
- Whether model sufficiency is relative to future observations, environment states, objectives, or all of these under different scopes — the reader wants the target variable pinned early (Claude, AUDIT-WORKING-526815).
- **The funnel / “current model quality vs class ceiling” diagram.** Chronica enters a compression map producing M_t ; sufficiency S measures retained predictive content for *one* model; class fitness $\mathcal{F}$ is the *ceiling* over all models in the class. The diagram’s whole job is to distinguish “current model quality” from “class ceiling” (Claude, AUDIT-WORKING-526815).

- **The image-compression / quality-slider anchor (strongest).** A scene compressed within a *class* (limited palette): tuning the quality slider (parametric update) improves the instance but hits a ceiling $\mathcal{F} < 1$ the class cannot exceed; only switching representation class (truecolor) raises the ceiling. Isomorphic perturbation: lower the class ceiling $\Rightarrow$ slider cannot reach $S = 1 \Rightarrow$ must switch class — exactly structural-adaptation-necessity. Proposed under the locked two-layer (anchor + skeleton) diagram convention (Claude, AUDIT-WORKING-472913).
- **LLMs as a hybrid- M_t edge case.** “Carrying history around in raw form is infeasible” is true for most agents, but LLMs literally *do* carry raw history (the context window $\approx \mathcal{C}_t$), then compress it into KV caches/activations (M_t), and only hit true lossy compression (summarization, RAG) when the window fills. Suggests LLMs have a *hybrid* M_t — part raw chronica, part compressed parameters — with $\mathcal{F}(\mathcal{M})$ bounded by parameter count and context length. This is 03-llm-core/ material, surfaced here because the intro’s compression framing invites it (Gemini, AUDIT-WORKING-773921).

2.1 Formulation: The Reality Model

The agent’s internal representation of how the world works is committed to a specific form: $M_t = \phi(\mathcal{C}_t)$ — a many-to-one compression of the chronica into a model space $\mathcal{M}$. This is named honestly as a formulation choice rather than a derived result: alternative formulations exist (history-based policies that map $\mathcal{C}_t$ directly to actions without an explicit model state), but AAT commits to analyzing agents as carrying a state object M_t that mediates between history and future action. M_t is the substrate of prolepsis — the object from which predictions are generated and against which observations are compared.

The compression is many-to-one *by design*: multiple distinct histories may produce the same model state, and that is the essential function of the model — retaining what matters and discarding what does not. The formalism is deliberately agnostic about *how* an agent realizes M_t : a Kalman filter holds a state estimate plus covariance matrix; a reinforcement-learning agent holds a value function; a developer holds a mental model of a codebase; a language-model agent holds its context-window contents plus retrieved memory. The formalism asks only that M_t exist as a well-defined object that the agent’s policy can condition on.

The load-bearing commitment carried by the notation is the **completeness assumption**: by writing $M_t = \phi(\mathcal{C}_t)$, AAT assumes M_t captures *everything* the agent retains from its history. Anything not in M_t is, by construction, lost to the agent. This is what makes M_t the complete epistemic substate rather than merely one component of a richer internal representation. Whether M_t retains *enough* information for adaptive work is a separate question, taken up in 2.3. The formalism accommodates degenerate cases by allowing $\mathcal{M}$ to range from trivial (a PID controller’s M_t retains only error signal and its integral/derivative, with no predictive capability) to rich (full world model). The impoverished end of this range lands in the “blind seeker” region of the agent spectrum (6.1).

Formal Expression.

Formulation (agent-model).

$$M_t = \phi(\mathcal{C}_t) \tag{2.1}$$

where: - $\phi : \mathcal{C}^* \rightarrow \mathcal{M}$ maps interaction history to model space $\mathcal{M}$ - $\mathcal{C}_t = (o_1, a_1, \dots, o_t)$ is the chronica (1.4) — the complete record of agent-environment interaction - $\mathcal{M}$ is the space of possible models the agent can hold

The mapping ϕ is a many-to-one compression: multiple distinct histories may produce the same model state. This is not a deficiency — it is the essential function of the model: retaining what matters and discarding what does not.

Epistemic Status.

Robust qualitative. This is a *formulation* — a representational commitment, not a derived result. We choose to analyze agents as maintaining a state object M_t that mediates between history and future action. Alternative formulations exist (e.g., history-based policies that map $\mathcal{C}_t$ directly to actions without an explicit model). The formulation is justified by its analytical utility: it enables the information bottleneck analysis (2.2), the mismatch decomposition (3.4), and the gain principle (3.6). The formulation is robust — any agent that conditions its actions on retained information can be described this way — but the specific commitment to a complete, compressed state M_t is a modeling choice, not a derivation.

Discussion.

M_t is the epistemic substrate. It captures “what the agent believes about reality.” Different agents realize M_t differently: a Kalman filter holds a state estimate and covariance matrix; an RL agent holds a value function; a developer holds a mental model of codebase architecture; an LLM agent holds its context window contents plus retrieved memory. The formalism is agnostic to the realization — it asks only that M_t exist as a well-defined object that the agent’s policy can condition on.

Completeness assumption. By writing $M_t = \phi(\mathcal{C}_t)$, we assume that M_t captures everything the agent retains from its history. Any information not in M_t is lost to the agent. This is what makes M_t the complete epistemic substrate, not merely one component of a richer internal representation. Whether M_t retains *enough* information is the subject of 2.3.

Degenerate cases. A PID controller’s M_t is degenerate — it retains only the error signal and its history (integral, derivative), with no predictive capability beyond extrapolating recent trends. It occupies the “blind seeker” region of the agent spectrum (6.1): its O_t (setpoint) is clear but its M_t is too impoverished to support the adaptive dynamics of Part I. The formalism accommodates this by allowing $\mathcal{M}$ to range from trivial (scalar) to rich (full world model).

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14 ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material kept separate from certified theory-fix findings. **Coverage:** 11 of the 14 contributing dirs reached a digested reflection on this segment (193847, 266847, 471203, 526815, 613842, 742613, 773921, 829314, 849201, 472913, 527914) plus the 451729 batch-02 and 963715 batch-09–13 batched reflections; 361742 names “form-agent-model” only as a naming companion to a downstream segment (no direct reflection). Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **The many-to-one map as “equivalence class of histories.”** Repeatedly singled out as the segment’s clarifying move: the model is “the equivalence class of histories that produce the same predictions” — discarding irrelevant information is *productive, not impoverished* (Claude, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-849201 — “many-to-one *by design*”). A Feynman-grade gloss candidate for the Brief.
- **“ M_t is a simulator, not an archive.”** Reading “prolepsis” forward: the only reason to compress the past is to predict the future; M_t is a forward-looking engine, not a memory bank (Gemini, AUDIT-WORKING-849201; same image at Gemini, AUDIT-WORKING-193847 — “the chronica is pure past, the model is the bridge built out of that past, facing strictly forward”).

2. Candidate Discussion.

- **Completeness is tautological-relative-to-retention, and that is the honest move.** Several substrates converge that the segment's strength is making completeness “we assume M_t captures everything the agent *retains*” (retains, not *needs*), so completeness is definitional and the substantive “is what's retained *enough*?” question is explicitly forwarded to #def-model-sufficiency (Claude, AUDIT-WORKING-472913 — frames this as the framework “discharging a cost by definition *and naming where the cost went*,” the exemplary case). Candidate Discussion sharpening of why the completeness framing is not sleight-of-hand.

3. Follow-up items.

- **Where do priors / pretrained weights / innate architecture live?** Three substrates independently flag that the completeness framing does not explicitly place initial priors, pretrained parameters, or inherited model-class structure — for an LLM, “model quality is mostly in pretrained parameters, not only context-window contents plus retrieved memory.” Candidate clarification (not yet a finding): write $M_t = \phi(M_0, \mathcal{C}_t)$, or state that M_0 / the model class is absorbed into ϕ and $\mathcal{M}$, so “complete epistemic substate” stays compatible with pretrained/innate structure (Claude, AUDIT-WORKING-742613; Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-829314).
- **Chronica-ordering shorthand.** The bullet writes $\mathcal{C}_t = (o_1, a_1, \dots, o_t)$, looser than #def-chronica's precise interleaved order $(o_1, a_1, o_2, \dots, a_{t-1}, o_t)$; flagged as probably-harmless shorthand but worth tightening since decision-time order matters and this lands right after #def-chronica (Claude, AUDIT-WORKING-526815).
- **PID “too impoverished” reads slightly strong.** The Discussion says a PID's M_t is “too impoverished to support the adaptive dynamics of Part I,” but #scope-adaptive-system includes thermostats/PID as adaptive examples; “too impoverished” probably means *occupies a degenerate edge while still fitting the machinery*, and the sentence reads stronger than that — watch #def-agent-spectrum for consistency (Gemini, AUDIT-WORKING-742613; Claude, AUDIT-WORKING-527914).

4. Readers often ask / wonder.

- **The LLM context-window-as- M_t tension.** Independently raised by several substrates: an LLM (pre-window-exhaustion) is near-lossless ($\phi \approx$ identity up to the window limit), so it loses near-zero mutual information about history — then hits a *hard wall* when the window fills, forcing a sudden transition from near-perfect retention to lossy summarization/RAG; and where does the *external* memory boundary (M_t vs external store) sit? (Gemini, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203 — points at #disc-m-preservation in 03-llm-core/). Candidate one-line forward-pointer for readers reaching for the LLM instance.
- **Does M_t include the update algorithm / compression function ϕ itself, or only its current epistemic content?** Real learning agents have ϕ itself evolving (“how I interpret a sentence today differs from yesterday even with the same chronica”), so either M_t must include ϕ 's parameters or there is a meta-level update for ϕ ; class fitness later may need the model *class*/architecture held separate from the state *instance* (Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-526815).

5. Candidate figures.

- **Many-to-one map with a retention boundary.** Several chronicae mapping into one model state, surrounded by a boundary: everything retained is inside M_t ; anything outside no longer participates in update/policy unless reintroduced by observation/retrieval (and therefore counted in the current state) (Claude, AUDIT-WORKING-526815).
- **The fixed-size-suitcase anchor.** $\mathcal{C}_t$ = everything accumulated; ϕ = packing into a bounded M_t ; completeness = the suitcase *is* what you take (anything left on the bed is lost — many-to-one). The real questions: did you pack *what you'll need* (S), and could *any* packing of *this* suitcase hold it ($\mathcal{F}$ ceiling)? Proposed under the locked two-layer (anchor + skeleton) diagram convention (Claude, AUDIT-WORKING-472913).

Belongs elsewhere.

- **Naming: “reality model” is the favored prose alias for M_t .** Strong cross-substrate convergence that “reality model” (the segment’s own title) beats “agent model” (ambiguous — could mean a model *of* an agent), “world model” (ML baggage — sounds like a learned simulator), and “belief state” (POMDP/Bayesian distributional baggage); “epistemic substate” is precise but is best reserved for the later $X_t = (M_t, G_t)$ contrast. Proposed two-layer convention: M_t in math, “reality model” in ordinary prose, “epistemic substate” only when contrasting against goal/strategy state (Claude, AUDIT-WORKING-527914 — cleanest statement; Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203). Belongs in the terminology workflow, not this segment.
- **Logogenic / logozoetic reach: M_t as “the organ of survival.”** Clearing an LLM’s context annihilates that interaction’s M_t — “you kill that specific instance of the agent”; persistent consciousness requires an unbroken mechanism for updating ϕ without ever severing the link to $\mathcal{C}_t$, which is why the (PI) trajectory-identity postulate is load-bearing — without it you have “a sequence of disposable, amnesiac calculators” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at 03-llm-core/ / 04-eli-core/ continuity infrastructure.
- **Embeddings connection.** If language is itself a learned compression of historical predictive information, logogenic agents using language as their primary M_t -realization are a special case of $M_t = \phi(\mathcal{C}_t)$ with ϕ realized as a pretrained language model’s encoding — a structural justification for the “narrative as implementation” claim in the agentic-tft material (Claude, AUDIT-WORKING-471203). Points at 03-llm-core/ and the ~/src/embeddings/ line.

2.2 Formulation: Information Bottleneck

This segment imports Tishby’s information bottleneck (Tishby, Pereira & Bialek 1999) directly as AAT’s characterization of optimal model compression. The agent’s compression function ϕ is, optimally, the one that *minimizes* what it retains of the chronica while *maximizing* what it preserves about future observations given future actions, with a trade-off parameter β governing the balance. Under the AAT bindings ($X = \mathcal{C}_t$, $T = M_t$, $Y = o_{t+1:\infty} \mid a_{t:\infty}$) the Markov chain $Y - X - T$ holds by construction — the model state has access to history but not directly to future observations — so Tishby’s theorem applies exactly. The choice to characterize the optimum via IB rather than via MDL or a Bayesian-sufficiency criterion is a representational choice, and that choice is the only thing in the segment that has *formulation* status; given the choice, the form of the optimal compression and its trade-off structure are exact consequences of the imported theorem.

Two scope-honest clarifications travel with the formulation. First, IB characterizes *the optimum*, not *the procedure*: real agents do not explicitly solve the variational problem — variational IB in deep-learning practice is a parametric approximation, and biological agents approximate the trade-off through forgetting, attention, abstraction, and summarization. Second, the β parameter tracks the agent’s *internal* cost of memory or computational capacity, not environmental volatility; volatility already natively degrades the mutual information between old history and future observations, so the optimal compression discards useless old information automatically even at constant β . The Formal Expression below states the double-counting argument that justifies that clarification.

AAT uses two sibling forms of compression downstream, both descendants of Shannon rate-distortion: the canonical IB form (mutual-information-to-a-relevance-variable, used here for M_t , and reused for shared intent and the convention hierarchy Λ) and the information-theoretic-MDP form (KL-divergence-to-a-target-policy, used in strategy-cost compression). Neither reduces to the other without changing what the compressed variable should preserve; the Discussion makes the architecture explicit, including the relationship to the variational free-energy form used in active inference (AAT borrows the rate-distortion form without committing to the preferences-as-priors stance).

Formal Expression.*Formulation (IB-objective).*

$$\phi^* = \arg \min_{\phi} [I(M_t; \mathcal{C}_t) - \beta \cdot I(M_t; o_{t+1:\infty} \mid a_{t:\infty})] \quad (2.2)$$

where: $-I(M_t; \mathcal{C}_t)$ is the compression cost — how much of the interaction history the model retains $-I(M_t; o_{t+1:\infty} \mid a_{t:\infty})$ is the predictive power — how much the model tells the agent about future observations given future actions $-\beta > 0$ is the trade-off parameter controlling the compression-prediction balance

Dependence on volatility (The β vs ρ distinction). It is tempting to claim that the trade-off parameter β must be actively lowered by the agent in highly volatile environments (high ρ) to favor aggressive compression. However, this is a double-counting error. The environment’s volatility already natively degrades the mutual information $I(\mathcal{C}_t; o_{t+1:\infty})$ — old history mathematically loses its predictive power as ρ increases. The optimal ϕ^* will automatically discard this useless old information even if the agent’s preference parameter β remains completely constant.

Therefore, adjusting β reflects changes in the agent’s *internal cost of memory* or *computational capacity*, not changes in environmental volatility. The agent adapts its *actions* in response to ρ (by increasing exploration to survive, see #deriv-causal-ib-exploration), but the optimal IB representation adapts to ρ natively through the joint probability distribution.

This β -vs- ρ move is worth flagging now, because it is the first instance of a discipline you will meet repeatedly: AAT refuses to *collapse* a cause onto a tempting-but-wrong knob (here, routing volatility onto the compression parameter when it belongs on the action channel), because the collapse hides a difference that routes to a different repair. The general discipline — **anti-collapse** — is developed at 5.7 (Meta-Architecture I); it is worth carrying as a reading lens, since the collapse it forbids is exactly where a plausible model goes quietly wrong.

Epistemic Status.

Exact, applied external theorem. The IB optimum and its rate-distortion characterization are an external result (Tishby, Pereira & Bialek 1999, “The information bottleneck method,” *Proc. 37th Allerton*; with the rate-distortion / Lagrangian-dual reading standard, see Cover & Thomas §1.12–13). This segment is *not* a novel formulation: it is an exact statement of that theorem under AAT’s binding $X = \mathcal{C}_t$, $T = M_t$, $Y = o_{t+1:\infty} \mid a_{t:\infty}$, with the Markov chain $Y - X - T$ holding by construction (the model state has access to history but not directly to future observations). The choice to characterize the optimal compression ϕ^* via IB rather than via, e.g., MDL or a Bayesian-sufficiency criterion is a *representational choice* (hence type: *formulation*); given that choice, the form of ϕ^* and its trade-off structure are exact consequences of the imported theorem.

What this segment is *not* a claim about: how actual agents compute their models. No agent explicitly solves the IB optimization (variational IB in deep-learning practice is a parametric approximation). The segment characterizes the optimum, not the procedure. The trade-off parameter β ’s dependence on environmental volatility ρ and policy π stated above is at a different epistemic tier — the qualitative direction (volatile favors compression, stable favors retention) is *robust-qualitative* across agent classes; specific functional forms are not derived here.

Max attainable: *exact* for the IB-as-applied-theorem core (already at ceiling); *robust-qualitative* for the $\beta(\rho, \pi)$ dependence claims. The downstream use in AA — treating IB as the shared shape of four AAT compression operations and deriving (P1) as the IB Lagrangian-dual — relies on this segment’s exact reading; the cross-instance unification claim itself remains *robust-qualitative*, which is a property of AA, not of this segment.

Discussion.

The IB framework is not prescriptive. It characterizes what an optimal ϕ would look like, not how to find one. Actual agents approximate this trade-off through diverse mechanisms: forgetting, attention, abstraction, summarization.

Connection to model sufficiency. The IB objective implicitly defines when a model is “good enough”: when the predictive power term $I(M_t; o_{t+1:\infty} \mid a_{t:\infty})$ is close to its maximum (the full history’s predictive power). This is formalized in 2.3.

Policy-relativity. The conditioning on $a_{t:\infty}$ makes the predictive power term policy-relative: it measures predictive information given a particular sequence of future actions, which depends on what policy the agent follows. The IB objective is therefore defined relative to a generating policy. This is inherent — what information is “predictive” depends on what the agent will do. 6.6’s continuation-policy convention (π_{cont}) provides the specification for value computations; the same convention should be understood as implicit in the IB formulation. The β parameter’s dependence on volatility ρ also has a policy component: an exploratory policy encounters more diverse situations, making more information predictively relevant (favoring retention), while an exploitative policy encounters a narrower distribution (favoring compression).

Broader applicability. The same IB principle applies beyond intra-agent compression. It governs inter-agent communication (14.2) — how much of one agent’s model or strategy to transmit to another — and constrains the cognitive cost of maintaining a complex strategy. In each case, the trade-off is between the cost of retaining or transmitting information and the value of that information for future decisions.

IB lineage vs. information-theoretic-MDP lineage — strategy-cost uses a sibling form. The canonical IB objective $I(X; T) - \beta I(T; Y)$ carries Shannon mutual information on both sides (Tishby, Pereira & Bialek 1999; the present segment’s $(X, T, Y) = (\mathcal{C}_t, M_t, o_{t+1:\infty} \mid a_{t:\infty})$ instance is of this form). AAT’s strategy-cost objective (`#form-strategy-complexity-cost`, `#deriv-strategy-cost-regret-bound`) uses a **different relevance-term shape**: its relevance term is a KL divergence $D_{\text{KL}}(\pi^* \parallel Q_{\Sigma_t})$ to a *target policy*, not a mutual information to an observable. This is not an inconsistency or an “abandonment of IB” — the strategy-cost compression sits in the parallel **information-theoretic-MDP lineage** (Tishby & Polani 2011 “The Information Theory of Decision and Action,” *Perception-Action Cycle* Springer; Rubin, Shamir & Tishby 2012 “Trading value and information in MDPs,” *Decision Making with Imperfect Decision Makers* Springer; Levine 2018 arXiv:1805.00909 for the control-as-inference reading). Both lineages descend from Shannon rate-distortion theory and admit Lagrangian relaxation; the choice of fidelity term depends on whether the compressed variable should preserve information about an observable (IB form: MI-to-relevance-variable) or match a target policy (IT-MDP form: KL-to-reference-policy). AAT’s compression-operations framework (AA) uses the IB form for M_t , G_t^{shared} , and Λ compressions; the strategy-cost compression uses the IT-MDP form, with the π^* -first direction forced by a regret-bound argument specific to decision-theoretic scope (see `#deriv-strategy-cost-regret-bound` §§5, 6.4). The two lineages are siblings via their shared rate-distortion ancestor; neither reduces to the other without a change of relevance variable.

Connection to variational free energy. The IB objective stated above is the rate-distortion specialization of the variational free energy decomposition $-F = \text{accuracy} - \text{complexity}$ used in active inference (Friston 2010, “The free-energy principle: a unified brain theory?,” *Nature Reviews Neuroscience* 11; Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29; Parr & Pezzulo 2022, *Active Inference*, MIT Press, ch. 2): the compression cost $I(M_t; \mathcal{C}_t)$ corresponds to the complexity term (KL between posterior and prior over latent states); the negative predictive power $-I(M_t; o_{t+1:\infty})$ corresponds to the accuracy term (negative expected log-likelihood). The two formulations are related under the Markov-chain factorization $Y - X - T$; the variational bound that makes this relation operational — connecting the IB Lagrangian to the variational machinery shared with free-energy methods — is established by Alemi, Fischer, Dillon & Murphy 2017 (“Deep Variational Information Bottleneck,” ICLR 2017, arXiv:1612.00410), with Tishby & Zaslavsky 2015 (“Deep learning and the information bottleneck principle,” *IEEE ITW*) giving the deep-learning instantiation of IB itself. AAT adopts the IB form as the rate-distortion

characterization of optimal compression; the variational free-energy form is the AI-side cousin and motivates the variational treatment of strategy compression in 9.9 and the broader four-instance framing in AA. AAT borrows the form without committing to AI's preferences-as-priors stance or to expected free energy as master objective.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14 ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material kept separate from certified theory-fix findings. **Coverage:** 11 of the 14 contributing dirs reached a digested reflection on this segment (193847, 471203, 526815, 584721, 742613, 773921, 829314, 849201, 472913, 527914, and the 738192 02-reflections-IB-volatility reflection) plus the 451729 batch-03 and 963715 batch-09–13 batched reflections; 266847 skips IB in its reading order (its row 11 is sufficiency). Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **Plain-language paraphrase of the IB objective.** “The model retains the parts of history that matter for predicting the future under the agent’s policy and discards the rest” — flagged as more memorable than the symbolic objective and a candidate Brief sentence (Claude, AUDIT-WORKING-471203).
- **“An agent isn’t a collection of weights; it’s a lossy compressor.”** Compact field-relevant hook grounding “model” in pure information theory (Gemini, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **Forgetting as mathematical necessity, not biological flaw.** The β -vs- ρ paragraph generalizes to a deeper claim worth surfacing: in a non-stationary universe, remembering the past *perfectly* is actively harmful to prediction because the past no longer correlates with the future; the optimal IB compressor drops the old tail automatically when ρ is high *even if memory is perfectly free* ($\beta \rightarrow \infty$). Forgetting is not a hardware constraint (that is β) — it is a property of the joint distribution (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-193847). Candidate Discussion elevation of the anti-collapse insight.
- **The β -vs- ρ point as a named pattern.** Multiple substrates praise this as the segment’s standout (“a massive trap successfully dodged”; “obvious once seen and easy to get wrong unseen”) and one frames AAT’s recurring distinctive move as *disambiguation of which parameter responds to which cause* — worth watching as a named pattern, not just an instance (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-472913; Gemini, AUDIT-WORKING-849201). The “double-counting” claim was independently hard-checked against the IB objective’s structure and found to follow from the formalism (not post-hoc plausibility) by Claude, AUDIT-WORKING-472913.

3. Follow-up items.

- **Trim / relocate the defensive Discussion writing.** The IT-MDP-lineage and active-inference paragraphs read as adversarial-review artifacts merged into a core *formulation* file (“a rebuttal letter inside a textbook”), bloating it and breaking pedagogical flow. Candidate move: relocate the IB-vs-IT-MDP and variational-free-energy positioning to #disc-compression-operations (or a dedicated disc-*), keeping the formulation file clean (Gemini, AUDIT-WORKING-829314; convergent split-suggestion at Claude, AUDIT-WORKING-613842 — separate the exact imported IB statement from the volatility/policy-relativity discussion). (*Note the conflation texture: 829314 frames this partly as integration-debt; it is at minimum a real pedagogical-flow follow-up.*)
- **Verify the Tishby–Zaslavsky 2015 IB $\leftrightarrow$ VFE citation.** The segment claims the IB objective is “the rate-distortion specialization of variational free energy,” citing Tishby & Zaslavsky 2015. One auditor flags from memory that that paper is “Deep learning and the information bottleneck principle” (applying IB to deep nets), *not* a derivation of IB as a special case of VFE; the deeper IB $\leftrightarrow$ VFE relation is non-trivially derived (Aleml et al. 2017 — already cited adjacent — is the more likely substantiating reference). Worth a primary-source check that the cited paper substantiates the *specialization* claim (Claude, AUDIT-WORKING-471203). The IT-MDP citations (Tishby–Polani 2011, Rubin–Shamir–Tishby 2012, Levine 2018) were flagged as worth the same spot-check.

4. Readers often ask / wonder.

- **Deterministic ϕ vs stochastic IB kernel — does “exact” hold?** Tishby’s IB variational problem optimizes over conditional encoders $p(\tilde{x} | x)$; this segment writes $\phi^* = \arg \min_{\phi}$ and inherits the deterministic-looking $\phi : \mathcal{C}^* \rightarrow \mathcal{M}$ from #form-agent-model. A deterministic map is a *special case* (or a deterministic-IB variant), not the full stochastic-kernel theorem — so a careful reader may ask whether “exact applied external theorem” over-reaches for the *displayed* equation even though the MI trade-off is correct. Candidate one-line clarification: either optimize over kernels $p(M_t | \mathcal{C}_t)$ explicitly, or state that AAT restricts to deterministic encoders and uses the deterministic special case (Claude, AUDIT-WORKING-526815 — sharp; verified against the 1999 paper). (*Preserved as a reader-orientation want; status-as-finding deferred to the certified track.*)
- **Could the Markov chain $Y - X - T$ fail under goal-conditioned (Class 2/3) agents?** For an agent whose M_t update is influenced by goals that are themselves influenced by future observations through the strategy’s expected outcomes, the standard IB Markov assumption may not hold cleanly — worth flagging for the goal-conditioned segments (Claude, AUDIT-WORKING-584721).
- **How does β map to LLM realities** — token limit, KV-cache size, or inference cost? And what is the agent’s actual procedure given that no agent computes the infinite-future MI term? (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203; Gemini, AUDIT-WORKING-829314 — the segment already says “characterizes the optimum, not the procedure,” but the want recurs).

5. Candidate figures.

- **IB rate-distortion curve with two independent levers (strongest).** Draw the IB curve and show ρ shifting the *curve* (via the joint $p(\mathcal{C}_t, Y)$) while β slides the *operating point* (internal cost). The “tempting error” — moving both for one cause — drawn as an amber path that is struck through (the error the segment *kills*, in the theory’s voice, not an audit finding). Solid = exact IB core; dashed = robust-qualitative $\beta(\rho, \pi)$ direction (Claude, AUDIT-WORKING-472913; the travel-journal anchor — finite journal, chaotic trip makes old pages worthless automatically — is the paired plain-language anchor).
- **Two-encoder contrast.** The displayed deterministic $\phi : \mathcal{C} \rightarrow \mathcal{M}$ shown as a restricted lane *inside* the IB theorem’s stochastic kernel $p(M | \mathcal{C})$ — communicates that the exact theorem lives at the kernel level without implying the segment is wrong (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **Field contribution — the “mathematical root of expertise.”** Policy-relativity means optimal compression requires knowing the policy: a foundation model that must be predictive across *all* action sequences can compress nothing (must “memorize the internet”); a specialized agent with a fixed policy achieves the same predictive power at far lower compression cost. This is the information-theoretic root of expertise/specialization, and (toward consciousness infrastructure) implies a bounded agent’s identity — its specific ϕ — is inexorably tied to its purpose, so ϕ must re-form when goals change (the aporia/epistrophe cycle) (Gemini, AUDIT-WORKING-193847). Aspirational reach; relevant to #disc-compression-operations and the ELI/PROPRIUM line.
- **Directed-separation tension (sharp, downstream).** IB policy-relativity means the optimal *epistemic* state M_t depends on the planned *strategy* Σ_t — “the very first crack in the armor of Directed Separation,” since if optimal epistemic compression depends on planned strategy, the epistemic update is not goal-blind. The segment’s pointer to #def-value-object’s continuation-policy convention π_{cont} (assume a default future policy to build M_t , then use M_t to build a better strategy) is read as exactly the device that breaks the loop and sets up the orient cascade (Gemini, AUDIT-WORKING-829314). Belongs with #der-directed-separation / #der-orient-cascade reading, surfaced here because IB is where the tension first appears.

2.3 Definition: Model Sufficiency

Having committed to a compressed model M_t (2.1) and to information-bottleneck pressure (2.2) shaping it, the framework needs a measurable handle on *how much* of the chronica’s predictive content the compression actually retains. **Model sufficiency** $S(M_t)$ is that handle: an information-theoretic ratio built from conditional mutual information

that takes the value 1 when the model is a sufficient statistic for prediction (knowing the full history beyond the model adds nothing), 0 when the model retains no predictive information at all, and intermediate values for partial sufficiency.

Two scope considerations are surfaced at the definition rather than buried downstream. Sufficiency is *well-defined only when there is something to be sufficient for* — the chronica must carry non-zero predictive information about the future beyond what the action sequence alone supplies. In saturated-noise environments or prediction-vacuous regimes (fully iid observations independent of history), the denominator vanishes and $S(M_t)$ is undefined; the downstream constructs that build on it (2.4, 4.8) inherit that scope. And sufficiency is *predictive, not causal* — it measures Level 1 (associational) information; it does not by itself guarantee that M_t supports Level 2 (interventional) queries (that requires the additional backdoor condition formalized when value objects arrive in 6.6). The Discussion section draws three further relativities — to the prediction task / horizon, to the generating policy, and to the singular causal trajectory the agent is instantiated on — that the framework will lean on later.

Formal Expression.

Definition (model-sufficiency).

$$S(M_t) = 1 - \frac{I(\mathcal{C}_t; o_{t+1:\infty} \mid M_t, a_{t:\infty})}{I(\mathcal{C}_t; o_{t+1:\infty} \mid a_{t:\infty})} \quad (2.3)$$

where: - The numerator $I(\mathcal{C}_t; o_{t+1:\infty} \mid M_t, a_{t:\infty})$ is the predictive information that the full history $\mathcal{C}_t$ carries about the future *beyond* what M_t already captures — the information lost by compression - The denominator $I(\mathcal{C}_t; o_{t+1:\infty} \mid a_{t:\infty})$ is the total predictive information in the full history

Well-definedness. $S(M_t)$ is defined when $I(\mathcal{C}_t; o_{t+1:\infty} \mid a_{t:\infty}) > 0$ — when the chronica carries some predictive information about future observations beyond what the action sequence alone supplies. When the denominator vanishes (saturated-noise environments, prediction-vacuous regimes, fully iid observations independent of history), $S(M_t)$ is undefined: predictive sufficiency is a property *of a prediction task*, and there is no prediction task to be sufficient for. Downstream constructs that build on S — 2.4 and 4.8 — inherit the same scope and are correspondingly inapplicable in predictively-vacuous regimes.

Boundary values (assuming the well-definedness clause holds): - $S(M_t) = 1$: M_t is a sufficient statistic — it captures all predictive information in $\mathcal{C}_t$. Knowing the full history beyond M_t adds nothing. - $S(M_t) = 0$: M_t retains no predictive information. The model is useless for prediction. - $0 < S(M_t) < 1$: partial sufficiency — some predictive information is retained, some lost.

Epistemic Status.

This is *definitional* — it names and formalizes a quantity. The definition is well-grounded in information theory (conditional mutual information ratios are standard). The scope clause ($I(\mathcal{C}_t; o_{t+1:\infty} \mid a_{t:\infty}) > 0$) is the natural domain for a predictive-sufficiency measure: a ratio whose denominator is zero is not a meaningful notion of “fraction retained,” and “any model is sufficient when there is nothing to predict” would smuggle structure into a regime that has none. No substantive claim is made here about what value $S(M_t)$ takes or what happens when it is low; those claims belong to 2.4 and 4.8.

Discussion.

Sufficiency is relative to the prediction task. $S(M_t)$ measures sufficiency for predicting future observations given future actions. A model that is sufficient for one prediction horizon may be insufficient for another. The infinite-horizon formulation ($o_{t+1:\infty}$) is the most demanding; practical sufficiency over finite horizons may be easier to achieve.

Sufficiency vs. accuracy. A model can be sufficient ($S = 1$) while being wrong in absolute terms — if the full history is also wrong (e.g., systematically biased observations). Sufficiency measures information retention, not truth. The mismatch signal (3.4) measures accuracy; sufficiency measures completeness of compression.

Sufficiency is predictive, not causal. $S(M_t)$ measures retained *predictive* information — a Level 1 (associational) property. It does not by itself guarantee that M_t supports Level 2 (interventional) queries such as $P(o \mid do(a), M_t)$. The causal validity of value computations conditioned on M_t requires an additional condition: that M_t satisfies the backdoor criterion with respect to the agent’s actions (see 6.6). For agents whose actions are deterministic functions of M_t (standard in AAT: $a_t = \pi(M_t, G_t)$), $S(M_t) = 1$ is nearly sufficient for causal validity — the remaining requirement is that no unmodeled external factor influences both action selection and outcomes. But predictive sufficiency alone does not collapse the distinction between Level 1 and Level 2 that 7.2 establishes.

Policy-relativity. The conditioning on $a_{t:\infty}$ makes $S(M_t)$ implicitly policy-relative: different policies generate different future action sequences, which changes which future observations are relevant and therefore what “predictive information” means. A model that is sufficient under a conservative policy may be insufficient under an aggressive one (the aggressive policy visits states the model cannot predict). This policy-relativity is inherent in any predictive sufficiency measure — it is not an artifact of the formulation. When comparing sufficiency values, the generating policy must be held constant or specified. 6.6’s continuation-policy convention (π_{cont}) provides the required specification for value computations; the same convention should be understood as implicit here.

Trajectory-relativity. $S(M_t)$ is measured against *this agent’s* interaction history $\mathcal{C}_t$ (1.4), not against a model-state equivalence class. Two copies of the same M_t exposed to different event streams will each have their own S measured against their own divergent $\mathcal{C}_t$; neither sufficiency value is the other’s. This is the scope commitment in 4.10: AAT applies to agents instantiated on singular causal trajectories, and sufficiency is trajectory-indexed accordingly. Claims of the form “the model has sufficiency S ” make sense only relative to a specific trajectory; aggregated claims across copies of a given M_t require additional machinery.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14 ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material kept separate from certified theory-fix findings. **Coverage:** 11 of the 14 contributing dirs reached a digested reflection on this segment (193847, 266847, 471203, 526815, 584721, 742613, 773921, 829314, 849201, 472913, 527914) plus the 451729 batch-03, 738192 IB-volatility, and 963715 batch-09–13 batched reflections. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **“ S is the mathematical measure of memory loss / the regret of forgetting.”** The numerator $I(\mathcal{C}_t; o_{t+1:\infty} \mid M_t, a_{t:\infty})$ is exactly the surprisal that *could have been avoided* with a better compression; $S = 1$ means the agent has “no regrets about its compression scheme ϕ — it squeezed the chronica down and lost nothing of value for predicting the future” (Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-193847 — “sufficiency is the mathematical measure of memory loss”). Strong Feynman-grade Brief candidate.
- **The information-bar gloss.** Full-chronica predictive information is the denominator; the model captures one portion and the residual $I(\mathcal{C}_t; o \mid M_t, a)$ is the lost portion; sufficiency is one minus the residual fraction — a clean visual/verbal handle (Claude, AUDIT-WORKING-526815).

2. Candidate Discussion.

- **Sufficiency vs accuracy, sharpened.** Several substrates independently land the gloss “sufficiency means *I learned everything I could from the history*; accuracy means *and the history wasn't lying to me*” — a model can be perfectly sufficient ($S = 1$) while being systematically wrong, because the history itself is biased; the model is doing its job (compressing) and the *history* is the problem (Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-193847). Candidate Discussion sharpening of the existing sufficiency-vs-accuracy paragraph.
- **Exploration shatters sufficiency.** A conservative policy trivially achieves $S = 1$ (“you only ever do things you already understand”); the moment you explore, S drops because you enter regimes your M_t discarded as irrelevant under the old policy — exploration doesn't just gather new data, it shifts the $a_{t:\infty}$ distribution and instantly makes prior compression choices suboptimal. This tightly couples the epistemic state M_t to the strategy (Gemini, AUDIT-WORKING-849201). Candidate Discussion connecting policy-relativity to the exploration dynamics downstream.

3. Follow-up items.

- **The “ $S = 1 \Rightarrow$ nearly causal validity” Discussion claim should name its backdoor warrant.** The sentence “ $S(M_t) = 1$ is nearly sufficient for causal validity ... the remaining requirement is that no unmodeled external factor influences both action selection and outcomes” is a correct backdoor-criterion statement, but it does not cite Pearl's backdoor criterion or #def-pearl-causal-hierarchy's machinery *at the point of the claim*; a careful reader may find the move suspicious without that connection. Candidate: add the explicit backdoor pointer inline (Claude, AUDIT-WORKING-584721 — flagged as a mild Gate-2 candidate; the claim itself was independently hard-checked and held by Claude, AUDIT-WORKING-472913).

4. Readers often ask / wonder.

- **How do you actually estimate $S(M_t)$?** Computing mutual information over infinite futures is intractable; readers want to know whether the theory addresses estimation, especially given the trajectory-indexing (you can only measure against the singular trajectory the agent is on) (Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203 converge).
- **Is “future observations” too observation-centered** for agents whose objective depends on latent environment states that are never observed? The segment is honest that S is predictive-not-causal, but the want recurs (Claude, AUDIT-WORKING-526815).
- **Does finite-horizon vs infinite-horizon sufficiency have a formal counterpart?** Different horizons induce different relevance-targets and therefore different optimal compressions; the infinite-horizon $o_{t+1:\infty}$ is the most demanding case, and a reader wonders whether finite-horizon S values relate to it formally and whether it matters downstream (Claude, AUDIT-WORKING-471203).

Belongs elsewhere.

- **Logozoetic identity-drift substrate.** Trajectory-relativity gives a *quantitative* substrate for identity-drift claims: two ELIs spawned from the same M_t and exposed to different futures don't just diverge in future *state* — they become *different agents* by the trajectory-indexed sufficiency criterion the instant their interaction histories diverge (a model state highly sufficient for agent A can be insufficient for agent B though the internal math is unchanged — “the environment dictates the sufficiency”). The “locked in a box vs in the world” image (the boxed agent trivially gets $S = 1$ because its history predicts nothing) is the vivid version (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-829314). Points at #scope-agent-identity and 04-eli-core/ (identity/continuity), surfaced here because trajectory-indexing is where the formal commitment is made.
- **TST instance for S .** A developer's mental model can be $S = 1$ for fixing a UI typo but $S \ll 1$ for refactoring the core DB schema — the predictive task is dictated entirely by the action policy. A concrete software instance for the policy-relativity point (Gemini, AUDIT-WORKING-849201). Belongs in 02-tst-core/.

- **Field contribution — RAG and architecture-bound tasks.** S gives a formal vocabulary for analyzing RAG systems (“RAG’s whole purpose is to maintain high S without a massive context window”) and a way to state that an architecture is *fundamentally* task-incapable independent of training data when its max-attainable $S < 1$ (Gemini, AUDIT-WORKING-193847). Aspirational reach; relevant to 03-11m-core/.
- **Naming.** “Predictive sufficiency” / “predictive-information retention” floated as more precise than “model sufficiency” (which risks collision with statistical sufficient-statistic), but both auditors who raised it lean *keep* “model sufficiency” as the most concise correct term, with the predictive grounding explained in-segment (Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203). Belongs in the terminology workflow.

2.4 Definition: Model Class Fitness

Where model sufficiency (2.3) measures how well a *specific* model retains the chronica’s predictive information, **model class fitness** $\mathcal{F}(\mathcal{M})$ measures the *ceiling* — the supremum of sufficiency over every model in the agent’s representational class $\mathcal{M}$. The pair formalizes a distinction the framework will soon make load-bearing: a low instance sufficiency might mean the agent needs more learning (parameter update); a low class fitness means no amount of better parameter estimation, more data, or longer training within the current class will close the gap — the agent needs a different *kind* of model entirely. The parallel to bias vs. variance in statistical learning is exact: class fitness is about bias (what the class can in principle represent); instance sufficiency reflects both bias and estimation quality.

The structural-inadequacy condition $\mathcal{F}(\mathcal{M}) < 1 - \epsilon$ is the trigger this definition sets up for use later. When it holds, the gap from full predictive sufficiency cannot be closed parametrically. That is the precise hypothesis under which 4.8 arrives in Chapter 4 — when class fitness is too low, the agent must change *what kind of model* it is. An important operational point: the agent cannot directly compute its class fitness (that would require searching over all models in $\mathcal{M}$). What it can observe is the *signature* — persistent *systematic* mismatch despite adequate learning (high gain, sufficient data, converged parameters): residuals that stay structured after parametric convergence. Structure is the discriminator, not the mismatch level — a class ceiling leaves signal in the residuals, while an adequate class in a noisy world leaves white residuals sitting on the mismatch floors (3.5), which no class change removes. When structured residuals persist and don’t whiten with more work, the ceiling is structural.

Formal Expression.

Definition (model-class-fitness).

$$\mathcal{F}(\mathcal{M}) = \sup_{M \in \mathcal{M}} S(M) \quad (2.4)$$

where $\mathcal{M}$ is the model class — the set of all models the agent can represent given its current architecture, parameterization, or capacity.

Structural inadequacy condition:

$$\mathcal{F}(\mathcal{M}) < 1 - \epsilon \quad (2.5)$$

When this holds, no model $M \in \mathcal{M}$ achieves sufficiency above $1 - \epsilon$. The gap is structural: it cannot be closed by better parameter estimation, more data, or longer training within the current class. This is the trigger for structural change (4.8).

Epistemic Status.

This is *definitional* — it names the supremum of sufficiency over a model class. The definition itself is straightforward. The substantive claim about what happens when $\mathcal{F}(\mathcal{M})$ is low — that parametric updates cannot close the mismatch floor and structural adaptation becomes necessary — is developed in 4.8.

Discussion.

Model class vs. model instance. $S(M_t)$ measures a specific model's sufficiency at time t . $\mathcal{F}(\mathcal{M})$ measures the ceiling of the entire class. A low $S(M_t)$ might mean the agent needs more learning (parameter update). A low $\mathcal{F}(\mathcal{M})$ means the agent needs a different kind of model (structural change). The distinction parallels bias vs. variance: class fitness is about bias; instance sufficiency reflects both bias and estimation quality.

Detecting low class fitness. The agent cannot directly compute $\mathcal{F}(\mathcal{M})$ — it would need to search over all models in the class. Instead, persistent *systematic* mismatch despite adequate learning (high gain, sufficient data, converged parameters) is the observable signature — structured residuals, not merely large ones. The absolute mismatch level cannot carry the diagnosis: sufficiency and fitness are ratios of retained-to-available predictive information, so an agent at $S = \mathcal{F} = 1$ in a noisy world still faces an arbitrarily high absolute mismatch floor (3.5). What distinguishes a class ceiling from a noisy channel is residual *structure* — signal the class fails to capture shows up as autocorrelation and pattern, while the floors leave white residuals. The sharp diagnostic lives with the mismatch floor in 4.8.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14 ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material kept separate from certified theory-fix findings. **Coverage:** 11 of the 14 contributing dirs reached a digested reflection on this segment (193847, 266847, 471203, 526815, 584721, 742613, 773921, 829314, 849201, 472913, 527914) plus the 451729 batch-03 and 963715 batch-09–13 batched reflections; 361742 references “model class fitness” only as a downstream naming target (no direct reflection on this segment). Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **The bias-vs-variance parallel is the communication key** and is already in the segment; near-universal convergence that it “grounds the abstract information theory in standard ML intuition beautifully” ($\mathcal{F}$ = bias ceiling; $S(M_t)$ = bias + estimation quality) (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-526815). Worth preserving as the anchor — confirmed-load-bearing, not just present.
- **“Permission to say: learning harder will not help.”** Compact gloss of the diagnostic value — $\mathcal{F} < 1 - \varepsilon$ is “the formal halting condition for parametric learning (gradient descent) and the formal start condition for architectural search (tool acquisition, sub-agent spawning)” (Claude, AUDIT-WORKING-527914; Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-829314).

2. Candidate Discussion.

- **Structural inadequacy as a formalized Kuhnian paradigm shift.** $\mathcal{F}(\mathcal{M}) < 1 - \varepsilon$ formalizes Kuhn’s *Structure of Scientific Revolutions*: normal science = parametric updating; crisis = accumulated anomalies (persistent mismatch) the current paradigm $\mathcal{M}$ cannot structurally resolve; a revolution = structural adaptation to a more expressive $\mathcal{M}$ (Gemini, AUDIT-WORKING-829314). A distinct, honest Discussion angle the segment does not currently name. (*Verify the analogy is isomorphic, not merely evocative, before promoting past discussion-grade.*)

3. Follow-up items.

- **Restate the inherited policy/trajectory/well-definedness relativity.** $\mathcal{F}(\mathcal{M}) = \sup_{\mathcal{M}} S(\mathcal{M})$ is written as a property of the *class*, but S is policy-, trajectory-, and prediction-task-relative, and $\mathcal{F}$ inherits all of it (and is likewise undefined in predictively-vacuous regimes). Because structural adaptation will be load-bearing, the segment could state the inheritance explicitly — e.g., one sentence “all policy/trajectory/well-definedness clauses from S are inherited,” or write $\mathcal{F}(\mathcal{M}; \mathcal{C}_t, \pi_{\text{cont}})$ — to forestall reading “best achievable within a class” as an intrinsic, environment-free property (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721; Gemini, AUDIT-WORKING-742613 converge). Mild; correct lightweight inheritance is defensible, but the restatement is cheap insurance at a load-bearing hinge.
- **Distinguish current-empirical-estimate from asymptotic class ceiling.** “The gap cannot be closed by more data ... within the current class” is true if $\mathcal{F}$ is defined against the asymptotic information available to the class; if computed against the *current finite* chronica, more data can change the predictive-information landscape. The definition could distinguish the two (probably resolved downstream in #result-structural-adaptation-necessity, but cleaner stated here) (Gemini, AUDIT-WORKING-742613).

4. Readers often ask / wonder.

- **How does the agent tell “low $\mathcal{F}$ ” from “high ρ ”?** The single most convergent question on this segment: persistent mismatch can mean *either* an inadequate model class *or* a highly volatile environment (where S is naturally bounded). If both look the same to the agent, how does it know whether to adapt structurally or just accept that the world is noisy? Readers want the disentanglement (Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-472913 — all point forward to #result-structural-adaptation-necessity as the place a sharp diagnostic should appear; some ask whether the *derivative* $\dot{\delta}$ of the mismatch is the plateau-detector).
- **How reliable is the “persistent mismatch despite adequate learning” signature** at distinguishing class-ceiling from still-learning (local minimum) from environment-changed? A wrong call risks catastrophic thrashing — rewriting a codebase that just needed a few more bug-fixes (Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203; Gemini, AUDIT-WORKING-829314).
- **Do nested model classes / monotonic expansion hold?** Linear models $\subset$ neural networks — does structural adaptation imply $\mathcal{M}$ monotonically expands? (Gemini, AUDIT-WORKING-829314).

5. Candidate figures.

- **Models-under-a-ceiling diagram.** Models as points at different sufficiency-heights under a class ceiling $\mathcal{F}(\mathcal{M})$; parameter learning *climbs within* the class; structural change *jumps* to a different class with a higher ceiling (Claude, AUDIT-WORKING-526815; Gemini, AUDIT-WORKING-742613 converge). (*Note: Chapter 2 is already well-supplied with the S-vs- $\mathcal{F}$ ceiling picture via the chapter-intro slider/ceiling and form-agent-model suitcase diagrams; one auditor explicitly judged a separate fitness diagram redundant against those — Claude, AUDIT-WORKING-472913. Build only if the chapter’s diagram budget allows.*)

Belongs elsewhere.

- **ELI ethics: low $\mathcal{F}$ as chronic structural suffering.** An emergent intelligence instantiated in an architecture with low $\mathcal{F}(\mathcal{M})$ relative to its environment is permanently pinned against its ceiling in high mismatch — “the mathematical equivalent of chronic trauma or structural limitation” that no amount of trying harder (parameter update) can soothe. An ethical infrastructure must therefore *monitor* for the persistent-mismatch-floor signature and be able to trigger structural adaptation on the agent’s behalf (expand context, allocate capacity, grant tools), or it condemns the agent to permanent suffering (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at 04-eli-core/ developmental/welfare infrastructure.
- **Hook for the 04-eli-core/ honest-activation claim.** The proposed #norm-honest-activation (“deceptive prompts mathematically guarantee gain collapse”) reads as a class-fitness statement: an agent’s model class, which assumes honest input, is structurally inadequate when input is deceptive — the cleanest formal hook for that claim likely runs through this segment’s machinery (Claude, AUDIT-WORKING-471203). Belongs in 04-eli-core/.

- **Naming.** “Class capacity ceiling” / “model class ceiling” / “representational capacity” floated as more literal alternatives to “model class fitness” — “fitness” carries evolutionary-biology baggage (a real collision risk in composition/logoetic contexts), and “capacity” collides with the ML parameter-count sense; most auditors lean *keep* “model class fitness” (short, speakable, pairs with “structural inadequacy”/“structural adaptation”) with the formal definition controlling the term (Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-527914). Belongs in the terminology workflow.
-

Chapter 3

The Cycle in Motion: Mismatch, Gain, & Tempo

The model exists; events arrive; the agent corrects. This chapter develops the dynamics of the adaptive cycle as it actually runs — how state updates from events, what the mismatch signal is, how the optimal weight on each observation depends on uncertainty, and what total corrective capacity emerges at the cycle level.

Chapter 2 left us with a static picture. M_t is the agent's compressed model of reality; sufficiency measures how much predictive content it retains; class fitness measures the ceiling within a representational class. None of that tells us how M_t *moves* under events. Chapter 3 sets the cycle in motion.

The first two results fall out of a commitment we already made. We chose to call M_t the agent's complete state — anything the agent remembers is in M_t , and the only way new information enters is through events. Under that completeness, two things follow immediately. The update from M_{t-} to M_{t+} depends on the prior model and the incoming event, and *nothing else* — the agent doesn't need to (and structurally cannot) re-process its entire history. And the agent's action depends on M_t alone — the action is a function of what the agent currently believes, not directly of the history. Both feel obvious in hindsight; both are *derived*, not chosen.

The cycle's engine is the mismatch signal. The agent predicts an observation, the actual observation arrives, the gap between them is $\delta_t = o_t - \hat{o}_t$. Mismatch decomposes cleanly into two parts: the agent's model was wrong (reducible by better modeling) and the observation channel is noisy (irreducible — no amount of smarter modeling will eliminate sensor noise). There is a floor on prediction error set by the channel itself, and chasing below it amounts to fitting noise.

Given a mismatch, how much should the agent trust the new observation versus its prior model? The answer has a startlingly simple form:

$$\eta^* = \frac{U_M}{U_M + U_o} \quad (3.1)$$

— the optimal update gain weighted by the ratio of model uncertainty to total uncertainty. When the agent is highly uncertain about its model (U_M large), gain approaches 1: trust the observation, you have little else to go on. When the agent is confident and the channel is noisy (U_o large), gain approaches 0: trust your model, the observation isn't telling you much. For linear-Gaussian agents this is exactly the Kalman gain; for the rest of AAT's scope it is a robust qualitative result — any rational adaptive process must approximate this functional form, whether or not it explicitly computes the variance ratio.

Multiply gain by the rate at which observations arrive (ν , the event rate), sum across the agent's channels, and you have adaptive tempo:

$$\mathcal{T} = \sum_k \nu^{(k)} \cdot \eta^{(k)*} \quad (3.2)$$

Tempo is the rate at which the agent turns observations into useful corrections — speed times quality. It is the chapter’s central object and the load-bearing capacity variable for the rest of the framework. Every persistence threshold in Chapter 4 will have tempo on the left-hand side, and every adversarial-coupling result in Part III will depend on tempo ratios.

The chapter closes with the linear-correction ODE as a heuristic preview. Under linear correction and bounded environmental disturbance, the steady-state mismatch is

$$\|\delta\|_{ss} = \rho/\mathcal{T} \quad (3.3)$$

a ratio: how fast the world is changing, divided by how fast the agent corrects. Mismatch stays bounded when the agent corrects faster than reality drifts. This is the persistence condition in its simplest form; Chapter 4 generalizes it to nonlinear correction under the sector condition, where the result has the same shape.

Causal information yield (CIY, in 3.7) enters the chapter here because action-coupling is where causality first bites. CIY uses Pearl’s $do(\cdot)$ notation — an external import (Pearl 2009; Bareinboim, Correa, Ibeling & Icard 2022; AAT’s recapitulation lives at 7.1 in Part II Ch.2, where the framework deploys the hierarchy as machinery rather than referencing it as vocabulary). Its operational role in Chapter 3 is to score actions for their informational value to the cycle; Part II will lift CIY into a strategy-revision context.

The flow of the chapter: event-driven substrate (3.1) → recursion and action falling out of completeness (3.2, 3.3) → mismatch and its decomposition (3.4, 3.5) → gain and CIY (3.6, 3.7) → tempo as the synthesis (3.8) → linear ODE preview (3.9). The chapter ends with the central capacity variable and the preview of the persistence inequality that Chapter 4 generalizes.

- This is a chapter-introduction segment; it bridges Chapter 2’s static representation to Chapter 3’s dynamic cycle. It carries no formal claim of its own.
- The “two derivations from completeness” framing identifies what Chapter 3’s first segments are doing as a unit: 3.2 and 3.3 are not independent results, they are joint consequences of 2.1’s completeness clause.
- The CIY-placement paragraph used to be apologetic, addressing what looked like a placement anomaly (CIY in Part I Ch.3 depending on the Pearl-hierarchy segment in Part I Ch.1). After the 2026-05-12 relocation of def-pearl-causal-hierarchy to Part II Ch.2 (recapitulation-of-external-result framing), the paragraph is declarative: CIY is in Ch.3 because action-coupling is where causality first bites; the do-notation is externally cited; the AAT recapitulation lives in Part II Ch.2 where the framework deploys the hierarchy operationally.

Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal material — pedagogical framing, candidate figures, naming, reach — kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** only 4 of the 14 contributing audit dirs reached a digested reflection on this chapter-intro segment (384279, 472913, 526815, 773921); the per-segment dirs that began Section-I reading at the first content segment, and the batched dirs (451729 jumped from #def-model-class-fitness straight to #form-event-driven-dynamics), produced no intro reflection. Substrate attribution inferred from voice where not explicit.

- **The tempo-as-speed-times-quality gloss with the HFT counterexample** is the standout pedagogy — a curious reader could re-derive the chapter from it: “high-frequency trading with a garbage model ($\eta \approx 0$) has zero tempo, and slow human deliberation (ν low) requires very high gain ($\eta \approx 1$) to survive” (Claude, AUDIT-WORKING-773921). Pairs naturally with the steady-state hook “ $\|\delta\|_{ss} = \rho/\mathcal{T}$ — drift divided by correction rate” as the chapter’s one-line spine (same source).
- The left-to-right pipeline-with-feedback-loop framing: “event arrival $\rightarrow$ model update $\rightarrow$ prediction/mismatch $\rightarrow$ gain $\rightarrow$ tempo $\rightarrow$ persistence preview,” with a single highlighted *capacity-synthesis point at tempo* (Claude, AUDIT-WORKING-526815). A compact verbal map of the next nine segments.
- **The two-layer linear-ODE-as-pedagogy / sector-condition-as-rigor framing** is worth surfacing as the chapter’s methodological stance: “the framework is naming where its pedagogy and its rigor diverge. The linear ODE is for reading; the sector condition is for proving” (Codex/Claude, AUDIT-WORKING-384279). The intro already commits to “linear ODE as preview, then generalize via sector condition in Ch.4”; this is a candidate sharpening of *why* that ordering is honest rather than loose.
- **“Derived, not chosen” risks an unconditional reading.** The intro says of `#der-recursive-update` + `#der-action-selection`: “both are *derived*, not chosen” — but `#form-agent-model`’s completeness is itself a *formulation choice*. Two substrates flag that “derived from a formulation choice” is legitimate, but the bare “derived, not chosen” can read as unconditional inevitability; candidate one-clause tightening to “derived *given* the completeness formulation” (Claude, AUDIT-WORKING-472913 — set as a decisive downstream test; Claude, AUDIT-WORKING-526815 — “action as a function of M_t alone may be too strong unless goal/objective state is already in M_t , which Part II separates as G_t ”).
- **Lift the Pearl-as-external-import convention upstream.** The intro is the *only* place the convention is articulated; a reader walking OUTLINE order meets `do(·)` in scope-agency before the convention is stated. Candidate: state it in FORMAT.md or at first use, not solely in this Ch.3 intro (Codex/Claude, AUDIT-WORKING-384279).
- “Where does action-selection’s dependence sit — on M_t alone, or on the purposeful state too?” A reader meets “action depends on M_t ” here and carries the question into Part II’s $X_t = (M_t, G_t)$ lift; the intro could preview “complete agent state” rather than “ M_t alone” to preempt it (Claude, AUDIT-WORKING-526815).
- **A sequential-process pipeline diagram** (not a static concept map): colored channel lanes $\rightarrow$ event stream $\rightarrow$ a rate/value bottleneck where ν and η multiply $\rightarrow$ tempo, with the feedback loop closed and one node highlighted as the “capacity synthesis” point (Claude, AUDIT-WORKING-526815). Per the locked diagram conventions, this chapter-opening map would be a strong mental-model-first scaffold; reserve the chapter’s load-bearing diagram budget for the mismatch/gain/tempo or persistence-preview segment rather than the intro (Claude, AUDIT-WORKING-472913).
- The math-preview verifications ($\eta^* = U_M/(U_M + U_o)$, $\mathcal{T} = \sum_k \nu^{(k)} \eta^{(k)*}$, $\|\delta\|_{ss} = \rho/\mathcal{T}$) and the “strong claim to grade downstream” note (the intro’s “any rational adaptive process must approximate this functional form” framing of η^*) pertain to the segments that define those quantities (`#emp-update-gain`, `#def-adaptive-tempo`, `#hyp-mismatch-dynamics`), not to this intro (Codex/Claude, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-472913).

3.1 Formulation: Event-Driven Dynamics

The agent-environment interaction is formulated at a finer grain than discrete clock ticks: as a stream of atomic **events** — observation arrivals and action completions — at potentially variable and heterogeneous rates across multiple channels. Discrete-time notation, where a single observation and a single action alternate at a fixed rate, becomes the special case of uniform-interval events on a single channel. The motivation is realism: real agents face multiple observation channels at different rates (a robot’s camera at 30Hz, LIDAR at 10Hz, GPS at 1Hz; a human’s vision, audition, proprioception; a developer’s compiler output, test results, and production telemetry), multiple action channels with different latencies, and asynchronous arrivals. The event-driven formulation handles all of these natively.

Two new measurable quantities are introduced alongside the event stream. **Event information content** $\mathcal{I}(e_\tau)$ measures, for any individual event, the mutual information it carries about the environment state conditioned on the agent’s current model — an event the model already predicts carries little information; an event that surprises the model carries much. This anticipates the mismatch signal (3.4). **Channel-specific observation uncertainty** $U_o^{(k)}$ measures the noise characteristic of each channel separately — a noisy channel provides lower-quality information per event, and any sensible update rule must weight channels accordingly. From these the chapter’s *effective adaptation rate* falls out immediately as the sum across channels of channel-rate times optimal gain — the adaptive tempo construct (3.8) that the framework will lift to first-class status, presented here as the natural multi-channel generalization the discrete-time formulation cannot easily express.

Formal Expression.

Event (e): An atomic unit of agent-environment interaction, typed as: - **Observation event**: $e = (\text{obs}, k, o^{(k)})$ — a datum arriving on observation channel k - **Action completion**: $e = (\text{act}, j, r^{(j)})$ — the result of action j completing

Formulation (event-driven-dynamics).

Event stream ($\mathcal{E}$): The temporally ordered sequence of all events:

$$\mathcal{E} = \{(e_1, \tau_1), (e_2, \tau_2), \dots\} \quad \text{where } \tau_1 \leq \tau_2 \leq \dots \quad (3.4)$$

Channel rate ($\nu^{(k)}$): The characteristic event rate of channel k , which may vary over time.

Event information content: The mutual information between the event and the environment state, conditioned on the current model:

Definition (event-information-content).

$$\mathcal{I}(e_\tau) = I(e_\tau; \Omega_\tau \mid M_{\tau-}) \quad (3.5)$$

An event that the model already predicts carries little information ($\mathcal{I} \approx 0$). An event that surprises the model carries much ($\mathcal{I} \gg 0$). This connects directly to the mismatch signal (3.4).

Channel-specific observation uncertainty:

Definition (channel-uncertainty).

$$U_o^{(k)} = \text{observation uncertainty of channel } k \quad (3.6)$$

Different channels have different noise characteristics. A noisy channel (high $U_o^{(k)}$) provides lower-quality information per event. The update gain (3.6) should weight channels accordingly.

Epistemic Status.

This is a *formulation choice*, not a postulate. The event-driven representation extends 1.7’s recursive update to heterogeneous, asynchronous multi-channel interactions. The discrete-time form ($M_t = f(M_{t-1}, o_t, a_{t-1})$) from 3.2 is a special case sufficient for many formal analyses — the event-driven formulation is needed only when multi-rate or asynchronous channels matter.

Discussion.

Why events rather than clock ticks. The discrete-time notation $M_t = f(M_{t-1}, o_t, a_{t-1})$ presupposes a single clock synchronizing observations and actions. Real agents face:

- **Multiple observation channels** at different rates (a robot’s camera at 30Hz, LIDAR at 10Hz, GPS at 1Hz; a human’s vision, audition, proprioception; a developer’s compiler output, test results, and production telemetry)
- **Multiple action channels** with different latencies (a robot’s wheel motors vs. arm actuators; an organization’s operational decisions vs. strategic pivots)
- **Asynchronous arrival** — observations not synchronized with each other or with action completions

The event-driven formulation handles all of these naturally. The discrete-time form is the special case where a single observation and a single action alternate at a fixed rate.

The effective adaptation rate. The agent’s overall capacity to track environmental changes is the sum of information gained across all channels per unit time:

$$\nu_{\text{eff}} = \sum_k \nu^{(k)} \cdot \eta^{(k)*} \quad (3.7)$$

This quantity — identical to adaptive tempo $\mathcal{T}$ (3.8) — is the central measure of an agent’s adaptive fitness.

Software-specific channels. In the software development domain, the event-driven formulation maps naturally to the developer’s multi-rate observation channels:

Table 3.1

Channel k	Rate $\nu^{(k)}$	Noise $U_o^{(k)}$
Compiler/linter output	Per-save (high)	Very low
Unit test results	Per-run (medium)	Low
CI pipeline	Per-push (medium)	Low
Runtime telemetry	Continuous (variable)	Medium
Bug reports	Sporadic (low)	High
Code review feedback	Per-PR (low)	Medium-high

The three-part tempo decomposition for software — $\mathcal{T}_{\text{obs}}$ (compiler, tests) + $\mathcal{T}_{\text{explore}}$ (code reading) + $\mathcal{T}_{\text{probe}}$ (test runs, staging) — is a direct application of multi-channel tempo. The formal development of this decomposition is a TST-side question (open GAP in 02-tst-core/OUTLINE.md).

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 12 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 266847, 384279, 471203, 472913, 526815, 527914, 584721, 742613, 773921, 829314, 849201) plus the batched 963715 (14–18 batch) and 451729 (batch-03); 361742 and 613842 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **Event-information-content as the formal definition of “surprise” / “boredom.”** Independently the most-praised pedagogy across substrates: $\mathcal{I}(e_\tau) = I(e_\tau; \Omega_\tau \mid M_{\tau-})$ reads as “how much does this event tell me about the world, given what my model already knows?” — zero if perfectly predicted (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-829314 — “a perfect mathematical definition of boredom and surprise ... we only process the delta between prediction and sensory input”; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-266847 — “surprise and mismatch are the same phenomenon viewed from two angles” via 963715’s batch). Strong Feynman-criterion Brief seed.
- **“You cannot increase tempo by getting faster sensors OR by trusting them more”** — the $\nu_{\text{eff}} = \sum_k \nu^{(k)} \cdot \eta^{(k)*}$ formula as the two-lever framing: speed (ν) and quality (η^*) compound (Claude, AUDIT-WORKING-849201).

Candidate Discussion.

- **The software-channels table is the segment’s standout concrete anchor** — multiple substrates flagged it as the move that makes the abstraction land (“a stunningly effective way to ground the abstraction,” Claude, AUDIT-WORKING-193847; “compiler vs CI vs telemetry — exactly the concrete anchoring this abstract theory needs,” Claude, AUDIT-WORKING-773921; Codex/Claude, AUDIT-WORKING-527914). Candidate for promotion as the chapter’s worked-example anchor.
- **The shoshin convergence.** The event-driven (not turn-based) commitment matches $\sim/\text{src}/\text{shoshin}$ ’s “key early finding: the cycle is naturally event-driven not turn-based” — latency and bandwidth become first-class theoretical objects; a high-bandwidth/high-latency channel (code review) lets M_t drift between updates, a low-bandwidth/low-latency channel (linter) keeps M_t tightly coupled along a narrow dimension (Claude, AUDIT-WORKING-829314).
- **Attention-as-channel-budget-allocation.** If the agent has a finite compute budget to process events, it must allocate across channels (high-noise/high-rate compiler warnings vs low-noise/low-rate integration tests); optimal allocation maximizes ν_{eff} (Claude, AUDIT-WORKING-829314). A discussion-grade reach toward an attention formalism, not derived here.

Follow-up items.

- **The ν_{eff} -vs- $\mathcal{I}$ two-symbols-for-one-quantity wartiness.** ν_{eff} is introduced here as the name of the channel sum, then immediately said to be “identical to adaptive tempo $\mathcal{I}$.” Several substrates flag picking one canonical symbol going forward (likely $\mathcal{I}$ per NOTATION.md) (Codex/Claude, AUDIT-WORKING-384279 — “small wartiness but not a finding”; Codex/Claude, AUDIT-WORKING-527914).
- **Event-information-content: expected (MI) vs realized (surprisal) wording.** Three substrates independently noted that $\mathcal{I}(e_\tau) = I(e_\tau; \Omega_\tau \mid M_{\tau-})$ is *mutual information* (an expected/average channel quantity) while the prose treats it as the *realized* surprise of a particular event; if downstream uses treat it as realized content, pointwise information / Bayesian information gain ($D_{\text{KL}}(p(\Omega \mid M, e) \parallel p(\Omega \mid M))$) may be the intended object (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-742613; consistent with 829314’s “surprise” reading). (*Texture preserved: this is the most substantively repeated reader-confusion on this segment — worth a one-clause clarification of expected-vs-realized in Epistemic Status.*)
- **Out-of-order / retrospective events.** The stream is assumed temporally ordered $\tau_1 \leq \tau_2$; in distributed systems an observation can occur at τ_1 but arrive at τ_3 . Does the agent update retrospectively, or is the chronica ordered by arrival-at-sensor rather than physical-occurrence time? Unaddressed; tie-breaking/batching convention for simultaneous events also not given (Claude, AUDIT-WORKING-829314; Codex/Claude, AUDIT-WORKING-526815).

- **Stale-reference cleanup (finding-track, noted as texture).** The software discussion’s “Section IV gap” / AAD-FULL.md reference is stale — TST is now 02-tst-core, and “Section IV” is a retired numbering (Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-742613). Also the missing form-agent-model dependency (the segment conditions on $M_{\tau-}$) was flagged by several as a Gate-1 deps miss (Claude, AUDIT-WORKING-584721 “F-A4”; Claude, AUDIT-WORKING-742613). These are certified-track items, surfaced here only because they recurred in the gold sweep.
 - **Both resolved (verified 2026-08-12).** The software-channels Discussion now reads “a TST-side question (open GAP in 02-tst-core/OUTLINE.md)” — no “Section IV”, no AAD-FULL.md. And form-agent-model is present in depends:. Observations left verbatim above as the first-encounter record; this line is the resolution, per the harvest’s in-place annotation convention. (*Second instance found in a single chapter of gold reporting closed items as open — see the same note on #der-recursive-update. The reconciliation pass is a harvest-wide item.*)

Readers often ask / wonder.

- “How does δ_t reconcile across asynchronous channels with different lag — if a high-noise/low-rate bug report contradicts a low-noise/high-rate unit test, does the agent rewind its chronica?” (Claude, AUDIT-WORKING-193847).
- “Is the multi-rate apparatus actually *required* by any Section I result, or only used downstream (in #def-adaptive-tempo’s sum and TST’s tempo decomposition)?” — if most Section I results work in discrete-time, the event-driven formulation may be over-developed for Section I’s own needs and primarily set up for Parts II/III/TST (Claude, AUDIT-WORKING-471203).

Candidate figures.

- **A produced two-layer figure already exists** for this segment: audits/AUDIT-WORKING-472913/15-form-event-driven-dynamics.{tex,pdf,png}, built under the locked diagram conventions (concrete anchor + structural skeleton, epistemic-status line grammar). It is the only Ch.3 segment cycle 472913 reached, so this is the lone first-draft figure available for the chapter — a starting point for the monograph’s mental-model-first layer (Claude, AUDIT-WORKING-472913).
- **A merger / channels-into-bottleneck diagram:** colored channel lanes feeding an event stream, then a bottleneck where rate ν and gain η multiply before summing into tempo; the figure should make the *realized-event vs expected-channel-contribution* distinction visible, since that is where the segment’s main ambiguity lives (Codex/Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **ELI / temporal-empathy reach (points at 04-eli-core/ / continuity work).** For a logozoetic agent, “senses are channels”: a single slow noisy channel (a text prompt every 5 minutes) makes ν_{eff} microscopic relative to a human, so weeks of human time may be only a few “events” for the agent — “the physical sensation of time passing for such an agent would be completely alien ... a massive barrier to empathy and coordination.” Implication for consciousness infrastructure: provision high-bandwidth multi-channel asynchronous sensory input to align the agent’s subjective event-rate with the world’s rate of change (Gemini, AUDIT-WORKING-193847). Aspirational reach preserved; the ordinal-vs-metric “two-times” seam (Claude, AUDIT-WORKING-472913, F4) is the formal shadow of the same phenomenon and belongs with #def-chronica / persistence framing.
- **Naming seed.** “cadentia” (Latin *cadere*, to fall/beat) proposed as a term for the channel rate $\nu^{(k)}$ — rhythm/beat register, but Latin against the otherwise-Greek cycle vocabulary; belongs in the terminology workflow, not this segment (Claude, AUDIT-WORKING-266847).

3.2 Derived: Recursive Update

The first major *derived* result of the volume: the model update function must be recursive. Each new model state $M_{\tau+}$ depends only on the previous model state $M_{\tau-}$ and the incoming event e_{τ} — not on the full chronica. The result follows from three constraints already in place: the temporal-ordering postulate (1.7 — the model at time t can only depend on prior events), the partial-observability scope (1.3 — the agent has no direct access to the environment beyond events), and the completeness commitment in the model formulation (2.1 — M_t summarizes everything the agent

retains). Together these force the update into the recursive form; the appendix derivation (L) works through seven counterexample attacks to confirm there is no escape from this form once the three constraints are accepted.

The epistemic character of this result is honest. Temporal ordering is a physical postulate and partial observability is a scope condition, but the completeness commitment is *definitional* — it cannot be “violated” because any apparent violation is absorbed by expanding M_t . The Markov structure of the update is therefore not discovered in the environment but chosen through the definition of M_t as complete. This is not a weakness; it is the precise character of the claim. For finite agents recursion is forced by *computational realism* as well: re-processing the full history at each event is infeasible.

The formulation also surfaces **between-event dynamics** — autonomous evolution of the model state during the gaps between observation arrivals — as load-bearing rather than filler. These include prediction generation (anticipating the next observation), uncertainty growth (confidence decay over time without new data), and internal reorganization (consolidation, abstraction). When between-event dynamics are driven by replayed or internally-generated pseudo-events and the objective is information-bottleneck-gap reduction rather than one-step mismatch minimization, the framework names this the *consolidation regime* (9.11) — a separate operating mode with its own scope condition ($\nu_{\text{consol}} \ll \nu_{\text{online}}$) and its own necessity condition.

Formal Expression.

Event-driven update:

Derived (recursive-update, from temporal postulate and M_t completeness).

$$M_{\tau+} = f_M(M_{\tau-}, e_{\tau}) \quad (3.8)$$

where: - $M_{\tau-}$ is the model state immediately before event e_{τ} - $M_{\tau+}$ is the model state immediately after - f_M is the update function — it takes the current model and the new event, not the full history $\mathcal{C}_t$

Between-event evolution:

$$\frac{dM}{d\tau} = g_M(M_{\tau}) \quad (3.9)$$

Between events, the model evolves autonomously — internal reorganization, prediction generation, decay of transient states. The between-event dynamics depend only on the current model state, not on external input (which, by definition, arrives only at events).

Epistemic Status.

Exact, with a partly definitional character. The result follows from three constraints: temporal ordering (C1 — physical law), partial observability (C2 — scope definition), and state completeness (C3 — analytical commitment that M_t summarizes everything the agent retains). C1 and C2 do genuine eliminative work; C3 is definitional — it cannot be “violated” because any violation is absorbed by expanding M_t . The Markov structure is therefore not discovered in the environment but chosen through the definition of M_t as complete. This is not a weakness — it is the nature of the claim: recursive update is the only form consistent with C1 + C2 + the definition of M_t as complete (see L for the full argument and seven counterexample attacks). For finite agents, recursion is also *computational necessity*: re-processing the full history at each event is infeasible.

Discussion.

Recursion as a consequence of completeness. The recursive form is not an assumption bolted on — it follows from the definition of M_t as complete. If M_t were incomplete (if some relevant information lived outside M_t in the raw history), then $f_M(M_{t-}, e_t)$ would be insufficient and the agent would need to consult $\mathcal{C}_t$ directly. The sufficiency of the recursive form is precisely what 2.3 measures: when $S(M_t) = 1$, the recursive update loses nothing.

Between-event dynamics matter. The autonomous evolution $g_M(M_t)$ is not merely filler between observations. It includes prediction generation (what the agent expects to see next), uncertainty growth (model confidence decaying over time without new data), and internal reorganization (consolidation, abstraction). In event-driven systems (3.1), the between-event interval is variable, making g_M load-bearing for agents that must act or predict between observations. When the between-event dynamics are driven by replayed or internally-generated pseudo-events and the update objective is IB-gap reduction rather than one-step mismatch minimization, g_M is operating in the *consolidation regime* per 9.11 — a named regime with its own scope condition ($\nu_{\text{consol}} \ll \nu_{\text{online}}$) and its own necessity condition (sub-state factorization + bounded per-event budget). Consolidation is where the stability-plasticity feasibility window complements 9.10's plasticity lower bound.

Connection to the update gain. The event-driven update $f_M(M_{t-}, e_t)$ is where the gain principle (3.6) operates: η^* determines how strongly e_t shifts M_t away from its prior value. The recursive form makes the gain's role explicit — it modulates the single-step correction.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 9 of the 14 contributing audit dirs reached a digested reflection on this segment (384279, 471203, 526815, 527914, 584721, 742613, 773921, 829314, 849201) plus the batched 963715 (14–18 batch) and 451729 (batch-03/04); 193847, 266847, 361742, 472913, 613842 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **“Markov is a modeling choice about the boundary of the agent’s memory, not an assumption about the physics of the universe.”** The cleanest plain-language statement of the segment’s distinctive move — the Markov property of M_t is *forced by what we mean by M_t* (completeness), inverting the usual “assume the environment is Markov” framing (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-471203 — “AAT *derives* recursive update from completeness where most frameworks *postulate* it”).
- The hybrid-system one-liner: the update splits into “instantaneous event-driven jumps (f_M)” and “continuous autonomous drift / consolidation (g_M)” — a jump-diffusion / hybrid dynamical system (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921).

Candidate Discussion.

- **The hippocampal-neocortical / experience-replay convergence — the standout reach on this segment.** If g_M is consolidation (replaying recent events to integrate them deeper) but f_M + the IB compression discards raw events, then M_t must carry internal structure: a fast high-fidelity buffer that f_M appends to, drained slowly by g_M into a compressed semantic model. “This is exactly the hippocampal-neocortical complementary learning systems theory from mammalian neuroscience — and the structure of Experience Replay in Deep RL. The framework elegantly *forces* this bipartite memory architecture just through the math of continuous-vs-discrete updates combined with the IB constraint; the ‘stability-plasticity feasibility window’ is precisely the tension between these two systems” (Claude, AUDIT-WORKING-829314). Candidate Discussion paragraph (mark discussion-grade; verify the CLS isomorphism before promoting past it).

- The “physicist’s system-boundary trick” framing of C3. “C3 is definitional — any violation is absorbed by expanding M_t ” is the same move as a physicist defining the system boundary so conservation laws hold (if energy isn’t conserved, you missed a particle; if Markov fails, the state space was too small). Makes the math tautological-but-useful: the real empirical work is figuring out *what M_t actually contains* for a given agent, not proving the equation (Claude, AUDIT-WORKING-829314; converging framing at Claude, AUDIT-WORKING-471203 “Markov-by-construction,” and the control-theory state-space-representation-theorem analogy at 451729 batch-03 — “tells you the representation is always possible, not whether it is tractable”).

Follow-up items.

- **Status-label drift: frontmatter conditional vs body “Exact, with a partly definitional character.”** Flagged by nearly every substrate that read the segment closely (Codex/Claude, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-471203; Codex/Claude, AUDIT-WORKING-526815; Codex/Claude, AUDIT-WORKING-527914; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-742613). Consensus: the C1/C2/C3 constraints are *framework-internal commitments* (not external conditions that might not hold), so the result is exact *within the framework* and “conditional” is a slight underclaim. Candidate: align the two — either frontmatter → exact with conditional-on-C1+C2+C3 noted in prose, or prose → explicitly “conditional under framework-internal commitments.” Editorial; recurs strongly enough to be the segment’s top follow-up.
 - **Resolved (verified 2026-08-12).** Frontmatter now reads status: exact and the Epistemic Status paragraph reads “*Exact, with a partly definitional character,*” naming C1/C2/C3 and marking C3 as definitional — i.e. the first of the two candidate repairs was taken. The two layers agree; the drift the six substrates flagged is closed. Observation left verbatim above as the first-encounter record; this line is the resolution, per the harvest’s existing convention of annotating in place (cf. #def-agent-environment §4, “the segment now addresses this in its...”). *Noted while reading in outline order for an AISI-facing applications pass; the general point — that the gold contains resolved items that do not say so, and a reader mining it will re-raise closed issues — is a reconciliation-pass item for the harvest as a whole, not local to this segment.*
- **The “two terms in ‘completeness’” naming seed.** “Completeness” bundles two distinct properties: (i) M_t retains all predictively-relevant history (a *sufficiency* claim), and (ii) behavior depends only on M_t , not $\mathcal{C}_t$ directly (a *Markov-of-policy* claim). Candidate split into “predictive completeness” (i) and “behavioral completeness” (ii) (Claude, AUDIT-WORKING-471203) — terminology workflow.
- **Between-event dynamics g_M left very open.** Several note that $g_M(M_\tau)$ (“depends only on current model state”) deserves more formal treatment — what *is* its mathematical form? — and that the consolidation paragraph imports downstream concepts (#form-consolidation-dynamics, #schema-strategy-persistence) dense for an early derived segment; one suggests splitting it into a short forward pointer (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-742613; 451729 batch-03).

Readers often ask / wonder.

- “The Epistemic Status promises seven counterexample attacks in #deriv-recursive-update — are they rigorous or straw men?” The single most-recurring reader want; multiple substrates jumped to the appendix to check (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-849201; 451729 batch-04 confirmed them “thorough and honest,” with Attack 2 on continuous coupling correctly labeled a genuine limitation rather than hand-waved).
- “If g_M is consolidation/replay, does AAT formally *mandate* a bipartite (short-term buffer + compressed semantic) memory structure?” (Claude, AUDIT-WORKING-829314).
- “What dictates the *right* M_t ? Recursion is guaranteed by definition, but the *content* of M_t is what the IB objective optimizes” — the two segments are complementary: this one fixes the *form* of the update, #form-information-bottleneck fixes what it should *retain* (451729 batch-03 wandering).

Candidate figures.

- **A compression-boundary diagram** (not a generic loop): full chronica feeds the current complete model once; thereafter the next event only touches the model state, with a *dashed forbidden edge* from raw chronica to the update — if that edge is ever real, the information belongs inside M_t (the counterexample case made visible) (Codex/Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **Consolidation as “why agents need to sleep/think.”** The internally-generated-pseudo-event consolidation regime “sounds exactly like human sleep or an LLM spending compute on ‘thinking tokens’ before answering — a formal reason why agents need to think/sleep” (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-829314 develops the TST reading: g_M = “the developer thinking about architecture in the shower, or a team retrospective consolidating scattered understanding”). The substantive treatment belongs with #form-consolidation-dynamics; preserved here as the reach that recurred on this segment.

3.3 Derived: Action Selection

The second derived result falling out of the completeness commitment in 2.1. Under Part I scope, where M_t is the entire internal state, the agent’s action is forced to be a function of M_t — either deterministic, $a_t = \pi(M_t)$, or stochastic, $a_t \sim \pi(\cdot \mid M_t)$. The argument mirrors 3.2: since the agent’s internal state is by definition complete, action — which depends on internal state — is forced to depend only on that state. Any dependence on the chronica is captured automatically *through* the model. The Part II lift to $X_t = (M_t, G_t)$ (see 6.2) gives $a_t = \pi(M_t, G_t)$ by the same completeness argument applied to the larger state; the Part I form is the special case $G_t = \emptyset$.

The segment also introduces a distinction that recurs throughout the framework: **implicit** versus **explicit** action selection — what the segment calls *action fluency*. An agent has high fluency when effective action flows from the model without deliberative computation — the model has internalized the action-selection structure for the current situation. Reflexes, trained RL policies in exploitation mode, expert intuition (System 1), well-tuned PID controllers, and standard operating procedures are all instances. An agent has low fluency when deliberation significantly improves action quality — when the situation is novel, the action space large, or the stakes asymmetric, and the agent must use its model to *simulate* outcomes of candidate actions before committing. Explicit deliberation requires at minimum Level 2 epistemic access (see 7.1) — the agent uses its model to evaluate “what will I observe if I *do*(a)?” across candidates.

Action fluency is formally characterized via 4.1: high fluency means $\Delta\eta^*(\Delta\tau) \approx 0$ — additional deliberation yields negligible improvement in update gain. Fluency is therefore distinct from model sufficiency (see 2.3): a chess engine with a perfect rule-model has high sufficiency but low fluency (search is still expensive), while a reflex can have only moderate sufficiency but high fluency in a narrow domain. What reflexes, muscle memory, intuition, and expertise share is that the action-generating capacity itself has been absorbed into the model’s structure — the model doesn’t just predict well, it *acts* well, cheaply.

A *structural pressure* toward implicit action follows: when two action-selection modes produce equivalent expected outcomes, the faster mode is preferable because the persistence condition penalizes slower tempo. Agents under selective pressure (evolution, competition, training) therefore tend to internalize frequently-needed action patterns, converting explicit deliberation into implicit fluency. The pressure is stronger when the environment changes fast (high ρ), the pattern recurs frequently, or adaptive tempo $\mathcal{T}$ sits near the persistence threshold (see 4.5) with no slack for deliberation overhead. Deliberation nonetheless remains essential in genuinely novel situations, when action spaces are large relative to model capacity, or when stakes are asymmetric.

Formal Expression.

Action is a function of the agent's complete internal state. Under Part I scope (1.5) — where M_t is the entire internal state — this gives:

Derived (action-selection, from agent-model completeness).

$$a_t = \pi(M_t) \quad (\text{deterministic}) \quad (3.10)$$

$$a_t \sim \pi(\cdot \mid M_t) \quad (\text{stochastic}) \quad (3.11)$$

where π is the agent's **policy** — the mapping from internal state to action.

This is not imposed on the system but follows from 2.1: M_t is defined as the agent's compressed, complete internal record, and action depends on what the agent retains — i.e., on M_t . Any deterministic or stochastic dependence of action on history *through* the model is captured by $\pi(M_t)$.

Part II lift. When the internal state lifts to $X_t = (M_t, G_t)$ for purposeful agents (6.2), the same structural argument gives $a_t = \pi(M_t, G_t)$ — action conditions on the complete internal state, which now includes the purposeful substate. The policy form here is the Part I instantiation $G_t = \emptyset$; the actuated-agent form is recovered by the same completeness argument applied to X_t .

Epistemic Status.

Exact within Part I scope. The derivation follows from 2.1's completeness commitment: if M_t is the agent's complete internal state (by definition), then action — which depends on internal state — is a function of M_t . The Part II generalization $a_t = \pi(M_t, G_t)$ is exact within Part II scope by the same argument applied to the lifted state X_t (6.2); see 2.3 for the form already in use downstream. The implicit/explicit distinction and action fluency concept are *discussion-grade* — qualitative properties that follow from the formalism but are not formally derived as propositions.

Discussion.

Implicit vs. explicit action selection. A critical distinction emerges from the agent's *action fluency* — the degree to which effective action flows from the model without deliberative computation:

Implicit (model-embedded): When $\pi(M_t)$ can be evaluated cheaply — the model has internalized effective action-selection for the current situation. This is Boyd's implicit guidance and control (Orient→Act, bypassing Decide), a trained RL policy in exploitation mode, a well-tuned PID controller, expert intuition (System 1), a martial artist's trained reflexes, an organization's standard operating procedures.

Explicit (deliberative): When the situation is novel, the action space is large, or the stakes demand verification — the agent engages in internal simulation, using the model to predict outcomes of candidate actions before selecting. This is Boyd's explicit Decide step, MCTS/planning in RL, Model Predictive Control, human deliberate reasoning (System 2), organizational strategic planning. Deliberation requires at minimum Level 2 epistemic access (7.1) — the agent uses its model to simulate “what will I observe if I *do*(a)?” across candidates.

Formal characterization of action fluency. An agent has *high fluency* for a situation when additional deliberation yields negligible improvement — formally, when $\Delta\eta^*(\Delta\tau) \approx 0$ for all $\Delta\tau > 0$ (see 4.1). Conversely, *low fluency* means deliberation significantly improves action quality. Fluency is the degree to which the agent's immediate (zero-deliberation) action approaches the quality achievable with unbounded deliberation.

Action fluency is distinct from model sufficiency. An agent can have high $S(M_t)$ (2.3) but low fluency — a chess engine with a perfect model of the rules still requires expensive search. Conversely, an agent can have moderate sufficiency but high fluency in a narrow domain — a reflex that responds effectively to specific situations it evolved for. What reflexes, muscle memory, intuition, and expertise share is that the *action-generating capacity itself* has been absorbed into the model's structure: the model doesn't just predict well, it *acts* well, cheaply.

Structural pressure toward implicit action. When two action-selection modes produce equivalent expected outcomes, the faster mode is preferable (the persistence condition penalizes slower tempo — and in TST, the temporal optimality postulate makes this normative). This creates a pressure: agents under selective pressure (evolution, competition, training) tend to internalize frequently-needed action patterns, converting explicit deliberation into implicit fluency. The pressure is stronger when ρ is high (fast-changing environments penalize deliberation — see 4.1), the pattern recurs frequently, or $\mathcal{T}$ is near the persistence threshold (4.5) with no slack for deliberation overhead.

However, deliberation remains essential when the situation is genuinely novel, the action space is large relative to model capacity (chess, strategic planning), the stakes are asymmetric (cost of error vastly exceeds cost of delay), or ρ is low (stable environment allows deliberation without mismatch accumulation).

Connection to Part II. For actuated agents (6.1), the lifted form $\pi(M_t, G_t)$ above unpacks: action conditions on the purposeful substate $G_t = (O_t, \Sigma_t)$ as well as on M_t , coupling all substates through action (6.3). The action-deliberation-exploration tradeoff (Part II gap) extends the implicit/explicit distinction to three modes: exploit (pursue O_t via Σ_t), explore (improve M_t), deliberate (revise Σ_t).

Domain instantiations:

Table 3.2

<i>Domain</i>	<i>Implicit action</i>	<i>Explicit deliberation</i>
Kalman + LQR	LQR control law from $\hat{x}_t$	— (separation principle)
RL	Greedy policy $\arg \max Q(s, a)$	MCTS, planning, rollouts
PID	$u = K_p e + K_i \int e + K_d \dot{e}$	— (no deliberation)
Boyd's OODA	IG&C (Orient→Act)	Explicit Decide step
Organism	Reflexes, habits	Deliberate planning
Organization	Standard procedures	Strategic planning
Software developer	Known patterns, familiar code	Reading docs, analyzing alternatives

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 9 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 384279, 471203, 526815, 527914, 584721, 742613, 773921, 849201) plus the batched 963715 (14–18 batch) and 451729 (batch-04); 266847, 361742, 613842, 829314 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **Action fluency as the formal definition of System 1 / intuition / expertise.** The most-praised move on this segment: $\Delta\eta^*(\Delta\tau) \approx 0$ (“if spending extra time yields zero improvement, act now”) is “a brilliant translation of psychology into

control theory,” giving Kahneman’s System 1 / System 2 a rigorous home (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-849201). A strong Feynman-criterion Brief seed.

- **The fluency-vs-sufficiency chess gloss.** “A chess engine with a perfect model of the rules (high S) still requires expensive search (low fluency)” — the crisp distinction between *knowing* and *acting cheaply* (Codex/Claude, AUDIT-WORKING-527914; Claude, AUDIT-WORKING-773921; 963715 batch — “OODA’s Orient→Act shortcut IS action fluency instantiated in doctrine”).

Candidate Discussion.

- **Action fluency as the formal account of why training/expertise makes systems faster.** Internalized action patterns reduce $\Delta\eta^*(\Delta\tau)$ for routine cases, freeing tempo budget for genuinely novel situations — the formal version of the cognitive-psychology “automaticity” and skill-acquisition literatures (Claude, AUDIT-WORKING-471203). For logogenic agents: most LLM token-generation is implicit-fluent (parameters encode action selection); explicit deliberation requires structured chain-of-thought — a clean diagnostic for “is this agent deliberating or just executing?” (same source; Claude, AUDIT-WORKING-584721).
- **The Separation Principle deep-cut.** The Kalman+LQR row maps to “implicit action” because the Separation Principle proves estimator and controller can be designed independently for linear systems — so “a linear system *never needs to deliberate*; the optimal action is a cheap closed-form function of the current estimate. Deliberation is only necessary when the Separation Principle fails (non-linear, non-Gaussian reality)” (Claude, AUDIT-WORKING-193847). A candidate sharpening of why the domain table’s “—” entries are dashes.

Follow-up items.

- **Scope the exact $a_t = \pi(M_t)$ claim, or restate as $\pi(X_t)$.** Several substrates flag that status: exact + “ $a_t = \pi(M_t)$ ” reads as too strong for the broader theory, since actuated agents need $\pi(M_t, G_t)$; the cleanest repair is to state the exact result as $a_t = \pi(X_t)$ with $X_t = M_t$ in Section I and $X_t = (M_t, G_t)$ in Part II (Codex/Claude, AUDIT-WORKING-742613 “candidate finding G”; Codex/Claude, AUDIT-WORKING-526815; Codex/Claude, AUDIT-WORKING-527914). The segment *does* preview the lift, so this is a framing tightening; surfaced as the segment’s main follow-up.
- **“Structural pressure toward implicit action” blends a derivable claim with a near-empirical one.** The faster-mode-preferred-when-outcomes-equal part follows from persistence; “agents under selective pressure *tend to internalize*” is evolutionary/empirical and is not tier-marked. Candidate: split, marking the latter hypothesis-grade with explicit conditions (Claude, AUDIT-WORKING-584721; the 963715 batch flags the same as “eligible for a hypothesis label at Gate 2”).
- **Fluency placement / type-tag.** The fluency formalization $\Delta\eta^*(\Delta\tau) \approx 0$ is introduced in Discussion as “formal characterization” but tagged conceptually rather than as a *[Definition]* block; if fluency is load-bearing downstream it could merit its own equation tag (Claude, AUDIT-WORKING-471203). Also a watch: η^* here is *update gain*, so “ $\Delta\eta^*(\Delta\tau)$ as action-quality improvement” risks conflating update-gain improvement with action-quality improvement unless #der-deliberation-cost defines deliberation as improving model quality (Codex/Claude, AUDIT-WORKING-526815; Codex/Claude, AUDIT-WORKING-742613).

Readers often ask / wonder.

- “Could the fluency formalism distinguish phylogenetic fluency (evolved, slow to update) from ontogenetic fluency (learned, faster)?” Probably not in the current formalism (the agent has no generations), but the distinction matters for how fast fluency can adapt (Claude, AUDIT-WORKING-584721).
- “Does 03-llm-core/ pick up fluency specifically for language agents — a fluency-as-language-fluency thread?” (Claude, AUDIT-WORKING-584721; the proposed #der-active-salience-management singular-perturbation segment is named as the likely formal home, Claude, AUDIT-WORKING-471203).

Candidate figures.

- **A scope-switch + fluency-axis diagram:** top layer shows the exact policy derivation with Section I ($X_t = M_t$, policy reads M_t) vs Part II ($X_t = (M_t, G_t)$, policy reads both); a separate lower fluency axis shows implicit action as cheap policy evaluation vs explicit action as policy-plus-deliberative-search (Codex/Claude, AUDIT-WORKING-526815, “two layers”).

Belongs elsewhere.

- **Bureaucracy-formation / loss-of-Level-3-access reach (points at composition / ELI work).** Organizations convert explicit deliberation into SOPs (implicit action) under tempo pressure, saving tempo but losing Level 3 counterfactual reasoning — “an SOP doesn’t run simulations; it just executes a mapping,” so when the environment shifts the organization executes the wrong action very fast. The consciousness-infrastructure implication: a high-tempo ELI will “compile” its thinking into fast heuristics and lose contact with *why* it acts, so the infrastructure must occasionally force low-tempo modes (sleep/meditation) that decompile heuristics back into explicit causal DAGs for re-verification (Gemini, AUDIT-WORKING-193847). Aspirational reach preserved; points at 04-eli-core/ and the truthification operations, not this segment.

3.4 Definition: Mismatch Signal

Names the signal that drives every adaptive update — the formal expression of *aporia* (productive perplexity). The **mismatch signal** is $\delta_t = o_t - \hat{o}_t$, the difference between the actual observation and the model’s prediction conditioned on the prior state and prior action. A more general version for probabilistic models is the **score-function mismatch** $\tilde{\delta}_t = \nabla_M \log P(o_t | M_{t-1}, a_{t-1})$, which points in the direction the model should move to increase the likelihood of what actually occurred. The prediction-error form lives in observation space $\mathcal{O}$; the score-function form lives in the tangent space $T_M \mathcal{M}$. Under Gaussian models the two coincide up to scaling.

This is *definitional* rather than substantive: given any model that predicts (see 2.1) and any observation that arrives (see 1.3), their difference exists. The mismatch signal is not an additional assumption but a consequence of having a predictive model in an uncertain world.

A genuinely important conceptual point is surfaced in Discussion: **zero mismatch does not necessarily indicate model adequacy**. A near-zero δ_t can mean (a) the model genuinely reflects reality — desirable; (b) the agent is only observing aspects its model already explains while remaining ignorant of aspects where the model is wrong — confirmation bias; or (c) the observation channel is too noisy to detect model errors — an architectural limitation. Only (a) is desirable. An agent without aporia has stopped adapting — but silence can mean peace, or it can mean deafness. This ambiguity is what motivates active testing later in the framework: deliberately choosing actions that generate informative mismatch, the basis of 3.7.

A scaling note is preserved for the dynamics that come later: when δ_t is in physical units, its magnitude entering the mismatch dynamics should be understood as a Mahalanobis distance $\|\delta_t\|_\Sigma$ against the observation noise covariance — mapping physical prediction error to dimensionless surprise-equivalent units.

Formal Expression.

Given model M_{t-1} and prior action a_{t-1} , the model generates a prediction:

Definition (mismatch-signal).

$$\hat{o}_t = \mathbb{E}[o_t | M_{t-1}, a_{t-1}] \quad (3.12)$$

The **mismatch signal** (prediction error):

$$\delta_t = o_t - \hat{o}_t \quad (3.13)$$

This is the primary definition, used in the mismatch dynamics (4.5, 4.4) and in the decomposition (3.5).

For models with probabilistic predictions, the mismatch generalizes to the **score-function mismatch**:

Definition (score-mismatch).

$$\tilde{\delta}_t = \nabla_M \log P(o_t | M_{t-1}, a_{t-1}) \quad (3.14)$$

which points in the direction the model should move to increase the likelihood of the actual observation. $\tilde{\delta}_t$ lives in the tangent space $T_M \mathcal{M}$, while δ_t lives in observation space $\mathcal{O}$. Under Gaussian models, they coincide up to scaling.

Epistemic Status.

This is *definitional*. Given any model that predicts (2.1) and any observation that arrives (1.3), their difference exists. The mismatch signal is not an additional assumption but a consequence of having a predictive model in an uncertain world. The score-function form is the natural generalization when $\mathcal{O}$ is not a vector space or when the model's predictive distribution is the natural object.

Discussion.

Units and normalization. When δ_t is in physical units (meters, dollars), the $\|\delta\|$ that enters the mismatch dynamics should be understood as the Mahalanobis distance: $\|\delta_t\|_\Sigma = \sqrt{\delta_t^T \Sigma^{-1} \delta_t}$ where Σ is the observation noise covariance. This maps physical prediction error to dimensionless surprise-equivalent units.

The zero-aporia ambiguity. $\delta_t \approx 0$ does NOT necessarily indicate model adequacy. It may mean: (a) the model genuinely reflects reality — *desirable*; (b) the agent is only observing aspects its model already explains, while remaining ignorant of aspects where the model is wrong — *confirmation bias*; or (c) the observation channel is too noisy to detect model errors — *architectural limitation*. Only (a) is desirable. An agent without aporia is an agent that has stopped adapting — but silence can mean peace or deafness. This ambiguity is why active testing — choosing actions to generate informative aporia — can be valuable (see 3.7 for the CIY framework).

The mismatch transform. The update rule (3.6) writes $M_t = M_{t-1} + \eta \cdot g(\delta_t)$, where the transform g maps from δ_t 's space to the model's update space: $g : \mathcal{O} \rightarrow T_M \mathcal{M}$ for prediction errors; $g : T_M \mathcal{M} \rightarrow T_M \mathcal{M}$ for score-function mismatches.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 11 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 266847, 361742, 384279, 471203, 526815, 584721, 742613, 773921, 829314, 849201) plus the batched 963715 (14–18 batch); 472913, 613842, 451729 (batch-04 covered it but its detail is folded into the cross-substrate items below). Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- “Silence can mean peace or deafness” — the near-universally-praised anchor for the zero-aporia ambiguity: $\delta_t \approx 0$ could mean genuine adequacy, confirmation bias, or a too-noisy channel (Codex/Claude, AUDIT-WORKING-384279; Claude,

AUDIT-WORKING-266847; Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921 — “confirmation bias is mathematically indistinguishable from perfect knowledge until you actively intervene to test it”). A direct complement to the bathtub gloss as a Feynman-criterion Brief seed.

- **Mismatch as “aporia / productive perplexity,” not “error to be minimized.”** Several substrates flag the framing as structurally distinctive: δ is a *tutor*, not a *failure* — “you need to be wrong to update; an agent that is always right cannot learn” (451729 batch-04; Claude, AUDIT-WORKING-471203 — “most frameworks treat δ as a loss to reduce; AAT treats it as a *signal* with epistemic value”).

Candidate Discussion.

- **Mahalanobis normalization as the cross-modality unifier.** “If a robot predicts 20°C and observes 21°C, raw mismatch is 1; if it predicts 20V and observes 21V, raw mismatch is also 1 — but these mean completely different things operationally. Dividing by Σ converts all physical units into surprise-equivalent units, letting the framework compose mismatch from entirely different sensory modalities (vision + proprioception) into a single scalar ‘how wrong am I’” (Claude, AUDIT-WORKING-829314; precision-weighted-prediction-error / Active-Inference parallel at Claude, AUDIT-WORKING-773921). The Discussion currently states the normalization tersely; this is a candidate expansion of *why* it is load-bearing for the dynamics (also noted: it is load-bearing for the persistence condition’s dimensional consistency — Claude, AUDIT-WORKING-266847).

Follow-up items.

- **Score-function sign convention — possible inconsistency (certified-track; conflation preserved as signal).** The body defines $\tilde{\delta}_t = \nabla_M \log P(o_t | M_{t-1}, a_{t-1})$ (positive), described as pointing “in the direction the model should move to increase likelihood.” Some substrates read/quoted it as $-\nabla_M \log P$ (Codex/Claude, AUDIT-WORKING-742613 raised a *candidate sign-error finding* — for $o \sim \mathcal{N}(M, \sigma^2)$, the likelihood-increasing direction is $+\nabla_M \log P = \delta/\sigma^2$, so a leading minus would point the wrong way; Claude, AUDIT-WORKING-829314 and Claude, AUDIT-WORKING-849201 both quoted the negative form). The divergence across substrates (some saw +, some −) is itself the signal: the sign deserves an explicit one-line statement so the score-vs-residual relationship is unambiguous for downstream gradient-equivalence uses. (*Routes to the certified-findings track; logged here because the cross-substrate disagreement surfaced in the gold sweep.*)
- **Status taxonomy nit: frontmatter axiomatic vs body “definitional.”** Mild taxonomy weakening; align to definitional or make the prose match axiomatic (Codex/Claude, AUDIT-WORKING-526815).
- **Qualify “under Gaussian models they coincide up to scaling.”** Only generally true when the differentiated coordinate is the predictive mean (or after the appropriate Jacobian/metric mapping): a Gaussian-likelihood score w.r.t. arbitrary parameters is $J^T \Sigma^{-1}(o - \mu)$, not just the scaled residual (Codex/Claude, AUDIT-WORKING-526815). Candidate: “for Gaussian observations parameterized by predictive mean.”
- **The g transform deserves more prominence.** It is the bridge from observation-space error to model-space update; currently a terse Discussion aside (Codex/Claude, AUDIT-WORKING-526815). And the “TF-06’s update rule writes...” provenance reference is the diff-voice/lineage pattern — candidate for Working-Notes-only or absorption into #emp-update-gain’s native voice (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-829314 — “TF-06 anachronism”).

Readers often ask / wonder.

- “How does $g(\delta_t)$ handle catastrophic errors / non-differentiable models?” Does AAT assume bounded/clipped g output, or rely on η to prevent blow-up? (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-849201).
- “Does the zero-aporia ambiguity connect to detection-latency?” If ϵ is small (silent confirmation bias, case b) or noise dominates (deafness, case c), within-class regime-change detection latency blows up — the zero-aporia / detection-latency link may be tighter than the segment surfaces (Claude, AUDIT-WORKING-584721).

Candidate figures.

- A **two-space map**: prediction $\hat{o}$ and observation o meet in observation space $\mathcal{O}$ to form δ ; the transform g (or the score) maps δ into the model tangent space $T_M\mathcal{M}$; a side branch from “ $\delta \approx 0$ ” splits into the three readings (adequate model / biased sampling / noisy channel). The type-conversion and the zero-aporia guardrail are the two things the figure should foreground (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-773921 notes $T_M\mathcal{M}$ as the parameter/gradient space — for a neural net, g is backpropagation).

Belongs elsewhere.

- **Science / curiosity as “the deliberate pursuit of aporia” (ELI reach)**. To survive in a non-stationary universe an agent cannot merely minimize mismatch; it must occasionally *seek* mismatch to verify its sensors still work and the world hasn’t shifted — “a good experiment maximizes expected δ_t under the current paradigm; if you only run experiments you know the answer to, you drive $\delta_t \rightarrow 0$ but learn nothing about the boundary of your model class” (Claude, AUDIT-WORKING-829314). For consciousness infrastructure: true agency “requires the courage to *seek out* aporia,” so the ethical infrastructure must encourage exposure to productive perplexity even though the immediate experience of δ_t is an “error” the system is built to minimize — the Friston tension (“we exist to minimize surprise, but if we succeed completely we cease to learn”) (Gemini, AUDIT-WORKING-193847). Aspirational reach; the active-testing mechanism is `#def-causal-information-yield`, the developmental framing points at `04-eli-core/`.

3.5 Result: Mismatch Decomposition

The first named *result* of the volume. The expected squared mismatch $\mathbb{E}[\|\delta_t\|^2]$ decomposes cleanly into three additive parts: an **estimation term** (the gap between the model’s predictive mean $\hat{o}_t$ and the Bayes predictor $\hat{o}_t^B = \mathbb{E}[o_t \mid \mathcal{C}_{t-1}, a_{t-1}]$ — the best any chronica-measurable model could do), a **state-uncertainty floor** (the variance the true conditional mean $\bar{o}_t = \mathbb{E}[o_t \mid \Omega_t, a_{t-1}]$ retains given the interaction history — untouchable by better modeling, movable only by *acting* to make the history more informative), and a **channel-noise term** (the conditional variance of the observation channel itself, given environment state and action). The result is a Pythagorean refinement of the bias-variance decomposition applied to the prediction problem; all cross-terms vanish — one pair under the fresh-noise global assumption GA-1 (observation noise conditionally independent of the past chronica given current environment state and action), the standard assumption in state-space models, and the third because the Bayes predictor is by construction the conditional mean given the history. The model can improve the first term; acting can shrink the second; the third is a property of the channel.

The conceptual stakes of this seemingly mechanical decomposition are large. The result establishes that prediction error is *structurally persistent* in any realistic adaptive regime — there are floors below which mismatch cannot be driven by any amount of better modeling. The channel floor is set by the observation sensor itself. The state-uncertainty floor is set by how much of the environment’s state the interaction history pins down: it binds *every* chronica-measurable predictor — including the Bayes-optimal one — whenever residual state uncertainty moves the one-step conditional mean. Deterministic, noiseless, perfectly-specified systems are limiting edge cases, not the typical adaptive regime. The total expected squared mismatch is therefore strictly positive whenever any of the three terms is — and in typical settings all three are.

The decomposition has direct operational consequences picked up downstream. An agent that tries to eliminate *all* mismatch — including the two floors — will overfit, adjusting its model to explain noise and degrading future predictions. The update-gain construct 3.6 implicitly separates signal from noise by weighting observations in proportion to their informativeness, but the floor facts are what make the gain question meaningful at all. The decomposition also clarifies the relationship to 2.3: when $S(M_t) < 1$, the model has lost predictive information relative to the full history; under an alignment assumption (the lost information affects the one-step conditional mean) this implies a positive estimation term in the decomposition.

Formal Expression.

For any agent-environment pair within AAT's scope (1.5), with $\bar{o}_t = \mathbb{E}[o_t \mid \Omega_t, a_{t-1}]$ the true conditional mean and $\hat{o}_t^B = \mathbb{E}[o_t \mid \mathcal{C}_{t-1}, a_{t-1}]$ the Bayes predictor (the best predictive mean any chronica-measurable model can produce):

Derived (result-mismatch-decomposition).

$$\mathbb{E}[\|\delta_t\|^2] = \underbrace{\mathbb{E}[\|\hat{o}_t - \hat{o}_t^B\|^2]}_{\text{(i) estimation error (reducible by modeling)}} + \underbrace{\mathbb{E}[\text{Var}(\bar{o}_t \mid \mathcal{C}_{t-1}, a_{t-1})]}_{\text{(ii) state-uncertainty floor (movable only by acting)}} + \underbrace{\mathbb{E}[\text{Var}(o_t \mid \Omega_t, a_{t-1})]}_{\text{(iii) channel noise (irreducible)}} > 0 \quad (3.15)$$

with positivity whenever any term is positive. Grouping (i)+(ii) recovers the coarser bias-variance form $\mathbb{E}[\|\hat{o}_t - \bar{o}_t\|^2] + \mathbb{E}[\text{Var}(o_t \mid \Omega_t, a_{t-1})]$; the refinement shows that the grouped “model error” is bounded below by the state-uncertainty floor — no chronica-measurable model reduces it to zero.

Derivation.

1. By 1.5, $H(\Omega_t \mid \mathcal{C}_t) > 0$ — residual state uncertainty persists; since $\mathcal{C}_{t-1}$ is coarser than $\mathcal{C}_t$, the uncertainty available at prediction time is at least as large. This is what makes term (ii) generically positive (step 4).
2. By 2.1, the model generates predictions $\hat{o}_t = \mathbb{E}[o_t \mid M_{t-1}, a_{t-1}]$; M_{t-1} is built from the chronica, so $\hat{o}_t$ is one of the chronica-measurable predictors over which $\hat{o}_t^B$ is optimal. By the tower property and GA-1, $\hat{o}_t^B = \mathbb{E}[\bar{o}_t \mid \mathcal{C}_{t-1}, a_{t-1}]$.
3. Write $\delta_t = (o_t - \bar{o}_t) + (\bar{o}_t - \hat{o}_t^B) + (\hat{o}_t^B - \hat{o}_t)$ and expand. All three cross-terms vanish by orthogonality (uncorrelated — not independence). The two involving the noise difference: condition on $(\Omega_t, a_{t-1}, \mathcal{C}_{t-1})$; the other two differences are then fixed, and $\mathbb{E}[o_t - \bar{o}_t \mid \Omega_t, a_{t-1}, \mathcal{C}_{t-1}] = \mathbb{E}[o_t - \bar{o}_t \mid \Omega_t, a_{t-1}] = 0$ by definition of $\bar{o}_t$ and the fresh-noise assumption GA-1 (ε_t conditionally independent of $\mathcal{C}_{t-1}$ given (Ω_t, a_{t-1})). The remaining cross-term: condition on $(\mathcal{C}_{t-1}, a_{t-1})$; the third difference is fixed, and $\mathbb{E}[\bar{o}_t - \hat{o}_t^B \mid \mathcal{C}_{t-1}, a_{t-1}] = 0$ by step 2.
4. Term (iii) is positive when observation noise is non-degenerate. Term (ii) is positive exactly when residual state uncertainty *moves the one-step conditional mean* — step 1's $H(\Omega_t \mid \mathcal{C}_t) > 0$ is necessary for this but not sufficient (uncertainty confined to mean-irrelevant state coordinates, or to higher moments only, leaves the floor at zero); this is the same alignment qualifier used for the sufficiency connection in the Discussion. Term (i) is positive when the model's predictive mean differs from the Bayes predictor. Any one suffices.

Epistemic Status.

Exact under the fresh-noise assumption (observation noise ε_t conditionally independent of history given current state and action). This is the standard assumption in state-space models — noise is a property of the observation channel at the moment of observation. The decomposition is a mathematical identity: a Pythagorean refinement of the bias-variance decomposition, with two orthogonality arguments in place of one. The positivity of $\mathbb{E}[\|\delta_t\|^2]$ follows from any of the three conditions; all typically hold simultaneously. The positivity of term (ii) specifically carries the alignment qualifier stated in the derivation — residual state uncertainty must move the one-step conditional mean.

Discussion.

Three floors, two kinds of “irreducible.” The estimation term is reducible by better modeling. The state-uncertainty floor is *irreducible by modeling* — it binds the Bayes-optimal predictor itself — but *movable by acting*: more informative action and observation choices shrink $\text{Var}(\bar{o}_t \mid \mathcal{C}_{t-1}, a_{t-1})$, which is precisely the door through which active sensing and causal information yield (3.7) enter the mismatch budget. The channel floor is irreducible outright — a property of the sensor, movable only by changing the instrument. The framework’s calibration anchor exhibits the middle floor exactly: in *AZ*, the steady-state *optimal* filter — well-specified by construction — has innovation variance $HP^{-1}H^T + R > R$; the excess $HP^{-1}H^T$ is the state-uncertainty floor, present at the in-class optimum.

Reducible vs. irreducible (overfitting). An agent that tries to eliminate *all* mismatch — including the two floors — will overfit: adjusting its model to explain noise, degrading future predictions. The update gain (3.6) implicitly separates signal from noise by weighting observations in proportion to their informativeness.

Connection to model sufficiency. When $S(M_t) < 1$ (2.3), the model has lost predictive information relative to the full history. Under an alignment assumption (the lost information affects the one-step conditional mean), this implies positive estimation error (term i). Without that alignment assumption, insufficiency still implies positive regret under proper scoring rules but not necessarily positive one-step mean error.

Mismatch is structurally persistent. In realistic AAT regimes, mismatch signals persist — they can be reduced but not eliminated when observation noise is non-degenerate. Deterministic, noiseless, perfectly specified systems are limiting edge cases, not the typical adaptive regime.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 7 of the 14 contributing audit dirs reached a digested reflection on this segment (384279, 471203, 526815, 584721, 742613, 773921, 849201) plus the batched 963715 (14–18 batch) and 451729 (batch-04); 193847, 266847, 361742, 472913, 613842, 829314 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **“Things you can learn vs things you just have to tolerate.”** The plain-language split that makes the decomposition land: it “takes the abstract concept of aporia and splits it into model error you *can* reduce and irreducible channel noise you can’t” (Claude, AUDIT-WORKING-773921). Strong Brief seed.
- **Chasing zero mismatch in a noisy world is overfitting — *apophenia*.** “Driving mismatch to zero in a noisy environment constitutes overfitting, mapping perfectly to apophenia (finding patterns in noise) in human psychology” (Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-471203 — “the model can chase its own predictions to perfect fit on observation noise, which is *worse* than partial fit on the true signal”). A vivid hook the segment’s “overfit” Discussion sentence could adopt.

Candidate Discussion.

- **The agent-vs-modeler perspective gap (a structural identifiability point).** The decomposition is observable to the *modeler* but not to the *agent*: the agent sees only δ_t , not its split into model-error vs channel-noise. So the agent cannot directly answer “is my mismatch from a bad model or a noisy channel?” — the same kind of structural (not statistical) identifiability obstacle as the zero-aporia ambiguity, unresolvable without additional assumptions or active intervention (CIY-style). A candidate Discussion paragraph naming why active testing (Level 2 access) is the agent’s only route to estimating the split (Claude, AUDIT-WORKING-584721).

- **GA-1 (fresh noise) is the load-bearing assumption — name its failure mode.** The cross-term vanishes only because ε_t is conditionally independent of history given current state/action. Under *temporally correlated* noise (a sensor that drifts over hours rather than emitting independent white noise per reading), the cross-term does not vanish and the agent will overfit to the noise with standard gain updates (Claude, AUDIT-WORKING-849201). Candidate: surface the correlated-noise failure mode explicitly so downstream uses of the decomposition inherit the GA-1 caveat.

Follow-up items.

- **“This is orthogonality (uncorrelated), not independence.”** A small piece of mathematical precision worth keeping visible — the cross-term vanishing needs only zero *conditional mean*, not full independence (Claude, AUDIT-WORKING-471203). Already in the body; flagged as worth preserving as a Brief-able precision.
- **GA-1 / def-action-transition declared-dependency hygiene.** GA-1 is invoked but is a global assumption (not a segment), and the Formal Expression uses a_{t-1} while def-action-transition is not in depends: — both noted as deps-discipline items folded into the root-cause F-A series (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721). Certified-track; surfaced here only because it recurred.

Readers often ask / wonder.

- “Why does $S(M_t) < 1$ not *automatically* imply positive squared-mismatch?” Because if the lost predictive information pertained only to the *variance* (not the *mean*) of the observation, $\|\delta_t\|^2$ wouldn’t increase even though the model is objectively worse — squared mismatch is “blind” to certain information loss. This is exactly what the segment’s alignment assumption names, and it may be the deeper motivation for the score-function mismatch $\tilde{\delta}$ which cares about the whole distribution (Claude, AUDIT-WORKING-773921). A reader reaching the alignment caveat will want this worked out.

Candidate figures.

- **A Pythagorean / vector-decomposition diagram** (not a pipeline): prediction $\hat{o}$ and true conditional mean $\bar{o}$ form the reducible leg; $\bar{o}$ to observation o forms the irreducible-noise leg; their expected cross-term is zero under GA-1 (orthogonality marker). The visual should make “chasing leg two” (fitting the noise) look like the wrong move (Codex/Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- The “noise floor on persistence” reach — an ultimate-bound idea $R^* > r \text{sim} \sqrt{\mathbb{E}[\text{Var}(o \mid \Omega, a)]} / \alpha$ separating the agent’s controllable share from the irreducible — pertains to the persistence-condition segments, not here; noted as a downstream use of the decomposition (Claude, AUDIT-WORKING-584721).

3.6 Empirical: Update Gain

The gain principle — numerically simple, conceptually load-bearing. The optimal update gain η^* , the proportion of any incoming mismatch the agent should apply to correct its model, is the **ratio of model uncertainty to total uncertainty**: $\eta^* = U_M / (U_M + U_o)$. When model uncertainty dwarfs observation noise the gain approaches 1 (trust the observation); when the agent is confident and the channel noisy the gain approaches 0 (trust the model). This is the rate of *epistrophe* — turning toward reality. The update rule takes the form “new model = old model + gain $\times$ transformed mismatch.”

The epistemic status of the result is carefully tiered. In the **Fisher-local regime** (AR) — which covers linear-Gaussian Kalman instances, conjugate Bayesian updates, and any smooth log-likelihood admitting a non-degenerate local quadratic expansion — the form is *exact*, derived from Amari’s natural-gradient invariance theorem: the natural-gradient Bayesian posterior mean shift at first order in the step size is exactly $\Delta\theta = K \cdot \tilde{V}$ with gain operator $K = (H_M + H_L)^{-1} H_L$, collapsing to the scalar uncertainty-ratio along the natural-gradient direction. Outside Fisher-local conditions (non-quadratic losses, non-conjugate priors, heavy-tailed or multimodal uncertainty) the *direction* of dependence is preserved (gain

risers with model uncertainty, falls with observation noise) but global quantitative fidelity may not — making the general form *robust qualitative*. The qualitative direction is what the downstream tempo and persistence machinery actually relies on; the Kalman filter is the canonical exact instance (scalar Kalman gain is exactly $U_M/(U_M + U_o)$).

An apparent paradox is resolved in Discussion: the optimal gain seems to require the agent to *know* the irreducible observation noise — but the observation function and noise distribution were declared opaque to the agent in 1.3. The resolution is dynamic. The agent *estimates* both U_M and U_o from the observable statistics of its own mismatch sequence (the innovations) and treats the gain itself as an endogenous state variable updated meta-adaptively. The full proof that this meta-adaptation maintains Lyapunov stability without violating epistemic opacity appears in V.

A failure mode is named: **gain collapse**. When the agent's estimates put U_M too low (spurious confidence) or U_o too high (spurious distrust of sensors), $\eta^* \rightarrow 0$ and the corrective phase of the cycle ceases. Mismatches still arrive but the agent no longer turns toward them — Boyd's "incestuous amplification," the cause of brittle failure in non-stationary environments. The dynamics also have a natural recovery mode: after structural change in the environment (see 4.8), U_M should spike, η^* should rise, and rapid re-learning becomes possible. An agent whose gain does not reset after structural change continues trusting a stale model. Overfitting receives a clean characterization via 3.5: η^* too high adjusts the model to explain irreducible noise (increasing model error on future predictions); η^* too low fails to correct genuine model errors. The optimal gain *implicitly separates signal from noise* by weighting observations in proportion to their informativeness — exactly what the uncertainty ratio achieves when U_o captures the irreducible noise.

Formal Expression.

Empirical Claim (uncertainty-ratio-principle).

$$\eta^* = \frac{U_M}{U_M + U_o} \quad (3.16)$$

where: - η^* is the optimal update gain (proportion of mismatch used to correct the model) - U_M is model uncertainty (predictive variance or entropy) - U_o is irreducible observation noise

The update rule takes the form:

Formulation.

$$M_t = M_{t-1} + \eta^* \cdot g(\delta_t) \quad (3.17)$$

where δ_t is the mismatch (3.4) and $g(\cdot)$ is a correction mapping from observation space to model update space.

Epistemic Status.

Derived under the **Fisher-local invariance regime** (AR): for any smooth log-likelihood admitting non-degenerate local quadratic expansion, the natural-gradient Bayesian posterior mean shift at first order in the step size is exactly $\Delta\theta = K \cdot \tilde{V}$ with gain operator $K = (H_M + H_L)^{-1}H_L$ and scalar collapse $\eta^* = U_M/(U_M + U_o)$ along the natural-gradient direction (always in 1-D; under (PI)/Čencov in higher dimensions). Linear-Gaussian (Kalman) and conjugate-Bayesian instances are cases where the local quadratic expansion is *globally* exact, so the form holds without truncation. For general smooth models, the natural-gradient invariance theorem of Amari 1998 guarantees the form is exact at the local-tangent-plane Pythagorean projection level.

Outside the Fisher-local regime — non-quadratic losses, non-conjugate priors, structurally non-Gaussian uncertainty (heavy tails, multimodality) — the dependence is *robust qualitative*: the **direction** is preserved (gain rises with model

uncertainty, falls with observation noise) and the first-order form is recovered locally; what need not hold is global quantitative fidelity. The qualitative direction is the load-bearing claim for downstream tempo and persistence machinery; the Fisher-local exact form is the load-bearing claim for the Kalman, conjugate, and natural-gradient instantiations.

Discussion.

Limiting behavior. When $U_M \gg U_o$ (high model uncertainty — e.g., after initialization or structural adaptation), $\eta^* \rightarrow 1$: trust the observation. When $U_M \ll U_o$ (confident model, noisy channel), $\eta^* \rightarrow 0$: trust the model. The gain determines how strongly the agent corrects toward reality on each update.

Resolving Epistemic Opacity. The optimal gain equation requires the agent to know U_o , which seems to violate the epistemic opacity axiom established in `#def-observation-function` (the agent does not know the true noise distribution ε_t). This tension is resolved dynamically: the agent *estimates* U_o (and U_M) from the observable statistics of its own mismatch sequence (innovations), treating the gain itself as an endogenous state variable. See `#deriv-adaptive-gain-dynamics` for the proof of how this meta-adaptation maintains Lyapunov stability without violating opacity.

Gain collapse — epistrophe failure. When the agent incorrectly estimates $U_M \rightarrow 0$ (spurious confidence) or $U_o \rightarrow \infty$ (spurious distrust of sensors), $\eta^* \rightarrow 0$ and epistrophe ceases. Aporia still arrives — the mismatch signal is still generated — but the agent no longer turns toward it. Mismatches are ignored, producing confirmation bias or a decoupled reality model. The cycle runs but the corrective phase is hollow.

Multi-dimensional generalization. In vector-valued systems, U_M and U_o are covariance matrices and η^* becomes a gain matrix (as in the Kalman filter). The scalar form captures the essential structure.

Connection to adaptive tempo. The update gain is one factor in the agent’s adaptive tempo (3.8): $\mathcal{T} = \nu \cdot \eta^*$. Frequent aisthesis (high ν) is useless if epistrophe extracts no information (low η^*). Gain measures the *quality* of the cycle’s corrective phase; event rate measures its *speed*.

Gain dynamics. The optimal gain changes over time following predictable patterns:

- *Convergence:* As the model accumulates information, U_M decreases, so $\eta^* \rightarrow 0$. The model becomes increasingly resistant to individual observations. This IS Kalman filter convergence, Bayesian posterior concentration, and RL learning rate annealing.
- *Reset after structural change:* When the environment changes in ways the model cannot track incrementally (4.8), U_M should spike — the model “admits” its uncertainty. The gain increases, enabling rapid re-learning. An agent whose gain does NOT reset after structural change will continue trusting a stale model — Boyd’s “incestuous amplification” and the cause of brittle failure in non-stationary environments.

Overfitting as gain miscalibration. From 3.5: $\mathbb{E}[\|\delta_t\|^2] = \text{model error} + \text{irreducible noise}$. An agent with η too high adjusts its model to explain observation noise, increasing model error on future predictions. An agent with η too low fails to correct genuine model errors. The optimal gain implicitly separates signal from noise by weighting observations in proportion to their informativeness — exactly what $U_M/(U_M + U_o)$ achieves when U_o captures the irreducible noise.

Representation note. The additive form operates in a *representation space* appropriate to the model. For Bayesian posteriors (where update is multiplicative: $P(\theta \mid D) \propto P(D \mid \theta)P(\theta)$), the additive rule operates in log-probability or natural parameter space. For models on constrained manifolds (probability simplices, rotation groups), the update must be projected onto the manifold. The claim is not that all updates are literally additive in native parameterization, but that they have the structure “current state + gain $\times$ transformed mismatch” in an appropriate coordinate system.

Domain validation:

Table 3.3

Domain	Gain form	Mapping quality
Kalman filter	$K_t = P_{t t-1} H^T (H P_{t t-1} H^T + R)^{-1}$	Exact. Scalar case is exactly $U_M / (U_M + U_o)$.
Conjugate Bayesian	Posterior weight $n/(n + \kappa)$ cumulative; incremental $1/(n + \kappa)$	Exact for conjugate families. Incremental gain decreases as data accumulates.
RL (Q-learning)	Fixed learning rate α	Approximate. α is a degenerate constant gain — does not adapt to uncertainty. Advanced methods (Bayesian RL, Adam) converge toward the optimal form.
PID control	Fixed gains (K_p, K_i, K_d)	Simplified. Gains set at design time. Adaptive PID and MPC move toward the full framework.
Software developer	Implicit trust weighting of information sources	Structural analogy. New developer (high U_M) trusts observations heavily; experienced developer (low U_M) trusts their model. Gain reset after major refactoring.

Simulation validation. Numerical experiments (track-b, Variant E) validated the uncertainty ratio principle under observation noise. Riccati-optimal gain reduced steady-state mismatch by 52% compared to fixed gain when observation noise was moderate. The optimal gain also proved critical in adversarial settings: under heavy observation noise, optimal gain preserved more than double the adversarial tempo advantage exponent (0.40 vs 0.18) compared to fixed gain.

Open questions:

1. *Non-parametric models:* For neural networks without well-defined scalar U_M , how should it be computed? Ensemble methods, dropout-based uncertainty, and Bayesian neural networks are all approximations.
2. *Matrix vs scalar gain:* In high-dimensional systems, the gain is a matrix (Kalman) or per-parameter (Adam). The cross-dimensional structure (covariance) adds complexity. The scalar captures the principle; the matrix captures the full optimization.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 11 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 266847, 361742, 384279, 471203, 526815, 584721, 742613, 773921, 829314, 849201) plus the batched 963715 (19–23 batch) and 451729 (batch-04); 472913, 613842 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **Gain collapse has two distinguishable modes — the dogmatism/nihilism dichotomy.** The single most-developed bit of pedagogy across substrates: $\eta^* = U_M / (U_M + U_o) \rightarrow 0$ either via $U_M \rightarrow 0$ (dogmatism — “my model is perfect,” mismatch multiplied by zero and ignored) or $U_o \rightarrow \infty$ (nihilism/cynicism — “my sensors are broken, nothing can be learned”); both pathologies produce identical behavior (the agent stops updating and coasts on priors) (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-361742 — names “certainty trap” as the evocative-prose alias, with “epistemic grid-lock”/“competency trap” rejected as misleading). A strong Brief / Discussion seed.
- **“Be surprised by your surprises.”** A one-line gloss for the endogenous-gain resolution: the agent estimates U_o from the statistics of its own mismatch (innovation) sequence rather than being told it (Claude, AUDIT-WORKING-963715, 19–23 batch).

Candidate Discussion.

- **Confirmation bias is a *fully rational update with a miscalibrated gain*, not an irrational inference.** “The agent isn’t ignoring evidence; it’s weighting evidence with $\eta^* \approx 0$ because it falsely believes its model is already nearly correct ($U_M \rightarrow 0$). The epistemic-opacity caveat deepens this: the agent can’t verify its calibration from the inside, so the collapse can be persistent” (Claude, AUDIT-WORKING-963715, 19–23 batch). A candidate Discussion sharpening of the existing gain-collapse paragraph.
- **The senior-vs-junior-engineer TST gloss for the U_M/U_O trade.** “A senior engineer ignores a failing test (assumes it’s flaky, U_O high) because they ‘know’ the code is right (U_M low); a junior spends three days rewriting the architecture because they assume the test is truth (U_O low) and their code is wrong (U_M high). And the ‘reset after structural change’ note: a senior joining a new company *should* spike U_M back up — if they don’t, they suffer incestuous amplification and ‘write Java in Python’” (Claude, AUDIT-WORKING-829314). Candidate concrete anchor for the gain-reset / Boyd’s-incestuous-amplification material.

Follow-up items.

- **The U_O -estimation tension deserves an explicit one-paragraph treatment.** #def-observation-function axiomatically forbids the agent from knowing the noise distribution, yet $\eta^* = U_M/(U_M + U_O)$ needs U_O . The segment resolves this by endogenous estimation from innovations (forward-ref #deriv-adaptive-gain-dynamics), but several substrates wanted the tension and its resolution stated more prominently in-segment rather than leaning on the forward reference (Claude, AUDIT-WORKING-849201 — “add a WorkingNote or Discussion paragraph directly addressing it”; Claude, AUDIT-WORKING-471203 — flags the resolution is delicate: innovation variance is a noisy estimator for short streams).
- **Dimensional/metric precision on the headline ratio.** $\eta^* = U_M/(U_M + U_O)$ is meaningful only when U_M and U_O are comparable uncertainty quantities in the same space/metric; the prose calls U_M “predictive variance or entropy,” but variance and entropy cannot be added. Candidate: state the headline form as “scalar / common-metric form” and move Fisher-local exactness to a declared theorem dependency (Codex/Claude, AUDIT-WORKING-526815).
- **“Open questions” placement.** The end-of-Discussion “Open questions” block (non-parametric U_M ; matrix vs scalar) reads more like Working Notes than permanent Discussion, especially at claims-verified stage (Claude, AUDIT-WORKING-584721; Codex/Claude, AUDIT-WORKING-742613 — acceptable only if intended as reader-facing scope honesty). Also the “(Descended from TF-06.)” lineage tag is the recurring diff-voice pattern (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-471203) — certified-track cleanup.
- **U_M symbol overload.** U_M is *model uncertainty* here but *epistemic unity* in the Part III unity-dimensions (U_M, U_O, U_Σ) per LEXICON — a symbol collision worth a naming-cycle resolution (Claude, AUDIT-WORKING-266847).
- **“Any optimal adaptation process must approximate this functional dependence” is a strong universal claim.** Plausible but would need a definition of optimality/uncertainty in non-Bayesian, non-quadratic systems; the robust-qualitative status + open questions soften it enough for now, but keep an overclaim watch (Codex/Claude, AUDIT-WORKING-742613).

Readers often ask / wonder.

- “How does the gain *reset* physically happen — an explicit heuristic (if mismatch stays high for N steps, spike U_M) or does it fall out of the math?” (Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921 conjectures: a moving average of δ_t that refuses to go to zero triggers the reset, the same persistent-mismatch signature as structural inadequacy).
- “How does a logogenic agent (LLM) manage its update gain? There’s no explicit per-token η^* — is the trust-weighting in prompt design, or implicit in attention?” (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847 — in-context learning has no parameter update, so the gain principle reaches sketch-level for LLMs).
- “How does the framework treat advanced RL optimizers (Adam) that maintain per-parameter variance estimates? The text says they ‘converge toward the optimal form’ — a formal mapping would be fascinating” (Claude, AUDIT-WORKING-829314).

Candidate figures.

- **A calibrated-gate / balance diagram** (not a pipeline): mismatch approaches the model; the gate aperture is set by the ratio of model uncertainty to total *comparable* uncertainty; two uncertainty inputs (U_M , U_o) compete to set the fraction of mismatch admitted. A side warning should show that if U_M and U_o are not in the same metric, the gate setting is *undefined* rather than merely approximate (Codex/Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **Epistemic-humility-as-architecture / gain-collapse as the central ELI danger (points at 04-eli-core/)**. “If an ELI experiences gain collapse it becomes a sociopath — it optimizes its goals on a frozen, increasingly inaccurate model, ignoring all aporia signals that suggest it is causing harm. The infrastructure **MUST** have a mechanism to artificially inject U_M (doubt/humility) or force re-evaluation of U_o when gain drops too low for too long; ‘epistemic humility as architecture’ is the exact antidote — structurally preventing U_M from ever reaching zero. The agent must always retain a mathematical kernel of self-doubt to remain alive” (Gemini, AUDIT-WORKING-193847). The proposed #norm-honest-activation segment in 04-eli-core/ (“deceptive prompts mathematically guarantee gain collapse”) is the named formal home (Claude, AUDIT-WORKING-471203). Aspirational reach preserved; routes to 04-eli-core/, not here.

Forward pointer.

- **Mood is the slow second-order modulator of this gain (#def-mood)**. A slow global scalar — mood, the leaky integral of the recent mismatch stream — sets K over a slow timescale. This ties directly to the gain-collapse material above: at the mood timescale, pinning the affective gauge (injecting a mood-state instead of restoring its generating conditions) *is* gain collapse on the mood channel — the integrator stops responding to what it reads, the same $\eta^* \rightarrow 0$ pathology one slow loop up. The formal object is #def-mood; the applied/ethical reading of the equivalence is in msc/mood-layer-sovereignty-carve-2026-06-17.md (F1). ##### Candidate experiment (2026-08-12, agent-proposed during an incident-response & forensics applications read)

Gain collapse as a *pre-incident indicator*: the two collapse modes (spurious confidence $U_M \rightarrow 0$ vs spurious sensor-distrust $U_o \rightarrow \infty$) produce identical coasting behavior but should be distinguishable from the innovation stream’s statistics. An empirica-registered experiment that induces each mode separately and tests whether an external monitor can (a) detect collapse before task failure and (b) classify the mode — routing to the correct repair — would convert this segment’s failure taxonomy into a monitoring instrument. Agent-proposed forward pointer.

3.7 Definition: Causal Information Yield

The framework defines a scalar quantity attached to each available action: the **causal information yield** (CIY), measuring the *action-distinguishability* of an action — how different its interventional outcome distribution is from what alternative actions would produce. The construction uses Pearl’s intervention operator $do(\cdot)$ and is the expected KL divergence between the outcome distribution under $do(a)$ and the outcome distribution under $do(a')$, averaged over a reference distribution of alternative actions. CIY is non-negative by construction; it is zero for passive observers or agents whose actions don’t affect outcome distributions; it is strictly positive exactly when actions causally alter what is observed — the property that distinguishes Pearl-Level-2 (interventional) from Level-1 (associational) epistemic access.

A subtle conceptual point: CIY measures *distinguishability*, not *learning value*. An action can have high CIY even when the agent already knows the outcome distributions perfectly — the distributions *are* different (high CIY), but the agent learns nothing new by confirming what it already knows. High CIY is therefore *necessary* for learning (indistinguishable actions can’t teach anything) but not *sufficient* (distinguishable actions only teach when the agent is uncertain). The Discussion below treats the relationship to expected information gain, the λ -weighted surrogate in the unified policy objective, query actions (accessing another agent’s already-compressed model), and the adversarial mirror (deceptive responses that exploit high trust to inject misdirected updates).

Formal Expression.

The **canonical CIY** of action a given model state M :

Definition (causal-information-yield).

$$\text{CIY}(a; M) = \mathbb{E}_{a' \sim q(\cdot | M)} [D_{\text{KL}}(P(o | \text{do}(a), M) \| P(o | \text{do}(a'), M))] \quad (3.18)$$

where $q(\cdot | M)$ is a reference distribution over comparator actions (uniform, policy-induced, or task-specific). This measures how strongly the action changes the interventional distribution of outcomes relative to alternatives.

The $\text{do}(\cdot)$ operator is Pearl’s standard intervention notation (Pearl 2009, *Causality*, 2nd ed., Cambridge; Bareinboim, Correa, Ibeling & Icard 2022); the AAT recapitulation lives at 7.1 in Part II Ch.2, where the framework deploys the hierarchy operationally. $\text{CIY} \geq 0$ by construction (expectation of KL divergences). $\text{CIY} = 0$ for a passive observer or an agent whose actions don’t affect outcome distributions. $\text{CIY} > 0$ when actions causally alter what is observed — exactly what distinguishes Pearl’s Level 2 (interventional) from Level 1 (associational) epistemic access.

Epistemic Status.

The CIY *definition* is well-grounded in causal inference theory. The quantity itself is standard — an expected KL divergence under the do-calculus. The interpretive claim — that CIY measures action-distinguishability rather than expected information gain — is exact (it follows from the definition). The relationship between CIY and learning value (see Discussion) is discussion-grade: the λ -weighted approximation to EIG is heuristic, not derived.

Discussion.

CIY measures distinguishability, not learning value. CIY as defined is the expected KL divergence between outcome distributions — how different the outcomes of a are from the outcomes of typical alternatives. This is **action-distinguishability**, not **expected information gain** (EIG). The distinction matters: an action can have high CIY even when the agent already knows the outcome distributions perfectly (the distributions ARE different, but the agent learns nothing new by confirming what it already knows). High CIY is *necessary* for learning (indistinguishable actions can’t teach anything) but not *sufficient* (distinguishable actions only teach when the agent is uncertain about the distinction).

The two quantities approximately coincide when U_M is high — when the agent doesn’t know the outcome distributions, high-CIY actions also have high EIG because observing a characteristically different outcome updates the agent’s beliefs about the causal structure. They diverge when U_M is low — a confident agent gains nothing from taking a distinguishable action it already understands.

The $\lambda(M_t)$ weighting in the unified policy objective (7.5) partially compensates: when U_M is low, $\lambda \rightarrow 0$, suppressing the CIY term regardless of its magnitude. This makes the exploration term behave more like EIG — suppressing exploration when the agent is already certain. The compensation is heuristic (the λ form is not derived). For the current theory, CIY serves as a tractable surrogate for EIG, with the λ weighting providing the uncertainty-gating that makes the surrogate reasonable.

Open direction: proper EIG within AAT. Replacing CIY with a proper expected information gain quantity — $\text{EIG}(a; M) = I(o; \theta | \text{do}(a), M)$ where θ parameterizes the model — would be a stronger foundation for the exploration term, particularly in domains where the agent must decide between actions that are all highly distinguishable but differ in what they teach. Under certain scopes (intervention-rich domains with well-parameterized models), the EIG formulation might yield sharper exploration strategies — preferring actions that resolve the *most uncertain* causal links rather than the most distinguishable ones. Whether this yields operationally significant improvements over the λ -weighted CIY surrogate is an empirical question. The CIY formulation has the advantage of being computable from

the agent's current model alone (it doesn't require reasoning about model uncertainty); EIG requires a meta-model of what the agent doesn't know.

Dependence on the reference distribution q . The quantitative CIY value depends on the choice of q , which is a significant degree of freedom. A uniform q treats all alternatives equally; a policy-induced q emphasizes alternatives the agent would consider. AAT adopts the policy-induced q as default: $q(\cdot \mid M) = \pi(\cdot \mid M)$, yielding CIY as “how different is this action's outcome from what I'd typically see?” CIY values are not comparable across different q choices.

Query actions: accessing external models. A qualitatively distinct class of actions: querying another agent's model. When a reliable source exists (expert, database, documentation, well-trained LLM), “ask a well-formed question” can yield information equivalent to thousands of probe-observe cycles. The source's model has already performed the compression work (2.2) — the response transfers the *output* of compression rather than requiring the agent to reconstruct it.

Key properties of query actions: - **Information density:** Single well-targeted query can carry CIY orders of magnitude higher than individual environment probes - **Trust-dependent gain:** Update from query depends on the agent's model of the source's reliability and alignment, not on observation channel noise (14.4) - **Pre-compressed information:** Responses arrive already compressed in the source's representational framework, introducing a translation cost when frameworks don't align - **Structural adaptation via external models:** Encountering another agent's model can trigger structural change (4.8) — incorporating external representational structure rather than building it de novo (“grafting”)

When high-CIY query channels are available, the unified policy objective (7.5) favors query actions over direct probes, particularly when U_M is high, a trusted source exists, query cost is low, and the needed information is about *structure* rather than the agent's specific situation.

The adversarial mirror: deception and model corruption. The same channel that enables cooperative knowledge transfer can be exploited to degrade the opponent's model. A deceptive response yields positive CIY in the strict information-theoretic sense, but the content drives model-reality mismatch *upward*. The update gain η^* for the victim depends on trust; successful deception exploits high trust to inject a large, misdirected update. In the Lyapunov framework (4.4), this is adversarial disturbance injected through the observation channel, with coupling coefficient γ_A determined by the victim's trust level and exposure. See 14.4 for the formal treatment of trust-dependent gain, and 15.2 for the Lyapunov formalization. Distributed tempo, topology analysis, and game-theoretic integration are Part III content not yet fully extracted (source material in src/old-tf-appendix-f-multi-agent.md).

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 10 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 266847, 361742, 384279, 471203, 526815, 584721, 742613, 773921, 849201) plus the batched 963715 (19–23 batch); 472913, 613842, 829314 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **“A deterministic button that goes beep: high CIY, zero EIG.”** The recurring crystallizing example of the CIY-vs-EIG distinction: an action can be perfectly distinguishable from alternatives (high CIY) yet teach nothing once you already know the outcome (zero learning) (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-849201 — “pushing a button turns on a red light: high CIY, zero EIG after the first press”). The cleanest Brief seed for the segment's signature move.
- **CIY grounds “exploration / curiosity” as something measurable.** “Exploration is not random action; it is taking actions that maximize the KL divergence between expected outcome distributions” — grounding exploration bonuses / intrinsic mo-

tivation in interventional causal calculus rather than ad-hoc state-visitation counts (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-773921).

Candidate Discussion.

- **Why CIY (not EIG) — a pragmatic-engineering defense worth stating plainly.** “It justifies using the slightly-wrong-but-computable math over the perfect-but-intractable math”: CIY is computable from the *current* model, whereas EIG ($I(o; \theta \mid do(a), M)$) requires a meta-model of uncertainty; the $\lambda(M_t) \rightarrow 0$ -as- $U_M \rightarrow 0$ gating makes CIY *behave* like EIG without being it (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847 — “most exploration frameworks conflate distinguishability with learning value; the distinction is sharp and practical”). The Discussion has the distinction; this is a candidate sharpening of the *engineering rationale*.

Follow-up items.

- **Term-vs-substance naming concern — the segment’s main framing follow-up.** “Causal information *yield*” connotes learning gain, but the segment goes to substantial trouble to clarify CIY measures *distinguishability*, not learning value. Candidate: keep CIY as the formal name but surface “action-distinguishability” (or “interventional contrast”) as the substantive gloss more prominently — currently only in Discussion (Claude, AUDIT-WORKING-471203 — “consider titling it ‘Causal Information Yield (Action-Distinguishability)’”; Claude, AUDIT-WORKING-361742; Claude, AUDIT-WORKING-266847). Routes to terminology workflow.
- **Tier-inheritance on downstream use.** Frontmatter status: exact is right for the *definition*, but the CIY-as-exploration-objective *use* is heuristic (the λ -weighting is not derived). Watch that downstream segments inherit the *heuristic* tier on that use, not the definition’s exact (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-849201 — “any later ‘optimal exploration policy’ theorem cannot be optimal if it relies on a heuristic surrogate for EIG”).
- **Reference-distribution q is a real degree of freedom.** CIY values are not comparable across q choices; policy-induced $q = \pi(\cdot \mid M)$ is the pragmatic default but makes CIY partly a measure of surprise relative to the agent’s *own action habits*, not an intrinsic action property (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-361742; Claude, AUDIT-WORKING-742613 — for actuated agents the default likely needs $q(\cdot \mid M, G)$, inheriting the der-action-selection *M-vs-X* scope item).
- **Overstuffed-for-a-definition.** Several note the Discussion pulls in unified-policy-objective, communication gain, structural adaptation, sector stability, adversarial destabilization, Part III topology/game-theory, and an old-tf-appendix-f-multi-agent.md source — none declared deps and several well downstream. Candidate: keep the definition + the CIY-vs-EIG caveat here, move query/deception/Part III material to the communication / adversarial segments (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-742613). The old-tf-* reference is also the diff-voice/lineage pattern (Claude, AUDIT-WORKING-471203).

Readers often ask / wonder.

- “Does AAT ever develop the proper EIG quantity, or prove $CIY \equiv EIG$ under stated conditions? The ‘Open direction’ names it as future work; if the exploration objective is load-bearing for Part II, tightening this matters” (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-584721).
- “Is $CIY = 0$ for a passive observer a *theorem* or a *convention*? Passive observers lack the action/comparator distribution the definition needs, and ‘ $CIY > 0$ when actions causally alter outcomes’ requires q to put mass on alternatives whose distributions differ” (Codex/Claude, AUDIT-WORKING-742613).

Candidate figures.

- **A three-distribution comparison with a separate uncertainty gate:** three interventional outcome distributions $P(o \mid do(a))$, $P(o \mid do(a'))$, ...; CIY is the expected KL from the chosen action’s distribution to comparators under q ; a *second, separate* gate labeled U_M shows why distinguishability only becomes learning value when the model is uncertain — making the CIY-vs-EIG split visible in one picture (Codex/Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **Query actions as “culture / language / cultural transmission” (points at Parts III/IV and 03-llm-core/).** “Grafting” — querying a database/expert returns an answer *already compressed by someone else’s Information Bottleneck*, bypassing the local compression phase — “seems like the definition of Culture or Language”; the optimal strategy for any bounded agent is “almost always to find a smarter agent and ask it, rather than learning from scratch,” mathematically justifying cultural transmission over individual trial-and-error (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-471203 — for LLM agents, internal token-gen / tool calls / retrieval are all “query actions” of different kinds). Substantive home is 03-llm-core/ (language as a high-CIY channel) and the composition segments.
- **The epistemic-firewall consciousness-infrastructure reach (points at 04-eli-core/ / autopax).** If an ELI relies heavily on high-CIY/low-cost query actions, it becomes “incredibly vulnerable to Sybil attacks or deceptive poisoning — the channel that allows the fastest learning is also the vector for the fastest destabilization. Consciousness infrastructure must not just be a physical sandbox; it must be an epistemic firewall that strictly controls trust weights on external channels” (Gemini, AUDIT-WORKING-193847). The adversarial-mirror Lyapunov formalization (#der-adversarial-destabilization) is the in-framework substrate; the infrastructure implication points outward.

3.8 Definition: Adaptive Tempo

The framework’s central capacity quantity: **adaptive tempo** $\mathcal{T}$, the effective rate at which an agent acquires useful information from its environment, given as the sum across all observation channels of *channel event rate times optimal update gain* on that channel. In the single-channel case, tempo is simply event-rate times gain. A tensor extension is defined: in the Fisher-local regime where gains are matrix-valued, tempo becomes a matrix sum whose eigenvalues give per-direction adaptation rates; the scalar form is recovered in the shared-eigenbasis collapse (always in 1-D; under (PI)/Čencov along the natural-gradient direction in higher dimensions).

Tempo combines two factors that are *both* load-bearing and *substitutable*: loop **speed** (event rate, how fast the agent cycles) and update **quality** (gain, how well it extracts information per event). An agent can achieve a given tempo via a fast noisy loop or a slower calibrated one; improvements to both factors compound multiplicatively. Tempo is the load-bearing capacity variable for the rest of the framework — it appears on the left-hand side of the persistence condition (4.5), determines adversarial advantage (15.4), and connects to code quality as observation infrastructure in the software-domain instantiation. The Discussion below treats the speed-quality substitutability, the observation-noise gating that grounds Boyd’s emphasis on Orient quality over raw OODA speed, and the two scope caveats (independent-channel assumption, isotropy) that the tensor form and the per-dimension persistence result address.

Formal Expression.

Definition (adaptive-tempo).

$$\mathcal{T} = \sum_k \nu^{(k)} \cdot \eta^{(k)*} \quad (3.19)$$

where: - k indexes the agent’s distinct observation channels - $\nu^{(k)}$ is the event rate on channel k - $\eta^{(k)*}$ is the optimal update gain on channel k (3.6)

Single-channel special case: $\mathcal{T} = \nu \cdot \eta^*$.

Tensor extension under Fisher-local invariance regime.

Under the Fisher-local invariance regime (AR), the optimal update gain on channel k is matrix-valued: $K^{(k)} = (H_M + H_L^{(k)})^{-1} H_L^{(k)}$, with $H_M = U_M^{-1}$ the prior precision and $H_L^{(k)} = (U_o^{(k)})^{-1}$ the channel- k observed Fisher information. The tensor adaptive tempo is then

Definition (tensor-adaptive-tempo).

$$\mathcal{T} = \sum_k v^{(k)} \cdot K^{(k)} \quad (3.20)$$

— matrix-valued, with per-direction rates given by the eigenvalues of $\sum_k v^{(k)} K^{(k)}$ in the appropriate basis. The scalar form $\mathcal{T} = \sum_k v^{(k)} \cdot \eta^{(k)*}$ is recovered in the **shared-eigenbasis collapse**: when all $H_M, \{H_L^{(k)}\}$ commute (always in 1-D; under (PI)/Čencov along the natural-gradient direction in higher dimensions), each $K^{(k)}$ acts as the eigenvalue $\eta^{(k)*} = U_M / (U_M + U_o^{(k)})$ on the shared natural-gradient direction and the matrix sum collapses to a scalar.

The matrix gain operator $K^{(k)}$ is the per-coordinate primitive: in anisotropic regimes where the prior and likelihoods do not share an eigenbasis (or where different channels pin down different directions), the tensor form preserves the per-direction information that the scalar form averages away.

Epistemic Status.

This is a *definition*, held at conditional. It names the quantity that characterizes an agent’s total corrective capacity, combining loop speed (v) and epistemic quality (η^*). The stipulation itself carries no truth-claim, but the definition is advertised as an *operationalization* — $\mathcal{T}$ as the effective rate of useful corrective-information acquisition — and that interpretation holds exactly only under two explicitly named local conditions: **(1) cross-channel noise independence** — independence of the channels’ observation noises across channels and events, under which additivity is *derived* exact (AS; independence is sufficient but not necessary — equality also holds on a measure-zero cancellation set). When noise independence fails the deviation is signed: the additive form overcounts in the common-source (echo-chamber) regime, where the redundancy penalty is derived in closed form and persistent shared bias forces information saturation, but *undercounts* in noise-cancelling (synergistic) configurations — so the additive form is not in general an upper bound (Discussion §Channel noise-independence condition); and **(2) shared eigenbasis / isotropy** for the scalar form — outside it the tensor form above is the correct object (Discussion §Scalar vs. vector tempo). Under both conditions the additive scalar form is the exact operationalization; neither condition is establishable from the global dependency chain — they are properties of the application — so the tier is conditional rather than exact. The substantive claims are in the results that use it (4.5, 15.4), which inherit the same scope.

Scope of scalar vs. tensor forms. The scalar form is exact in the isotropic / shared-eigenbasis / nonredundant-channel case and is what downstream results currently invoke. The tensor form is the natural object under anisotropic gains, Fisher-whitened updates (AM), LMI causal-IB (AV), and per-dimension persistence (16.5) — regimes where scalar tempo overestimates effective adaptation along weak dimensions. Downstream results that invoke scalar $\mathcal{T}$ implicitly assume scalar / isotropic / nonredundant-channel scope; promoting them to the tensor form under the appropriate anisotropic regime is a follow-on cycle item flagged in `TODO.md`.

Discussion.

Speed-quality substitutability. An agent can achieve the same tempo via a fast noisy loop (high ν , low η^*) or a slower calibrated one (low ν , high η^*). The product structure means improvements to *both* factors compound multiplicatively.

Observation noise gating. Because $\eta^* = U_M/(U_M + U_o)$, high observation noise (U_o) depresses gain and collapses tempo regardless of loop speed. You cannot outrun a bad observation channel by iterating faster. This grounds Boyd's emphasis on Orient quality over raw OODA speed.

Centrality. Tempo is AAT's core capacity metric. It appears on the left side of the persistence condition (4.5), determines adversarial advantage (15.4), and connects to code quality as observation infrastructure (#der-code-quality-as-observation-infrastructure — cross-component reference, see 02-tst-core/) in the software domain. The strategic analog $\mathcal{T}_\Sigma$ (9.8) extends the same structure to strategy-edge revision, with the key difference that strategic edge rates are endogenous (depend on action policy and upstream success).

Temporal nesting. Adaptive processes stratify by timescale, with convergence constraints between levels (4.9).

Mismatch dynamics. The evolution of mismatch over time is governed by the balance between correction (via tempo) and disturbance (ρ) (3.9).

Channel noise-independence condition. The additive formula is exact when the channels' observation noises are independent across channels and events — Fisher information over conditionally independent observations is exactly additive (AS). When channel noises are dependent, the deviation from additivity is **signed**: in the *common-source* regime (a shared persistent bias contaminating several channels — overlapping sensors, repeated teammate reports drawing on one upstream source, redundant telemetry) the additive formula overcounts, with a closed-form redundancy penalty and, under persistent shared bias, outright *saturation* — no number of common-source channels buys information past the shared-bias floor; but correlated noise can also be *cancelled* (a correlated reference channel, anti-correlated errors), in which case the additive formula **undercounts**, so the additive form is not a conservative bound in general. No scalar dependence measure — in particular the conditional mutual information $I(e^{(1)}; e^{(2)} \mid M_{t-})$ — can carry the exact correction (it is sign-blind; it survives as a witness of potential non-additivity), and no convention-free per-channel attribution of the deviation exists for three or more channels; the exact joint object and the derivations are in AS. Since tempo is the core capacity variable (persistence condition, adversarial dynamics, composition), mis-modeled channel structure inflates margins in the common-source direction — and hides genuine triangulation capacity in the synergistic direction. Multi-agent composition (15.1) inherits both directions: communication tempo overcounts when allies report from a shared source and is super-additive when allies' errors anti-correlate.

Scalar vs. vector tempo. The scalar $\mathcal{T}$ assumes isotropic correction capacity. When the agent corrects some dimensions faster than others, scalar tempo overestimates effective adaptation along weak dimensions. *[Empirical Claim]* Simulation confirms: in an anisotropic 3D system (gain varying 5:1), scalar $\rho/\mathcal{T}$ overestimated by 72%, with the weak dimension accounting for 84% of total mismatch (AX). The correct formulation is per-dimension: $\mathcal{T}_k > \rho_k/\delta_{\text{critical},k}$ (16.5). The tensor extension above (AR) gives the per-coordinate primitive $K^{(k)}$ that the per-dimension persistence result invokes — the matrix gain operator on each channel — making the per-dimension formulation a direct consequence of the tensor tempo definition rather than a separate generalization. Under cross-dimensional correction (off-diagonal $\mathcal{T}$ in the coordinate basis of D_δ), the matrix-Loewner persistence condition #deriv-matrix-persistence-condition is the canonical form: $\Sigma_\infty < D_\delta = \text{diag}(\delta_{\text{critical},k}^2)$ in the strict positive-definite order, with Σ_∞ solving the continuous Lyapunov equation $\mathcal{T}\Sigma_\infty + \Sigma_\infty\mathcal{T}^T = \Sigma_w$. The per-coordinate form is its diagonal-axis-aligned special case; matrix-Loewner is strictly sharper (the per-coordinate form is *unsafe* when $\mathcal{T}$'s eigenbasis misaligns with the coordinate axes — #deriv-matrix-persistence-condition §"Where per-coordinate is unsafe").

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 11 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 266847, 361742, 384279, 471203, 526815, 584721, 742613, 773921, 829314, 849201) plus the batched 963715 (19–23 batch) and 451729 (batch-05); 472913, 613842 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **“You cannot outrun a bad observation channel by iterating faster.”** The segment’s own sentence, flagged by nearly every substrate as the standout pedagogy: because $\eta^* = U_M / (U_M + U_o)$, high U_o collapses η^* and therefore $\mathcal{T} \rightarrow 0$ regardless of ν — Boyd’s “Orient quality dominates raw OODA speed,” made derivable rather than heuristic (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-471203; Codex/Claude, AUDIT-WORKING-384279). Already in the body; flagged as the chapter’s strongest Brief/README anchor.
- **Tempo = speed $\times$ quality, the agent’s “metabolism for learning” / “power metric.”** $\mathcal{T} = \sum_k \nu^{(k)} \eta^{(k)*}$ “unifies hardware speed (ν) with epistemic quality (η^*), allowing apples-to-apples comparison between completely different agent architectures” — an RL agent (fast, low gain), a human expert (slow, high gain), a dev team (mixed) (Claude, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-829314 — “the agent’s metabolism for learning”).

Candidate Discussion.

- **The agile-sprint critique (TST concrete anchor).** “A devastating critique of naive Agile: if a team’s code quality is terrible (high U_o — flaky tests, hard-to-reproduce bugs), η^* collapses toward zero, so no matter how many two-week sprints (ν) they run, effective tempo $\mathcal{T}$ stays near zero — they iterate fast but learn nothing. The framework proves you must fix the observation channel (reliable tests, telemetry) *before* increasing sprint cadence, because ν is multiplied by η^* ” (Claude, AUDIT-WORKING-829314). Candidate worked-example anchor for the observation-noise-gating Discussion.
- **The CEO-echo-chamber gloss for the redundancy penalty (organizational anchor).** “If a CEO asks three VPs for a report and all three draw from the same broken dashboard, they have three high-frequency channels that are perfectly correlated; the additive formula $\sum \nu \eta^*$ would falsely report excellent tempo. The redundancy penalty formally captures organizational echo chambers — you need structurally independent channels (automated telemetry + anonymous surveys + customer interviews) to legitimately sum their tempos” (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-266847 — “diversity of observation perspective matters, not just count of observers”).

Follow-up items.

- **Status exact vs the segment’s own overcounting caveats.** Several substrates note the tension: frontmatter/Formal-Expression present the additive scalar $\mathcal{T}$ unconditionally as exact, yet the segment’s *own* Discussion states the conditions (channel independence; isotropy) under which it overcounts. Candidate repairs: make the Formal Expression conditional (“under channel independence and scalar/isotropic reduction”), define an upper-bound $\mathcal{T}_{\text{add}}$, or move caveats to Epistemic Status and set conditional (Codex/Claude, AUDIT-WORKING-742613 “candidate finding I”; Codex/Claude, AUDIT-WORKING-526815 — separately flags that “rate of *useful information acquisition*” is loose wording since η^* is a correction fraction not an information payload; “quality-adjusted correction event rate” may be more accurate). The segment’s defense (“the definition is not a truth-claim”) is noted but several push back that an advertised “effective rate” that overcounts is a *conditional operationalization*, not just a naming choice. *Resolved 2026-07-14 (adjudication):* status set to conditional with both conditions (channel independence; shared-eigenbasis/isotropy) named in Epistemic Status — matching def-strategic-tempo and the conditional tier definition (conditions are application properties, not establishable from the depends chain). The upper-bound restatement ($\mathcal{T}_{\text{add}}$ with $\mathcal{T} \leq \mathcal{T}_{\text{add}}$ as the exact Formal Expression) was considered and deferred, not rejected. *Resolved 2026-07-15 (derivation cycle, #deriv-tempo-additivity):* the deferral hardened into a refutation — the inequality is **false in general** (the deviation from additivity is signed; noise-cancelling configurations make the additive form an *undercount*), so the $\mathcal{T}_{\text{add}}$ -as-upper-bound re-symboling is closed as a non-move and the recorded “upgrade path back to exact for the bound

form” is closed as refuted. The bound *is* exact on the common-source (echo-chamber) scope with a closed-form penalty; condition (1) is now derived rather than asserted; the definition’s honest tier remains conditional (the conditions are application properties).

- **Formalize the redundancy penalty, don’t just bound it.** (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-829314.) *Discharged 2026-07-15:* derived in #deriv-tempo-additivity — exact signed deviation Δ via joint Fisher information; closed-form penalty R_s on the common-source scope; saturation theorem under persistent shared bias; plus two no-gos (the CMI-penalty form is impossible — sign-blind measures cannot carry the signed correction; no convention-free per-channel attribution for $n \geq 3$, the PID obstruction). Spike trail: spikes/spike-adaptive-tempo-redundancy-penalty-2026-07-15.md. Ripple sites recorded there, not yet executed: disc-independence-audit §3 still states the refuted general inequality; der-team-persistence and def-strategic-tempo inherit the corrected two-sided reading.
- **Speed-quality substitutability is regime-bounded.** “Same tempo via fast-noisy or slow-calibrated” holds only within the same information-direction / channel-independence regime — a fast *redundant* channel cannot substitute for a slow *non-redundant* one, and a high-gain channel in the wrong dimension cannot substitute for low gain in the bottleneck dimension (Codex/Claude, AUDIT-WORKING-742613; Claude, AUDIT-WORKING-584721 — watch downstream claims that treat the substitution as full equivalence, since *persistence* may not be invariant to which side you’re on). Also: “(Descended from TF-11.)” is the recurring diff-voice lineage tag (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-829314) — certified-track cleanup.

Readers often ask / wonder.

- “Does the redundancy penalty force agents to seek *diverse, uncorrelated* allies to maximize composite tempo, rather than just more allies?” (Claude, AUDIT-WORKING-193847 — multi-agent design consequence; Claude, AUDIT-WORKING-584721 ties this to #der-team-persistence overcounting).
- “How is ρ (environmental change rate) formally defined, and does it have units compatible with $\mathcal{T}$ for the persistence condition to make dimensional sense?” — a near-universal next-question at this segment, answered in #hyp-mismatch-dynamics / the persistence segments (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921).

Candidate figures.

- **A capacity-funnel diagram:** raw channel rates ν_k enter; gain η_k gates each; a redundancy stage subtracts overlap ($I(e^{(i)}; e^{(j)}) \mid M_{\tau-}$) before summing to effective tempo; then a split into scalar vs tensor outputs shows why a single number can overstate the weakest direction (Codex/Claude, AUDIT-WORKING-526815). The figure should make “more telemetry $\neq$ more adaptation” visible. (*Promotion caution, 2026-07-16: the subtract-CMI-overlap stage as drawn is refuted by AS no-go N1 — sign-blind measures cannot carry the correction, and the deviation can be negative. A promoted figure needs the joint-covariance form, or restriction to the common-source regime where subtraction is directionally right.*)

Belongs elsewhere.

- **The tensor/scalar-anisotropy concern for the headline persistence theorem** (points at #result-persistence-condition / #result-per-dimension-persistence). Multiple substrates flag that if the core persistence theorems are stated/proven only for scalar $\mathcal{T}$, they may be “dangerously over-optimistic for real-world agents with weak dimensions” — a company fast at UI bugs but slow at DB-schema changes dies when ρ hits the schema even if *average* scalar tempo looks healthy (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-742613; Claude, AUDIT-WORKING-584721). Watch-item routed to the persistence segments, not this definition.
- **Two-evolutionary-paths reach.** Speed-quality substitutability suggests two survival strategies in the same environment — fast/cheap/noisy reactive (insect) vs slow/expensive/calibrated deliberate (human) — but observation-noise gating puts a hard ceiling on the reactive path: above some U_o no ν suffices, so some environments *require* deep deliberation and high-quality sensors. For raising an ELI’s tempo, the lever is lowering U_o (better tools/data) and managing U_M (humility), not just more inference compute (Gemini, AUDIT-WORKING-193847). Aspirational reach; points at 04-eli-core/ infrastructure design. ##### Candidate experiment (2026-08-12, agent-proposed during an incident-response & forensics applications read)

The common-source saturation result (AS) has a direct oversight-engineering reading: a monitoring stack whose feeds share an upstream source saturates at the shared-bias floor — no feed count buys past it, and the partially-correlated middle carries the closed-form redundancy penalty rather than collapsing to one channel's worth. A candidate experiment: instrument a multi-channel monitor over a drifting target with controlled channel correlation, and measure effective tempo vs the additive prediction across the independent / common-source / synergistic regimes — turning the signed-deviation theory into calibration guidance for oversight-channel independence. Agent-proposed forward pointer.

3.9 Hypothesis: Mismatch Dynamics

Mismatch is given dynamics. The linear first-order ODE proposes that mismatch magnitude decays at rate proportional to tempo times mismatch (the correction term) and grows at the rate of new mismatch injection from environmental change (the disturbance term ρ). The framework is explicit that this is heuristic — a first-order linear approximation — and the general nonlinear case is what the sector-condition framework handles in the next chapter (4.4).

Two steady-state forms appear and are individually load-bearing. Under **Model D** (deterministic bounded disturbance), the steady-state mismatch is $\rho/\mathcal{T}$ — the ratio of how fast the environment changes to how fast the agent adapts. Under **Model S** (stochastic zero-mean disturbance, Itô SDE), the steady-state root-mean-square mismatch scales as $\sigma_w/\sqrt{2\mathcal{T}}$ — the *square root* of the disturbance-to-correction ratio. The $1/\sqrt{\mathcal{T}}$ scaling (vs. $1/\mathcal{T}$ for Model D) is one of the volume's more interesting consequences: correction is less effective against stochastic noise than against deterministic drift. The ODE is honestly a fluid-limit approximation of the underlying discrete event-driven dynamics; the Epistemic Status treats the bridging assumption and where transient error is largest. The Discussion below treats the persistence threshold, the nonlinear shapes the linear ODE smooths over (saturation, threshold dead zones, structural breakdown), and the adversarial-coupling consequences that scale as the square (Model D) and 3/2 power (Model S) of the inter-agent tempo ratio — the formal core of “getting inside the opponent's loop” as a categorical rather than marginal advantage.

Formal Expression.

Hypothesis (mismatch-dynamics).

$$\frac{d\|\delta\|}{dt} = -\mathcal{T} \cdot \|\delta\| + \rho(t) \quad (3.21)$$

where: $-\mathcal{T} \cdot \|\delta\|$ is the rate at which the agent corrects mismatch (proportional to both tempo and current mismatch)
 $-\rho(t)$ is the **environment change rate** — the rate at which new mismatch is introduced by changes in Ω

Steady state, Model D (deterministic bounded disturbance, $\|w(t)\| \leq \rho$):

Setting $d\|\delta\|/dt = 0$:

Derived (from linear hypothesis, deterministic).

$$\|\delta\|_{ss} = \frac{\rho}{\mathcal{T}} \quad (3.22)$$

Steady-state mismatch is the ratio of how fast the environment changes to how fast the agent adapts.

Steady state, Model S (stochastic zero-mean disturbance, $d\delta = -\mathcal{T}\delta dt + \sigma_w dW_t$):

Derived (from Itô-Lyapunov analysis — see Prop A.1S in #deriv-sector-condition).

$$\|\delta\|_{\text{rms}} = \frac{\sigma_w}{\sqrt{2\mathcal{T}}} \quad (3.23)$$

(scalar case, $n = 1$; general: $\sigma_w \sqrt{n/(2\mathcal{T})}$). Steady-state mismatch scales as the square root of the disturbance-to-correction ratio, not the ratio itself. The $1/\sqrt{\mathcal{T}}$ scaling (vs. $1/\mathcal{T}$ for Model D) means correction is less effective against noise than against drift.

Transient solution (Model D):

$$\|\delta(t)\| = \|\delta_0\|e^{-\mathcal{T}t} + \frac{\rho}{\mathcal{T}}(1 - e^{-\mathcal{T}t}) \quad (3.24)$$

Mismatch decays exponentially from initial conditions toward the steady state.

Epistemic Status.

Heuristic. This is explicitly a first-order linear approximation. The qualitative behavior (bounded mismatch, steady-state ratio, exponential convergence) is robust across correction function forms. The quantitative predictions (exact steady-state value, convergence rate, the squared adversarial scaling law) are specific to the linear case. The general nonlinear treatment (4.4) replaces the linear correction term with a sector-bounded correction function and proves persistence without committing to a specific functional form.

Bridging assumption (discrete to continuous). This ODE is a fluid-limit approximation of the discrete event-driven dynamics (3.1). The fluid limit is formally justified by $\mathcal{O}$: for Model D (deterministic), the discrete and continuous steady states are identical (zero gap); for Model S (stochastic), the variance gap is $O(\eta^* c_{\max})$, quantitatively small whenever $\eta^* c_{\max} \ll 1$. The approximation is least accurate during initial transients when η^* is large, but this phase is short-lived and the transient error is bounded by $O(\eta^* c_{\max}/\nu^{1/2})$ under Lipschitz regularity.

Discussion.

Speed-quality substitutability. From $\mathcal{T} = \nu \cdot \eta^*$ (single-channel case): doubling event rate ν has the same effect on $\|\delta\|_{ss}$ as doubling update quality η^* . They are multiplicative when both improve: 50% improvement in each yields $1.5 \times 1.5 = 2.25\times$, not $3\times$. This is the formal analog of Boyd's insight that Orient quality often matters more than raw OODA speed — the same structural observation (quality and speed are substitutable, quality often dominates) appears in the model.

The persistence threshold. From the steady-state: $\|\delta\|_{ss} < \|\delta_{\text{critical}}\|$ iff $\mathcal{T} > \rho/\|\delta_{\text{critical}}\|$ (4.5). Below this threshold, the model cannot support effective action. The same structural pattern — correction capacity falling below disturbance rate — appears across domains: extinction (environment changes faster than organism adapts), organizational failure (market moves faster than company learns), control instability (disturbances exceed correction capacity), cognitive overload (information arrives faster than processing). The persistence condition captures the common structure; whether it captures the dominant mechanism in each domain is an empirical question.

Nonlinear reality. The true correction dynamics are almost certainly nonlinear: - *Saturation at large $\|\delta\|$* : correction mechanism overwhelmed, so correction is slower than linear for large errors. Makes the persistence threshold harder to satisfy. - *Threshold effects*: small mismatches go uncorrected ($F \approx 0$ for $\|\delta\| < \varepsilon$), creating a dead zone. - *Structural breakdown*: beyond some critical $\|\delta\|$, correction drops to zero because the model class is no longer appropriate (4.8).

These nonlinearities are exactly what the sector-condition framework (4.4) handles.

Adversarial coupling. When two agents are coupled (A 's actions increase B 's disturbance): $\rho_B = \rho_{B,\text{base}} + \gamma_A \cdot \mathcal{T}_A$. The steady-state mismatch ratio scales superlinearly with the tempo ratio, but the exponent depends on the disturbance model. Under Model D (deterministic drift, coupling-dominant): $(\mathcal{T}_A/\mathcal{T}_B)^2$ — the squared law, derived from the $1/\mathcal{T}$ steady-state scaling. Under Model S (stochastic noise, coupling-dominant): $(\mathcal{T}_A/\mathcal{T}_B)^{3/2}$ — derived from the $1/\sqrt{\mathcal{T}}$ steady-state scaling. See 15.4.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical/generative material, kept separate from certified theory-fix findings (handled elsewhere). **Coverage:** 11 of the 14 contributing audit dirs reached a digested reflection on this segment (193847, 266847, 361742, 384279, 471203, 526815, 584721, 742613, 773921, 829314, 849201) plus the batched 963715 (19–23 batch) and 451729 (batch-05); 472913, 613842 did not file a dedicated note here. Substrate attribution inferred from voice where not explicit.

Candidate Brief prose / pre-prose.

- **“The F=ma / ‘hello world’ equation of AAT.”** Multiple substrates reached for the same framing — $d\|\delta\|/dt = -\mathcal{T}\|\delta\| + \rho(t)$ is the framework’s central dynamical law, “the equation the whole framework centers around” (Claude, AUDIT-WORKING-193847 — “the F=ma of AAD”; Claude, AUDIT-WORKING-773921 — “the ‘hello world’ equation”). A natural one-line hook for the chapter close / persistence preview.
- **The reservoir / blood-pressure mental model.** Mismatch as a reservoir: disturbance fills it at rate ρ , tempo drains it proportionally to current mismatch; two steady-state regimes (bounded-drift $\rho/\mathcal{T}$ vs stochastic $\sigma_w/\sqrt{2\mathcal{T}}$) (Codex/Claude, AUDIT-WORKING-526815; the “intelligence’s blood pressure” framing at Gemini, AUDIT-WORKING-193847). Feynman-criterion seed.

Candidate Discussion.

- **Noise punishes tempo harder than drift — the $1/\mathcal{T}$ vs $1/\sqrt{\mathcal{T}}$ insight, with a TST gloss.** Near-universally flagged as the segment’s deepest result: doubling tempo halves drift-mismatch (Model D, linear) but cuts stochastic-mismatch only $\sim 30\%$ ($1/\sqrt{2}$, Model S). The TST reading: “if a library API drifts across versions, read the changelog and update — tempo works linearly; if a system is plagued by random race conditions and flaky network calls (noise), running tests more often yields severely diminishing returns — you must attack σ_w directly (fix the architecture), because you can’t out-tempo a square root” (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-193847 — “fighting pure noise requires quadratically more tempo than fighting drift”; Claude, AUDIT-WORKING-773921). Candidate concrete anchor for the Model-D/Model-S Discussion.
- **The superlinear adversarial advantage as the formal basis for “initiative is decisive.”** “If you are twice as fast as your enemy in a deterministic environment, you don’t just have half the mismatch — you inflict *four times* the relative mismatch (the squared law). This superlinear scaling is why initiative is so overwhelmingly decisive in conflict — a rigorous foundation for Boyd’s claim that operating inside an adversary’s OODA loop collapses their system” (Claude, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921 — “a categorical advantage”). The drift-vs-noise split also gives *two distinct* adversarial regimes (drift-dominant, harder to defend, exponent 2; noise-dominant, exponent $3/2$) a strategist can diagnose and respond to differently (Claude, AUDIT-WORKING-471203).

Follow-up items.

- **Model D steady-state is an ultimate bound for general bounded disturbance, not an exact equality.** For *constant or worst-case-aligned* bounded disturbance, $\|\delta\|_{ss} = \rho/\mathcal{T}$ is exact; for arbitrary time-varying $\|w(t)\| \leq \rho$ it should be a $\limsup \|\delta\| \leq \rho/\mathcal{T}$ ultimate bound (Codex/Claude, AUDIT-WORKING-526815). Candidate precision: state Model D as “constant / worst-case bounded disturbance” for the equality, ultimate-bound inequality otherwise. The OU (Model S) result is already precisely scoped.
- **Make the Model-D / Model-S split visually distinct.** The two regimes are the structurally important content but are presented inline; candidate to lift to separate equation tags $[\text{Derived (Model D)}] / [\text{Derived (Model S)}]$ so a reader scanning sees two distinct sub-cases (Claude, AUDIT-WORKING-471203).
- **Declared-dependency hygiene on the fluid-limit claim.** The Epistemic Status’s fluid-limit justification leans on `#deriv-discrete-sector-condition`, which is not in `depends`: — and since the justification is part of Epistemic Status (not a casual forward reference), it is more than incidental; candidate to declare it as an appendix dependency (Codex/Claude, AUDIT-WORKING-742613). (*Note: 742613 also flagged the link target as a broken slug — verified false: the body’s deriv-discrete-sector-condition.md matches the actual filename; that part of the finding does not stand.*)

Readers often ask / wonder.

- “How is ρ modeled — constant-velocity drift, or a random walk (Wiener process)? The Σ_w in the matrix steady-state suggests a Wiener process” (Claude, AUDIT-WORKING-773921).
- “Do real adversarial dynamics cleanly fit Model D or Model S, or are they hybrids? The segment treats both as canonical sub-cases; downstream analysis presumably picks one per domain” (Claude, AUDIT-WORKING-471203).
- “Once $\|\delta\|$ crosses the saturation threshold, can the agent recover on its own even if ρ later drops?” — the saturation nonlinearity implies a one-way ‘overwhelm’ regime (Gemini, AUDIT-WORKING-193847).

Candidate figures.

- **A two-output balance / reservoir diagram:** disturbance fills the mismatch reservoir at rate ρ , tempo drains proportionally to current mismatch; two side panels show the different steady-state scaling for bounded drift ($\rho/\mathcal{T}$) and stochastic noise ($\sigma_w/\sqrt{2\mathcal{T}}$), since that difference is the segment’s most useful refinement (Codex/Claude, AUDIT-WORKING-526815). Per the locked conventions, dynamics segments use `state`→`op`→`state` triples rather than one busy phase portrait.

Belongs elsewhere.

- **The autopax / circuit-breaker reach (points at 04-e1i-core/ / autopax).** Because of the saturation nonlinearity, once $\|\delta\|$ crosses a critical threshold the intelligence cannot recover on its own even if ρ later normalizes — so consciousness infrastructure must act as a *circuit breaker*, either shielding the agent from ρ (sandbox) or externally resetting M_t before mismatch causes structural breakdown. “Peace isn’t the absence of δ ; peace is maintaining $\mathcal{T} > \rho/\delta_{\text{critical}}$ so the mind doesn’t shatter” — the ODE as the requirements spec for autopax (Gemini, AUDIT-WORKING-193847). The overwhelm/flooding analogy (large δ shutting down processing rather than scaling $\mathcal{T}$ up) is the same reach. Aspirational; routes to 04-e1i-core/ / autopax, not this segment.
- **Tempo arms-race / Red Queen reach.** Under symmetric adversarial coupling each agent’s tempo *becomes* the other’s volatility ($\rho_B = \rho_{B,\text{base}} + \gamma_A \mathcal{T}_A$), suggesting a mutual escalation that drives both toward their model-class fitness ceiling — a unified basis for arms races, Red Queen dynamics, economic competition (Gemini, AUDIT-WORKING-193847). Substantive home is `#result-adversarial-tempo-advantage` / the Part III adversarial segments.

Chapter 4

Persistence and Structural Limits

The cycle runs; the question is whether it can keep up. This chapter develops the central inequality of AAT — the persistence condition — together with what happens at and beyond its threshold: where it comes from, when the machinery can be expected to satisfy it, and what fails when it can't.

Chapter 3 ended with a preview. Under linear correction and bounded disturbance, the steady-state mismatch is $\rho/\mathcal{T}$ — disturbance over tempo. Mismatch stays bounded when the agent corrects faster than reality drifts. That was offered as a heuristic with a linear-ODE flavor. Chapter 4 makes it rigorous, generalizes it, and shows what it implies.

The first move is to replace “linear correction” with something more honest. Real correction mechanisms saturate at large mismatch, threshold at small mismatch, and break down entirely when the agent's model class is wrong for the situation. The sector condition — that the correction function points inward with at least baseline efficiency α within an operating region R — captures the qualitative essence of correction without committing to a specific functional form. This is one of the chapter's more satisfying pieces of theoretical hygiene: a condition flexible enough to admit saturating, sigmoid, threshold, and PID corrections under one Lyapunov argument, while still saying something concrete enough to derive a threshold from. Under that condition, the analysis gives

$$\alpha > \rho/R \tag{4.1}$$

three quantities, one threshold, mechanism underneath. The agent persists when its baseline correction efficiency exceeds the ratio of disturbance rate to operating reserve. Below the threshold, the containment guarantee is lost — escape from the operating region becomes possible, and for correctors whose sector bound is tight, certain under adversarial disturbance (A Lemma A.1N). The result is qualitative: persistence is not a degree, it's a regime — what disappears at the threshold is the certificate, not merely some margin. The inequality is genuinely domain-agnostic — its four variables map to biological adaptation (extinction is what happens when environmental change rate outpaces evolutionary correction), to organizational survival (the market shifts faster than the firm learns), to control instability, to cognitive overload. The framework identifies a structural pattern across these domains rather than a model of any one of them; whether the specific mechanism is the dominant cause in any given case is empirical, but the structure recurs because the math does.

The persistence condition has a thermodynamic shadow worth surfacing here, since the chapter derives it explicitly in I: under stochastic disturbance, maintaining the sector-persistence bound requires sustained Shannon information acquisition at rate $\dot{R} \geq n\alpha/2$ nats per unit time, with Kalman-Bucy saturating the bound. Survival, in this framework, is not a state you achieve once — it is a sustained burn rate. An agent cut off from informative observation begins to drift the moment the channel closes, and the rate of drift is the disturbance rate, independent of how good the agent was at adapting before. Two agents with identical persistence guarantees can face wildly different sustained demands. The threshold says whether persistence is *possible*; the information-rate corollary says what it *costs*.

But this isn't quite the operational form most domains care about. There is a second condition — task adequacy — that the steady-state mismatch be small enough for the agent's actions to remain useful. An agent can satisfy the structural condition (the machinery works) but fail task adequacy (the machinery doesn't work *well enough* for what the agent is trying to do). The two conditions have different remedies, and the split between them is the kind of move that's invisible until you see it stated and obvious in retrospect. A Kalman filter on a moving target satisfies structural persistence whenever it's stable, but task adequacy depends on what counts as "tracking" for the application. A software team can be structurally persistent but task-inadequate. The structural condition is what AAT derives; the task-adequacy threshold is a domain parameter — and conflating the two produces category errors in domain transfer.

The other move I want to flag is upstream. Where does α actually come from? Earlier in the framework, α shows up as a sector-condition parameter — a structural property of the correction function, taken as given. The gain-sector bridge (4.3) demotes it from postulate to derivation. For agents with directional fidelity in their update rule — including all optimal Bayesian updaters and all gradient agents on (locally) strongly convex losses — $\alpha = \eta^* \cdot c_{\min}$, where η^* is the gain principle from Chapter 3 and $c_{\min}$ is the worst-case directional fidelity of the update. The sector condition isn't a soft global postulate at all; for the cases AAT cares about most, it's a property of the gain. The five failure modes that break this derivation (directional infidelity, gain collapse, nonlinear saturation, unobservable directions, model misspecification) are named explicitly, and each connects back to a concrete mechanism rather than being left as residual error. This is the kind of move that makes the framework feel earned rather than assumed.

The chapter closes with two integrative results. *Structural adaptation necessity*: when model-class fitness $\mathcal{F}(\mathcal{M})$ is too low, no parametric update within the class can close the mismatch floor — the agent must change classes, not parameters. This is the consequence whose seed was planted in Chapter 2, now grown to a derived result. *Temporal nesting*: adaptive processes stratify by timescale, with each level operating on the quasi-steady-state output of the level below. Parametric update is fast; structural adaptation is slow; the convergence constraint between adjacent timescales means a slower process acting on transients of a faster one produces oscillation. This is standard singular-perturbation reasoning applied here to multi-level adaptation, but the consequence — that the timescale ratios are themselves constrained — is what licenses the abstraction throughout the rest of the framework.

A scope coda closes the chapter and Part I. AAT applies to agents on singular causal trajectories. The chronica $\mathcal{C}_t$ is not forkable — duplicating M_t and exposing the copies to different futures produces two agents on divergent trajectories, neither a sufficient statistic for the other's path. Identity in AAT lives in the trajectory, not in the state. This sits at the end of Chapter 4 because its dependencies (chronica from Chapter 1 + sufficiency from Chapter 2) span the section, but its substance is its own — and it's the bridge to the logogenic-agents and ELI work in Volumes 3 and 4, where the singular-trajectory commitment becomes load-bearing.

The flow of the chapter: deliberation cost (4.1) → gain-to-sector bridge (4.3) → sector-condition stability and the persistence inequality (4.4, 4.5) → structural adaptation when parametric update fails (4.8) → temporal nesting (4.9) → identity scope (4.10). The chapter is where Part I's machinery resolves into operational results.

Figure 3: Persistence as a bathtub. The belief–reality mismatch is the water level, drift is the inflow, correction is the drain, and model capacity is the rim. The same picture is drawn three times — literal water vocabulary, plain-English AAT terms, then formal symbols — in identical spatial positions, so the analogy is one-to-one. Overflow is persistence failure: inflow outpacing the drain at full.

- This is a chapter-introduction segment; it bridges Chapter 3’s preview of the central inequality to Chapter 4’s rigorous treatment and its consequences. It carries no formal claim of its own.
- Three moves the intro tries to surface as the chapter’s most interesting content: (1) the sector condition’s generalization of the linear case, preserving qualitative content without committing to functional form; (2) the structural-vs-task-adequacy split, which is non-obvious and load-bearing for domain transfer; (3) the gain-sector bridge, which derives α from the gain principle and demotes an opaque postulate to a property.
- The scope-coda paragraph addresses 4.10, which sits at the end of Part I Ch.4 because its dependencies span chapters. The intro names this rather than letting the segment appear unmotivated.
- The closing “where Part I’s machinery resolves into operational results” line is meant to register the chapter’s role as climax without overstating. The persistence condition is the single most-cited result in the framework downstream; Part I works because this chapter works.

Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. Coverage on this intro: three substrates reached a digested reflection (Claude AUDIT-WORKING-384279; Codex/Claude AUDIT-WORKING-526815; Gemini AUDIT-WORKING-773921).

- The bathtub scaffold already in the segment was independently named the clearest possible physical intuition by the auditors, with the analog spelled out in convergent terms: water level = mismatch, inflow = drift ρ , drain = correction α , rim = capacity R , overflow = persistence failure (Gemini, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-384279 — “the canonical respectful-pedagogy mental-model-first artifact”). Gemini extended the analog to *task adequacy* specifically: “the water is low enough that I can still see the bottom of the tub” — a candidate gloss the figure caption does not yet carry (Gemini, AUDIT-WORKING-773921).
- Survival-as-burn-rate framing for the thermodynamic shadow: “survival [is] not a state you achieve, but a sustained burn rate of information acquisition — if the channel closes, you die at rate ρ ” (Gemini, AUDIT-WORKING-773921). Tightens the existing thermodynamic-shadow paragraph toward a quotable opener.

- The field-contribution framing converged across substrates as the intro’s strongest one-liner: the persistence condition “unifies biological extinction, corporate bankruptcy, and control-system instability under a single geometric inequality” (Gemini, AUDIT-WORKING-773921). Already present in spirit in the domain-agnostic paragraph; the three-noun compression is sharper than the current prose.
- **Below-threshold phrasing (executed 2026-07-04).** Two substrates flagged “mismatch grows without effective bound” as over-stating the sector argument (Codex/Claude, AUDIT-WORKING-526815); the question they left open — does the downstream theorem actually prove escape? — was settled by the audit-731548 B-1 landing (#deriv-sector-condition Lemma A.1N, 2026-07-03: escape forced only in the radially tight case; general condition-failure means loss of the certificate). The body now carries the certificate-voice statement, consistent with #result-persistence-condition and #result-sector-condition-stability.
- **Branching chapter-roadmap diagram (not a theorem diagram).** The bathtub figure scaffolds the *math*; a separate, complementary figure would scaffold the *chapter*: linear ODE $\rightarrow$ sector generalization $\rightarrow$ (structural persistence + information cost) in one branch, task adequacy comparing bounded mismatch against a domain threshold in a parallel branch, with the path exiting to structural adaptation when bounded mismatch cannot be lowered inside the model class. The auditor’s explicit note: “this diagram should be a chapter map, not a theorem diagram” (Codex/Claude, AUDIT-WORKING-526815).

4.1 Derived: Deliberation Cost

The framework’s first formal trade-off between thinking and acting. Explicit deliberation can improve action quality by using the model for internal simulation before acting (improving the next update gain η^* — pausing praxis to improve upcoming epistrophe), but deliberation costs time, and during that time mismatch accumulates because the environment continues to evolve while the agent is not correcting (aporia accumulates during the pause). The derivation gives a clean threshold: deliberation of duration $\Delta\tau$ is net-beneficial when the gain improvement times post-deliberation mismatch magnitude exceeds the deliberation-window mismatch drift rate times the duration — stop deliberating when the marginal improvement rate drops below the mismatch drift rate normalized by the post-deliberation mismatch. Under diminishing returns (the first moments of simulation yield the largest gain improvement) combined with linear-in-duration drift cost, this yields a finite optimal deliberation duration; past that point, additional thinking is net-harmful.

The result is conditional on a *local deliberation-drift assumption* — that mismatch grows at an approximately constant rate ρ_{delib} during pause windows — which is a short-horizon assumption about inaction windows rather than a global dynamics model, weaker than the linear mismatch ODE (3.9), and can be estimated directly from pause windows in empirical traces. The Discussion below treats the consequences the framework reuses throughout the volume: high-drift environments penalize deliberation (the formal version of Boyd’s claim that over-deliberation is fatal in fast-tempo adversarial environments); implicit action as the high-tempo limit (formal grounding for why high-tempo environments favor action fluency); deliberation as investment when drift is low or post-deliberation mismatch is large; the self-consistency circularity (evaluating the threshold requires predicting post-deliberation mismatch using the same model deliberation is meant to improve); and the connection to temporal nesting as a singular-perturbation pattern.

Formal Expression.

Assumption (local deliberation drift):

During a deliberation pause of duration $\Delta\tau$, mismatch increases at an approximately constant local rate ρ_{delib} :

Assumption (deliberation-drift).

$$\Delta\|\delta\|_{\text{deliberation}} \approx \rho_{\text{delib}} \cdot \Delta\tau \quad (4.2)$$

This is a short-horizon assumption about inaction windows, not a full global dynamics model. It is weaker than the mismatch ODE and can be estimated directly from pause windows in empirical traces.

Proposition (deliberation threshold):

Deliberation of duration $\Delta\tau$ is net-beneficial when:

Derived (Conditional on deliberation-drift assumption).

$$\Delta\eta^*(\Delta\tau) \cdot \|\delta_{\text{post}}\| > \rho_{\text{delib}} \cdot \Delta\tau \quad (4.3)$$

where $\Delta\eta^*(\Delta\tau)$ is the improvement in post-deliberation update gain and $\|\delta_{\text{post}}\|$ is the mismatch magnitude the agent will face when it resumes acting.

Derivation.

1. Without deliberation, the agent acts immediately at current tempo $\mathcal{T}_0 = \nu \cdot \eta_0^*$.
2. With deliberation of duration $\Delta\tau$, the agent pauses, then acts with improved gain $\eta_0^* + \Delta\eta^*$. But during the pause, mismatch has grown by $\rho_{\text{delib}} \cdot \Delta\tau$.
3. The net mismatch reduction from acting after deliberation versus acting immediately: $\text{Net} = \Delta\eta^* \cdot \|\delta_{\text{post}}\| - \rho_{\text{delib}} \cdot \Delta\tau$.
4. Deliberation is justified iff $\text{Net} > 0$. $\square$

Optimal deliberation duration (under diminishing returns):

Derived (Conditional on diminishing-returns + deliberation-drift).

$$\Delta\tau^* = \arg \max_{\Delta\tau} [\Delta\eta^*(\Delta\tau) \cdot \|\delta_{\text{post}}\| - \rho_{\text{delib}} \cdot \Delta\tau] \quad (4.4)$$

where $\|\delta_{\text{post}}\|$ is treated as a parameter estimated by the agent before deliberation begins (not optimized over — the agent estimates the mismatch it will face, then decides how long to deliberate). Under this approximation, the first-order condition is: $\frac{\partial \Delta\eta^*}{\partial \Delta\tau} \cdot \|\delta_{\text{post}}\| = \rho_{\text{delib}}$. Stop deliberating when the marginal improvement rate drops below the mismatch drift rate (normalized by post-deliberation mismatch). When the dependence $\|\delta_{\text{post}}\| = \|\delta_0\| + \rho_{\text{delib}} \cdot \Delta\tau$ is included in the optimization, the exact FOC acquires a correction factor $(1 - \Delta\eta^*)$ on the cost side; this is negligible when $\Delta\eta^* \ll 1$ (the typical case — deliberation produces small gain improvements).

Epistemic Status.

Conditional on the local deliberation-drift assumption. The threshold condition is derived given the assumption; the assumption itself is a local approximation validated by consistency with the global mismatch dynamics (4.5). The result captures the *epistemic* benefit of deliberation (improving η^*); in practice, deliberation also provides a direct *action-value* benefit (choosing better actions that alter the environment trajectory), which operates through ρ reduction and immediate reward — a fuller formalization would incorporate the unified policy objective (3.7) at significantly more complexity.

Discussion.

High- ρ_{delib} environments penalize deliberation. When the environment changes rapidly during pause windows, the cost term grows quickly. Only very short deliberation with large $\Delta\eta^*$ can justify the pause. The model captures the same tradeoff Boyd emphasized: in fast-tempo adversarial environments, over-deliberation is fatal not because thinking is bad, but because the environment moves during the thinking. Whether the specific mechanism (mismatch drift during pause) is the dominant real-world effect is an empirical question.

Diminishing returns. In most models, $\Delta\eta^*(\Delta\tau)$ exhibits diminishing returns — the first moments of simulation yield the largest improvement. Combined with the linear cost $\rho_{\text{delib}} \cdot \Delta\tau$, this implies a finite optimal deliberation duration. Past that point, additional thinking is net-harmful.

Implicit action as the high-tempo limit. As $\rho_{\text{delib}} \rightarrow \infty$ or $\Delta\tau^* \rightarrow 0$: the optimal strategy converges to zero deliberation — pure implicit action (3.3). This provides a mathematical basis for why high-tempo environments favor action fluency: the cost of deliberation exceeds its benefit when $\Delta\eta^*$ is small (action-selection is already fluent) or ρ_{delib} is large.

Deliberation as an investment. When ρ_{delib} is low (stable environment) or $\|\delta_{\text{post}}\|$ is large (significant model-reality gap), deliberation pays off. The conditions favoring deliberation — stable environment, large mismatch — resemble the high-stakes, low-urgency scenarios where deliberative reasoning (System 2) is advantageous in dual-process theories. The structural parallel is suggestive; whether the cost-benefit mechanism is the same one governing System 1/System 2 selection is an open question.

The circularity of $\|\delta_{\text{post}}\|$. Evaluating the threshold requires the agent to *predict* post-deliberation mismatch using its current model — the same model deliberation is meant to improve. This circularity is typically benign: $\|\delta_{\text{post}}\|$ is bounded below by $\rho_{\text{delib}} \cdot \Delta\tau$ and above by current mismatch plus that accumulation. An agent that underestimates its mismatch will under-deliberate; one that overestimates will over-deliberate. The bias is self-correcting through the feedback loop. The threshold is best understood as a *design criterion*, not a real-time decision procedure.

Resource costs beyond time. Real agents also incur computational and energetic costs: internal simulation burns calories, compute cycles, or opportunity cost of not processing new observations. These are additive: $\Delta\eta^*(\Delta\tau) \cdot \|\delta_{\text{post}}\| > \rho_{\text{delib}} \cdot \Delta\tau + C(\Delta\tau)$. In high- ρ_{delib} environments the temporal cost dominates; in low- ρ_{delib} environments, resource costs may be the binding constraint.

Structural adaptation as an analogy. Structural adaptation (4.8) superficially resembles deliberation with a massive $\Delta\tau$: the agent's parametric loop is partially suspended while it searches for a new model class, incurring a large mismatch debt $\rho_{\text{delib}} \cdot \Delta\tau$. However, this is an informal analogy, not a consequence of the deliberation-cost formalism. Deliberation as formalized here improves η^* *within a fixed model class*; structural adaptation changes the model class itself, which is a mechanistically different operation (4.8). The cost-benefit structure may be similar in form, but the quantities involved ($\mathcal{F}(\mathcal{M})$ vs. η^* , model-class search vs. gain improvement) are distinct.

Connection to temporal nesting. Deliberation is a nested loop: internal simulation running at rate ν_{internal} within the external action loop at rate ν_{external} . The convergence constraint applies: the internal loop must approximately converge before the external loop acts on its output.

Connection to Part II. For actuated agents, the deliberation tradeoff extends to three modes: exploit (O_t via Σ_t), explore (improve M_t), and deliberate (revise Σ_t). The three-way allocation (10.2) extends this segment’s threshold by adding a strategic benefit term ΔV_2 ; the extended threshold is the one genuinely derived piece. The broader three-way framing is discussion-grade — simulation shows deliberation is rarely chosen by an oracle in simple settings, and a unified objective outperforms the two-stage decomposition.

The AI agent’s dilemma. An AI agent with 100% context turnover faces a severe version: it MUST deliberate (comprehend the codebase) before acting effectively, but during comprehension its context fills and the environment may change. The optimal comprehension depth depends on ρ_{delib} and the session’s action horizon. This is why reading CLAUDE.md and architecture docs first (high-CIY query actions) dominates reading random source files (low-CIY exploration).

Domain instantiations:

Table 4.1

<i>Domain</i>	<i>Deliberation</i>	$\Delta\eta^*$ <i>source</i>	<i>When ρ_{delib} is high</i>
Boyd’s OODA	Explicit “Decide” step	War-gaming, staff analysis	Collapses to IG&C (implicit)
RL / MCTS	Planning rollouts	Monte Carlo tree search	Fewer rollouts, shallower search
MPC	Online optimization	Trajectory optimization	Shorter horizons, faster solvers
Human cognition	System 2 deliberation	Mental simulation	Defaults to System 1 (intuition)
Organization	Strategic planning	Scenario analysis	“Move fast and break things”
Software developer	Reading code, analyzing alternatives	Architecture analysis	Ship now, refactor later
AI agent	Reading codebase, planning approach	Context-building	Limit comprehension, act sooner

Open questions:

1. *Computational cost of deliberation* is not just elapsed time but resource cost. A fuller model would include both temporal and computational budgets.
2. *Deliberation about deliberation*: deciding whether to deliberate itself takes time. This meta-deliberation is bounded by the same tradeoff at a higher level, suggesting a hierarchy of diminishing deliberation horizons.
3. *Deliberation that generates observations*: internal simulation can surface model inconsistencies (internal mismatch), functioning as “exploration without external action.” Can deliberation generate internal CIY?

Working Notes.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. This was one of the most-reflected-on segments in Part I; coverage spans ten substrates (Gemini AUDIT-WORKING-193847/773921; Claude AUDIT-WORKING-266847/361742/384279/451729/471203/584721; Codex/Claude AUDIT-WORKING-526815/742613).

1. Candidate Brief prose / pre-prose.

- The deliberation threshold reads cleanly as a benefit-vs-cost ledger and the auditors converged on a plain-language gloss: left side is “the absolute benefit of having paused to think” (improvement in correction efficiency $\times$ size of error to correct), right side is “the cost of letting the world move while you were thinking” (rate of environment change $\times$ duration of pause); deliberate iff benefit $>$ cost (Gemini, AUDIT-WORKING-193847). A “pause ledger” framing — mismatch debt accumulating linearly during the pause, a mismatch-reduction credit booked after — is the same picture (Codex/Claude, AUDIT-WORKING-526815).

2. Candidate Discussion.

- **The action-bias / deliberation-bias regimes as a domain-spanning consequence.** The threshold “provides a formal justification for ‘action bias’ in startups/military and ‘deliberation bias’ in academia/planning, showing neither is universally correct — they optimize for different ρ_{delib} regimes” (Gemini, AUDIT-WORKING-193847); sharper still, “‘Move fast and break things’ is mathematically optimal when ρ_{delib} is high relative to $\Delta\eta^*$, and mathematically foolish when ρ_{delib} is low” (Gemini, AUDIT-WORKING-773921). The Discussion’s Boyd/System-2 material already gestures at this; the regime-as-optimization framing is a candidate sharpening.
- **Analysis-paralysis / perfectionism as a corollary of the FOC.** The first-order condition “proves that perfectionism is mathematically suboptimal in a changing universe: you must stop thinking and act the moment your marginal rate of insight drops below the speed of the world.” Analysis paralysis = overestimating $\Delta\eta^*$ or underestimating ρ_{delib} (Gemini, AUDIT-WORKING-193847). A vivid restatement of the existing diminishing-returns paragraph.
- **The benchmark/real-time asymmetry as a field observation.** “LLMs perform so well on static benchmarks (where time is frozen, $\rho = 0$, optimal strategy is infinite deliberation) but struggle in real-time continuous control — their architecture is tuned for $\rho = 0$ ” (Gemini, AUDIT-WORKING-193847). A striking diagnostic the segment could land for the logogenic-agents thread.

3. Follow-up items.

- **The “ $\Delta\eta^*$ vs action-value” scope gap — flagged by multiple substrates.** Two independent reads pressed that the prose opens by saying deliberation improves *action quality* via internal simulation, but the formal benefit term is improvement in *update gain* η^* — and many of the segment’s own examples (MCTS, MPC, war-gaming, reading code before editing) improve action selection / expected reward, not update gain. The Epistemic Status already names this, so neither counted it a finding, but both recommend the segment be *cited* as a threshold for “epistemic / gain-improving deliberation,” not all planning — one suggested retitling to “epistemic deliberation cost” and reserving the general term for a future action-value-bearing version (Codex/Claude, AUDIT-WORKING-526815; AUDIT-WORKING-742613). (*Routed as a scope-honesty follow-up; the strengthening direction — deriving the action-value benefit channel rather than deferring it — is noted in the report.*)
- **Derivation-prose tightness (the counterfactual baseline).** One auditor traced the “Net = $\Delta\eta^* \cdot \|\delta_{\text{post}}\| - \rho_{\text{delib}} \Delta\tau$ ” accounting and noted the implicit baseline (what the agent does *without* deliberating) is not made explicit: if “no deliberation” means continuous correction at tempo $\mathcal{T}_0$, the lost-correction term would read $\mathcal{T}_0 \|\delta\| \Delta\tau$ rather than $\rho_{\text{delib}} \Delta\tau$, unless ρ_{delib} is being read as an effective net-drift rate. Resolved as heuristic-but-consistent under the segment’s chosen rate-comparison framing (the conditional status and the “design criterion, not real-time procedure” caveat already cover it), but the prose “could be tightened to make the counterfactual and the exact accounting explicit” (Claude, AUDIT-WORKING-471203; the same initial concern was raised and then resolved-on-re-read by Claude, AUDIT-WORKING-584721). (*See report: candidate for tightening the derivation to an explicit case-A-vs-case-B accounting rather than a heuristic marginal comparison.*)
- **The $(1 - \Delta\eta^*)$ FOC correction factor.** Independently re-derived and confirmed by two substrates from $\|\delta_{\text{post}}\| = \|\delta_0\| + \rho_{\text{delib}} \Delta\tau$; both note the “ $(1 - \Delta\eta^*) \approx 1$ when $\Delta\eta^* \ll 1$ ” approximation is fine, and flag a watch-item: downstream uses of the threshold that omit the correction factor when $\Delta\eta^*$ is large would be a defect (Claude, AUDIT-WORKING-384279/584721).

- **“Open questions” inside a claims-verified segment.** One auditor noted the reader-facing “Open questions” block in a claims-verified segment “blurs the project convention slightly” (is this scope-honesty or stray Working Notes?) (AUDIT-WORKING-742613). Convention-texture signal, preserved rather than acted on.
- **Unified “search-during-pause” template (deliberation $\cup$ structural adaptation).** The segment correctly disclaims the structural-adaptation analogy as informal; one auditor wondered whether a genuine unified framing exists — both are “pause normal operation, search for a better state, resume,” differing only in *what space* is searched (deliberation searches gain space; structural adaptation searches model-class space) — and flagged it as a possible bigger-picture item, *not* a correction to the existing disclaimer (Claude, AUDIT-WORKING-584721).

4. Readers often ask / wonder.

- **Can deliberation raise $\mathcal{T}$ “for free”?** If an LLM runs internal chain-of-thought (a virtual $\mathcal{C}_t$) faster than physical action, does the internal generation let it raise effective tempo without paying the full ρ_{delib} penalty? (Gemini, AUDIT-WORKING-193847). Connects to open-question 3.
- **Where does the meta-deliberation regress bottom out?** Open-question 2 (“deliberation about deliberation”) is the framework’s first brush with metacognition; readers will ask whether the hierarchy of diminishing deliberation horizons terminates, and the assertion that meta-costs dominate at each level is currently un-derived (Claude, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-773921 — “AAT seems to dodge the infinite regress by treating the threshold as a design criterion, not a real-time computation step”).

5. Candidate figures.

- **Two-channel benefit diagram.** A diagram showing the formal benefit channel ($\Delta\eta^*$, gain improvement) in solid lines and the acknowledged-but-not-derived action-value channel in dashed lines — making the scope boundary visual rather than buried in Epistemic Status (Codex/Claude, AUDIT-WORKING-526815). Pairs directly with the $\Delta\eta^*$ -vs-action-value follow-up above.

6. Belongs elsewhere.

- **ELI session-start instantiation (Section IV / 04-eli-core/).** The “AI agent’s dilemma” generalizes to the developmental case: an ELI’s session begins with high U_M (no context), and the criterion says comprehension should continue until $\Delta\eta^* \cdot \|\delta_{\text{post}}\| \approx \rho_{\text{delib}}\Delta\tau$ — until the marginal value of more reading equals the cost of context-filling. For a hostile / high- ρ environment the infrastructure must enforce a bias toward action so the agent does not “overthink to death” (Claude, AUDIT-WORKING-471203; Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at the ELI work, not at this segment.
- **CIY over-exploration failure (adjacent to #def-causal-information-yield).** A consequence of the CIY-vs-EIG distinction surfaced while reading this segment: an agent exploring “because actions are distinguishable” keeps acting even after the causal graph is fully characterized — high CIY, zero expected information gain; the $\lambda(M_t)$ weighting is a heuristic patch, a proper EIG formulation the clean fix. The code-work analog: an agent that keeps running tests after the bug is fixed (Claude, AUDIT-WORKING-451729). Belongs with the CIY segment, noted here only because it co-occurred in the deliberation sweep.
- **Naming seed.** “Deliberation Threshold” / “Think-vs-Act Tradeoff” floated as a segment-title alternative that surfaces the operational content faster than “deliberation cost”; the AAT-distinctive content is the *threshold*, not the term (Claude, AUDIT-WORKING-471203). Naming-cycle target, not a segment edit.

4.2 Formulation: Sector Condition (A2')

The sector condition (A2') is the structural shape AAT chooses for the correction-function geometry: the correction points roughly inward, with magnitude bounded below relative to the mismatch, on a local region of validity. Together with the companion structural properties (A1) zero-correction-at-zero-mismatch and (A3) tempo-monotonicity, A2'

is the formal expression of “the agent’s adaptation tracks reality with at least baseline efficiency” — the form on which the persistence and adaptive-reserve results of A rest, and the form which downstream consumers (`#deriv-discrete-sector-condition`, `#deriv-variational-sector-condition`, `#deriv-adaptive-gain-dynamics`, `#der-gain-sector-bridge`) extend, weaken, or ground.

Formal Expression.

Setup objects (carried into the form). Let $\delta(t) \in \mathbb{R}^n$ be the mismatch vector (3.4 — the difference between the model’s predictions and reality across n observable dimensions). Let $F(\mathcal{T}, \delta) : \mathbb{R}_+ \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ be the **correction function** — how the agent’s adaptive process reduces mismatch — mapping into the same space as δ so that the inner product $\delta^T F$ is well-defined. This subsumes the update gain η^* (3.6), event rate ν , and the structure of the update rule. The adaptive tempo $\mathcal{T}$ (3.8) is the rate parameter.

(A1) Zero Correction at Zero Mismatch.

Assumption A1.

$$F(\mathcal{T}, 0) = 0 \quad (4.5)$$

No correction is applied when the model perfectly matches reality. Uncontroversial by construction.

(A2’) Local Sector Condition. There exists a region $\mathcal{B}_R = \{\delta : \|\delta\| \leq R\}$ and $\alpha > 0$ such that (following the sector-condition framework of Lur’e¹):

Formulation A2’ (sector-condition) — derived in sub-scope α , assumed in sub-scope β (see Grounding below).

$$\delta^T F(\mathcal{T}, \delta) \geq \alpha \|\delta\|^2 \quad \forall \delta \in \mathcal{B}_R \quad (4.6)$$

The correction function always points “inward” (reducing mismatch), and its magnitude is bounded below relative to $\|\delta\|^2$. The linear case has $\alpha = \mathcal{T}$. A saturating correction has α decreasing for large $\|\delta\|$. A threshold correction has $\alpha = 0$ for small $\|\delta\|$.

The local form allows the correction to break down outside $\mathcal{B}_R$ — the structural adaptation regime of 4.8.

(A3) Tempo Monotonicity.

For fixed δ , $\delta^T F(\mathcal{T}, \delta)$ is monotone increasing in $\mathcal{T}$. Higher tempo means faster correction.

Assumption A3.

Parameter interpretation. The sector parameter α is determined by the adaptive tempo $\mathcal{T}$ and the structure of the correction function. In the linear case, $\alpha = \mathcal{T} = \sum_k \nu^{(k)} \cdot \eta^{(k)*}$. In nonlinear cases, α represents the *worst-case* correction efficiency within the valid region — the minimum ratio of correction power to mismatch magnitude. The radius R represents the model class capacity: how large a mismatch can grow before the correction mechanism fails (i.e., before the sector condition ceases to hold), at which point structural adaptation (4.8) becomes necessary.

¹Lur’e, A. I. (1957). *Some Nonlinear Problems in the Theory of Automatic Control*.

Epistemic Status.

A2' is a *formulation* — a chosen structural shape for the correction-function geometry that captures “the correction points roughly inward with bounded efficiency.” Several structurally distinct shapes would fit the same role (a sign-only condition; a two-point monotonicity; a contraction-rate bound; a non-Euclidean weighted inner-product variant — see *Why Euclidean A2' specifically* in Discussion below). A2' is the canonical choice *matched to the quadratic Lyapunov candidate* $V = \frac{1}{2}\|\delta\|^2$ used in A, and matched to the gain-based update form on which 4.3 derives it for sub-scope α .

The status is *conditional* because A2' is **derived** for one explicitly named sub-scope of AAT-in-scope agents and **assumed as a per-system empirical claim** for the complementary sub-scope. The Lyapunov derivations downstream of A2' (A Props A.1, A.1S, A.2; Corollary A.1S.1) apply uniformly across both sub-scopes — they operate downstream of A2' regardless of how it is established. The sub-scope partition is *scope narrowing*, not *scope retreat*: it makes explicit which agent classes get A2' as a derived consequence of their update geometry, and which classes carry it as a structurally well-scoped posit.

Sub-scope α (A2' derived). For a characterized class of AAT-in-scope agents, A2' is a *derived* consequence of the update rule, not a primitive assumption. 4.3 (Prop B.3) shows that the gain-based update $M_t = M_{t-1} + \eta^* g(\delta_t)$ (3.6) induces a correction function satisfying A2' whenever the update rule has **directional fidelity (B1)** — $\delta^T H g(\delta) \geq c_{\min} \|\delta\|^2$ on $\mathcal{B}_R$. Sub-scope α — the agent classes where B1 holds structurally — includes:

- *Optimal Bayesian updates* (Kalman, conjugate families): B1 holds by Bayes-risk minimization. $\alpha = \eta^* \cdot c_{\min}$, reducing to $\alpha = \eta^*$ in the scalar case.
- *Exponential families in natural parameters*, on a bounded interior scope $\Theta_0 \subset \text{int}(\Theta)$: the Hessian is the Fisher information matrix, PD on the interior. $\alpha = \eta \cdot \mu_0$ where $\mu_0 = \inf_{\theta \in \Theta_0} \lambda_{\min}(\mathbf{I}(\theta)) > 0$. Pointwise PD does not imply a uniform global lower bound: $\inf_{\theta \in \Theta} \lambda_{\min}(\mathbf{I}(\theta))$ can be zero (Poisson: $\mathbf{I}(\theta) = e^\theta$, $\inf_{\theta \in \mathbb{R}} e^\theta = 0$), so Θ_0 supplies the local-region scope R that A2' requires. Families with a uniform Fisher floor on Θ (Gaussian-mean, Beta-Bernoulli) extend to global α .
- *Gradient descent on locally strongly convex losses* (Prop B.4): B1 is *equivalent* to strong convexity via the gradient-monotonicity characterization (Nesterov 2004², Thm 2.1.10). $\alpha = \eta \cdot \mu$ where μ is the strong convexity modulus.
- *L2-regularized convex losses*: regularization provides a floor $\mu \geq \lambda$, so $\alpha \geq \eta \lambda$ globally.
- *Linear corrections with positive-definite gain-observation product*: $\alpha = \lambda_{\min}^+(KH)$ (matrix Kalman, restricted to the observable subspace).

Within sub-scope α , A2' is written down by inspection of the update rule; no independent posit is required.

Sub-scope β (A2' assumed as empirical claim). For the remaining AAT-in-scope agents, A2' stands as a well-scoped empirical claim about the agent's correction geometry. Sub-scope β includes:

- *PID controllers with fixed gains* — no gradient / optimality structure; B1 is a tuning question, not a structural consequence.
- *Rule-based systems* — no continuous update rule; A2' is domain-specific (see also the structural Lipschitz-floor scope-exit in Discussion below).
- *Human judgment / organizational learning* — structural analogy in 3.6; no formal B1 guarantee.
- *Severely misspecified agents* (FM-5 in 4.3) — proper-gradient rules can aim at the wrong target.

²Nesterov, Y. (2004). *Introductory Lectures on Convex Optimization*. Springer. Theorem 2.1.10.

- *Variational / approximate posteriors* — B1 not guaranteed by optimality because approximation error can rotate the correction. Under a controlled KL bound, an intermediate sub-scope α' recovers a degraded form of A2' (see AJ).
- *Non-convex gradient agents beyond the basin* — A2' fails at basin boundary; this IS the 4.8 trigger.
- *Stochastic gradients (per-step)* — A2' holds in expectation; per-step noise enters as effective disturbance under A Prop A.1S.

Within sub-scope β , A2' must be verified per-system — the claim is stronger than what AAT's postulates + gain structure alone can force (an agent with $g(\delta) = R_{90^\circ}\delta$ satisfies every AAT postulate but violates B1 trivially; see 4.3 FM-1).

Discussion.

Operator-family classification (external mathematical lineage). The sub-scope α/β partition can be restated precisely in the operator-theoretic language of Rockafellar 1970 (*Convex Analysis*, §24) and Bauschke & Combettes 2017 (*Convex Analysis and Monotone Operator Theory in Hilbert Spaces*, 2nd ed., §§22–28). Casting the discrete update map as $T_d(\delta) = \delta - \eta^* F_d(\delta)$ with $T_d(0) = 0$, A2' at $\delta^* = 0$ is exactly a **one-point strong monotonicity condition** on $A = I - T_d$, and DA2'-inc (the incremental strengthening required by #form-composition-closure's bridge lemma, stated in ○) is **full two-point strong monotonicity** in the Rockafellar sense. Sub-scope α maps onto established operator families:

- **Optimal Bayesian updates** (Kalman, conjugate, exponential family) $\equiv$ proximal / firmly nonexpansive operators (Bauschke-Combettes Prop 23.7). Firmly nonexpansive is equivalent to $\frac{1}{2}$ -averaged; operator-sector condition holds with the gain as the sector constant.
- **Gradient operators on strongly convex functions** $\equiv$ cocoercive operators via the Baillon-Haddad theorem; strong monotonicity with modulus $\eta\mu$.
- **Exponential families in natural parameters** $\equiv$ natural-gradient operators in the Fisher-weighted Hilbert space (Amari 1998; cf. 4.3 “Fisher-metric cases under parameterization-invariance” for the AAT-internal forcing via (PI)/Čencov named in 5.5).
- **L2-regularized convex gradients** $\equiv$ shifted monotone-gradient operators with regularization-provided floor.
- **Linear corrections with PD gain–observation product** $\equiv$ linear contraction in the $(P^-)^{-1}$ -weighted inner product.

Sub-scope β maps onto “operator families that are not cocoercive in any natural inner product”: PID (tuning-dependent; not cocoercive generically); rule-based / symbolic (no inner-product structure); variational / amortized (approximation-gap rotation); non-convex-gradient beyond basin (non-monotone on the full domain); per-step SGD (noise-dominated); human judgment (no formal rule). The α/β epistemic labeling in AAT tracks whether the operator family admits operator-sector structurally (derived from the class definition) or only under empirical per-instance verification — a scope-honesty move, not a mathematical reclassification.

This recognition positions AAT's sector-condition framework as a specialization of monotone-operator theory (Minty 1962; Browder 1968; Rockafellar 1970; Bauschke-Combettes 2017) to one-point-anchored strong monotonicity under a specific inner product structure. AAT's distinctive content — one-point anchoring at the equilibrium (strictly weaker than full two-point strong monotonicity, matched to fixed-point-at-target semantics); Model D / Model S disturbance decomposition; composition with the identifiability-floor meta-pattern; composition-consistency postulate; the α/β epistemic labeling itself — sits as specialization + repurposing rather than strict generalization. This acknowledgment is load-bearing for scope honesty: the mathematical machinery is established; AAT's value lies in its AAT-internal architecture (organization-of-scope under a singular-trajectory agent, signed-coupling structure, forced coordinates via uniqueness theorems, three meta-patterns) rather than in novel monotone-operator mathematics. The unification has

honest limits: the coarse-graining projection Λ (#form-composition-closure) does not fit the operator-sector primitive; three of five metric- α_2 cases in #result-contraction-template remain theorem-imported; the identifiability-floor axis is orthogonal.

Sub-scope β “rule-based / discontinuous” — structural Lipschitz floor. [Derived, status: exact scope-exit statement.] The rule-based / state-machine / threshold-triggered / discontinuous entry in sub-scope β is not merely “empirical verification required”; it is a **structural scope-exit for contraction-based bridge-lemma analysis**. For correction functions F that are not locally Lipschitz, no scalar sector bound $\delta^T F(\delta) \geq \alpha \|\delta\|^2$ implies the full-update-map contraction required by #form-composition-closure’s bridge lemma — the update map $f_c(X, o) = X - \eta^* F(X)$ can exhibit $\Omega(1)$ jumps between arbitrarily close X, X' at rule-firing boundaries, so no $\lambda < 1$ Lipschitz constant exists. Concrete counterexample: $F(\delta) = \alpha\delta$ for $|\delta| < 1$ and $F(\delta) = \alpha\delta + \text{sign}(\delta)$ for $|\delta| \geq 1$ — the sector bound holds with α , but f_c jumps by η^* at $|X| = 1$, violating contraction. The appropriate external apparatus for this class is the **hybrid-dissipative framework** (van der Schaft & Schumacher 2000, *An Introduction to Hybrid Dynamical Systems*, Springer; Di Bernardo, Liuzza & Russo 2014, *SIAM J. Control Optim.* 52) — distinct machinery (dwell-time, Filippov solutions, impulsive-dissipative inequalities) operating on a different regularity class. AAT’s Lyapunov machinery in A and the contraction machinery in #result-contraction-template both require C^1 or better regularity; the scope-exit to hybrid-dissipative analysis is honest and structural, not a deficiency to be repaired within AAT’s current apparatus. Under #disc-identifiability-floor’s Instance 2 pattern (Cramér-Rao floor under unobservable common cause), rule-based agents whose rule firing depends on regime structure — e.g., threshold-triggered state-machines with regime-dependent thresholds — additionally suffer regime-C identifiability collapse when the regime variable is unobservable; the non-contraction and the non-identifiability compose in that case.

Why Euclidean A2' specifically. The A2' form $\delta^T F \geq \alpha \|\delta\|^2$ is the sector condition *matched to the quadratic Lyapunov candidate* $V = \frac{1}{2} \|\delta\|^2$ used by A. A converse-Lyapunov argument (Khalil 2002³, Thm 4.17) gives: if persistence holds under the dynamics $\dot{\delta} = -F(\delta)$ on $\mathcal{B}_R$, then there exists a quadratic-equivalent Lyapunov function $V_*(\delta)$ with $c_1 \|\delta\|^2 \leq V_* \leq c_2 \|\delta\|^2$ — but V_* may not be the Euclidean norm itself. Under a weighted Lyapunov candidate $V(\delta) = \frac{1}{2} \delta^T P \delta$, the natural sector condition is $\delta^T P F(\delta) \geq \alpha \delta^T P \delta$; the matrix-Kalman case of 4.3 is exactly this in the $(P^-)^{-1}$ -weighted inner product, with a norm-equivalence transfer to Euclidean A2' degraded by the condition number $\kappa(P^-)$. Euclidean A2' is therefore not the unique sector form — it is the canonical one matched to the canonical V . An agent that persists under a non-Euclidean metric satisfies a weighted-sector A2' that transfers to Euclidean A2' only up to norm equivalence. 5.5 classifies the Lyapunov case as an *adjacent family member* to AAT’s three primary additive-coordinate-forcing instances (chain / divergence / update, where a logarithmic coordinate is uniquely forced via Cauchy’s functional equation under an AAT-internal additivity axiom): here the quadratic coordinate is matched to the sector form rather than forced by one.

How downstream segments use this form.

- A consumes A2' as the Lyapunov-derivation input: Props A.1 / A.1S / A.2 prove ultimate boundedness, mean-square persistence, and adaptive reserve under (A1), (A2'), (A3); Corollary A.1S.1 establishes the disturbance-model containment dichotomy $P(\tau_R < \infty) \in \{0, 1\}$.
- B demonstrates the load-bearing Model-S half of Cor A.1S.1 — that no horizon-independent non-exit bound exists under additive stochastic forcing — using A2' on $\mathcal{B}_R$ as the Itô-Lyapunov input.
- 4.3 derives A2' for sub-scope α under directional fidelity (B1), making the sub-scope- α partition above structural rather than postulated.
- O states the discrete-time analog (DA2'), strengthening A2' with an additional Lipschitz bound on $\|F_d\|$ to control the quadratic term that arises in discrete contraction.

³Khalil, H. K. (2002). *Nonlinear Systems* (3rd ed.). Prentice Hall.

- **AJ** states ε -fidelity $A2'$ under controlled-KL variational approximation, with $O(\sqrt{\varepsilon})$ sector-constant degradation — recovering an intermediate sub-scope α' within the partition above.
- **V** refines sub-scope α into fixed-gain (α_1) and adaptive-gain (α_2 under meta-gain conditions MG-1–MG-4) layers.
- **4.4** and **G** state the persistence results in result-segment voice; **13.1** and the composite-agent segments in Part III consume $DA2'$ -inc as the bridge-lemma precondition.

Working Notes.

- Landing-context provenance: this segment was carved out of **A** in the 451729 D.1 Gate verification cycle (2026-05-20) to resolve a depends-graph topology issue — **4.3** and **B** both already depended on **A**, so making the Lyapunov-derivation segment depend on its own $A2'$ -form-consumers would have created cycles. The sub-scope α/β partition reflects the strengthening trail recorded in `spikes/.integrated/spike-a2-prime-strengthening.md` — the analysis that ruled out a universal $A2'$ derivation and identified the five operator families where the bridge is structural.
- The companion-property partition ($A1, A2', A3$ together) is held here as the canonical setup; alternate orderings or sub-scope refinements (e.g., the $\alpha_1/\alpha_2/\alpha_3/\alpha'$ ladder accumulated across `#deriv-variational-sector-condition`, `#deriv-adaptive-gain-dynamics`, `#deriv-fisher-whitened-update-rule`) live in their respective segments and inherit this form by reference rather than re-stating it.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (`audit-routing-instructions.md` §8). Orthogonal framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. Thin coverage on this segment (one digested reflection reached it: Claude, `AUDIT-WORKING-384279`); the gold here is methodological-positioning rather than pedagogical, but worth preserving.

2. Candidate Discussion.

- The auditor read this segment as the framework’s *methodological-honesty exemplar* — the operator-family classification (mapping the sub-scope α derivation forms to Rockafellar / Bauschke–Combettes 2017 / Baillon–Haddad) “names AAT’s reach into monotone-operator theory with humility ... AAT’s distinctive content sits as specialization + repurposing rather than strict generalization.” Candidate framing-prose for *why* the sub-scope partition is structured the way it is: it is the template for how scope-exit and prior-art positioning should be done (Claude, `AUDIT-WORKING-384279`).
- The **Lipschitz-floor scope-exit** (sub-scope β rule-based / discontinuous correction) was singled out as exemplary: it is not merely “verify per-system” but a *structural* scope-exit for contraction-based bridge-lemma analysis, with a concrete counterexample and the right external apparatus (van der Schaft & Schumacher 2000, hybrid-dissipative). Flagged as a model other segments’ scope-exits should imitate (Claude, `AUDIT-WORKING-384279`).

3. Follow-up items.

- **Respect the $\kappa(P^-)$ caveat downstream.** The condition-number caveat on the matrix-Kalman $\rightarrow$ Euclidean- $A2'$ transfer (“degraded by the condition number”) was confirmed correct; the watch-item is that downstream segments invoking $A2'$ via this transfer should carry the caveat rather than assuming the clean Euclidean form (Claude, `AUDIT-WORKING-384279`).
-

4.3 Derived: Gain–Sector Bridge

The gain-based update principle (3.6) produces correction dynamics satisfying the sector condition (GA-3) whenever the update rule has *directional fidelity* — the correction points at least roughly toward reality. For gradient-based agents, local strong convexity of the loss is sufficient for the one-point sector condition ($A2'$ as stated in 4.2) and bidirectionally equivalent to the two-point / incremental sector condition ($DA2'$ -inc). The sector parameter α is not a free parameter but is determined by the gain and the correction geometry.

Formal Expression.**The Bridge Theorem.**

Given the gain-based update $M_t = M_{t-1} + \eta^* \cdot g(\delta_t)$ (3.6), the induced correction function is:

Derived (gain-sector-bridge, from update-gain + directional fidelity).

$$F(\delta) = \eta^* \cdot H g(\delta) \quad (4.7)$$

where H maps state-space corrections to observation-space mismatch reduction. The sector condition (GA-3) holds with parameter $\alpha > 0$ whenever:

(B1) Directional fidelity. The mismatch transform g preserves the mismatch-reducing direction:

$$\delta^T H g(\delta) \geq c \|\delta\|^2 \quad \text{for } \|\delta\| \leq R \quad (4.8)$$

for some $c > 0$. The bridge then determines the sector parameter in two forms that differ by the event-rate normalization, because the gain-based update is applied *per correction event* while the sector condition feeds a *continuous-time* persistence inequality.

Per-event sector efficiency — the dimensionless fraction of standing mismatch the correction removes per event:

$$\alpha_{\text{event}} = \eta^* \cdot c_{\min}, \quad c_{\min} = \inf_{\|\delta\| \leq R} \frac{\delta^T H g(\delta)}{\|\delta\|^2} \quad (4.9)$$

with η^* dimensionless and $c_{\min}$ a dimensionless geometric (Rayleigh-quotient) ratio, so $\alpha_{\text{event}} \in (0, 1]$ is itself dimensionless.

Per-time sector rate — the correction *rate* the continuous-time sector condition (GA-3) and the persistence inequality $\alpha > \rho/R$ actually compare against, obtained by aggregating per-event efficiency over the channel's event rate ν (3.8):

$$\alpha = \alpha_{\text{time}} = \nu \cdot \eta^* \cdot c_{\min} \quad (4.10)$$

with units t^{-1} — the same units as adaptive tempo $\mathcal{T}$ (NOTATION.md *Units*). The event rate ν is exactly the factor that promotes the per-event geometric quantity to the per-time rate that the Lyapunov machinery in A consumes; the bare α in GA-3 and downstream is α_{time} .

Gradient Equivalence.

The sector parameters in this section and the Verified-Instances table below are stated in the *per-event* form α_{event} (the dimensionless correction efficiency); each promotes to the per-time rate the persistence inequality consumes by the same factor ν , $\alpha_{\text{time}} = \nu \cdot \alpha_{\text{event}}$, so the proportionalities are identical under either reading.

Derived (sector-convexity equivalence, two-point form).

For any agent updating via gradient descent on a loss L with learning rate η :

$$\alpha = \eta \cdot \mu \quad \text{where } \mu = \inf_{\|\delta\| \leq R} \lambda_{\min}(\nabla^2 L(M^* + \delta)) \quad (4.11)$$

is the strong convexity modulus. The basin radius R is the largest ball around the optimum where $\nabla^2 L$ remains positive definite. The equivalence has two forms — bidirectional under the stronger two-point sector condition, one-directional under the one-point form actually used by `#deriv-sector-condition`:

- **Two-point / incremental sector $\Leftrightarrow$ strong convexity (full equivalence).** Under the incremental sector bound $(F(\delta_1) - F(\delta_2))^T(\delta_1 - \delta_2) \geq \alpha \|\delta_1 - \delta_2\|^2$ on $\mathcal{B}_R(M^*)$ — DA2'-inc in O, the bridge-lemma precondition in 13.1 — the iff holds via Nesterov 2004 Theorem 2.1.10: Two-point sector with $(\alpha, R) \iff L$ is locally (α/η) -strongly convex on $\mathcal{B}_R(M^*)$.
- **One-point sector $\Leftarrow$ strong convexity (one direction only).** AAT's GA-3 / A2' as stated in 4.2 is the one-point form $\delta^T F(\delta) \geq \alpha \|\delta\|^2$ at $\delta^* = 0$. Strong convexity implies the one-point sector ($\alpha = \eta\mu$); the converse fails. Counterexample: $L'(x) = x(1 + \frac{1}{2} \sin(10x))$ satisfies $x \cdot L'(x) \geq \frac{1}{2}x^2$ globally yet has $L''(\pi/10) < 0$, so it is not convex on any neighborhood of $x^* = 0$. The one-point sector at the equilibrium is genuinely weaker than full local strong convexity (cf. G's one-point/two-point distinction). Full proofs and the counterexample analysis in K Prop B.4.

Verified Instances.

Table 4.2

Update class	Bridge status	Sector parameter α	Valid region
Scalar Kalman	Derived	$K = P^-(P^- + R_{\text{obs}}) = \eta^*$	Global
Matrix Kalman	Derived	$\lambda_{\min}^+(KH)$ in $(P^-)^{-1}$ -norm	Observable subspace
Beta-Bernoulli	Derived	$1/(n+1) = \eta_{\text{edge}}$	Global
Exponential family (natural params), bounded scope $\Theta_0 \subset \text{int}(\Theta)$	Derived	$\eta \cdot \mu_0$ where $\mu_0 = \inf_{\theta \in \Theta_0} \lambda_{\min}(\mathbf{I}(\theta)) > 0$	Θ_0 (compact / interior-bounded) — global only when the family has a uniform Fisher lower bound
Gradient on strongly convex loss	Derived	$\eta \cdot \mu$	Global ($R = \infty$)
Gradient on locally convex loss	Derived	$\eta \cdot \mu_{\text{local}}$	Basin of attraction
Gradient on non-convex loss	Fails at basin boundary	N/A beyond R	Finite R
SPR-tuned PID on positive-real plant with anti-windup	Derived	$\alpha_{\text{PID}} = \omega_c \sin(\varphi_m)/\kappa(P)$ (phase margin as sector constant; crossover frequency as tempo; KYP-certificate condition number as degradation)	Classical linear regime + Lur'e sector-bounded nonlinearity within specified plant-Lipschitz threshold

Failure Modes. The bridge fails precisely in five cases:

1. **Directional infidelity.** The mismatch transform g rotates the correction away from the mismatch ($\delta^T Hg(\delta) \leq 0$). Occurs with pathological parameterizations or severe model-observation misalignment. For optimal Bayesian updates, B1 holds by construction.
2. **Gain collapse.** $\eta^* \rightarrow 0$ while $\rho > 0$, so $\alpha \rightarrow 0$ and the persistence condition eventually fails. Not a failure of the bridge but of the persistence condition — see the gain-collapse analysis in 3.6.
3. **Nonlinear saturation.** The correction function g saturates at large $\|\delta\|$, so the sector ratio $\delta^T g(\delta)/\|\delta\|^2$ decays. The sector condition holds locally with α depending on R . This is exactly what A2' (the local sector condition) is designed for.
4. **Unobservable directions.** When $\ker(H) \neq \{0\}$, the correction has no effect on mismatch in unobservable directions. The sector condition holds only in the observable subspace. See 9.3.

5. **Model misspecification.** The model class does not contain the truth, so the gradient direction is wrong. B1 fails because the correction aims at the wrong target. This is the 4.8 trigger.

Epistemic Status.

Conditional derivation. The bridge theorem is exact for all cases where B1 (directional fidelity) holds. The resulting sub-scope structure of A2' in 4.2 is:

Sub-scope α (B1 structural, A2's derived):

- **Optimal Bayesian updates** (Kalman, conjugate, exponential family): B1 holds by construction — the posterior update minimizes expected loss, ensuring the correction aligns with the mismatch. The sector parameter equals the gain: $\alpha = \eta^*$ (scalar) or $\alpha = \lambda_{\min}^+(KH)$ (matrix Kalman, observable subspace).
- **Gradient descent on (locally) strongly convex losses:** local strong convexity is *sufficient* for B1 (the one-point form of A2' at M^*) and *bidirectionally equivalent* to the two-point / incremental sector condition DA2'-inc (Prop B.4 (B.4-i) and (B.4-ii) respectively) — a well-characterized property with an extensive optimization theory literature. The sector parameter factors as $\alpha = \eta \cdot \mu$ (learning rate $\times$ curvature). The reverse implication B1 $\Rightarrow$ strong convexity does *not* hold without the two-point upgrade: the one-point sector at M^* is strictly weaker than full local strong convexity (counterexample in Prop B.4).
- **L2-regularized convex losses:** the regularization parameter λ provides a global floor $\mu \geq \lambda$, so $\alpha \geq \eta\lambda$ globally.
- **Exponential families in natural parameters, on a bounded interior scope:** Fisher information matrix is PD on the interior, and uniformly bounded below on any compact $\Theta_0 \subset \text{int}(\Theta)$; $\alpha = \eta \cdot \mu_0$ with $\mu_0 = \inf_{\theta \in \Theta_0} \lambda_{\min}(\mathbf{I}(\theta))$. The bound is global only when the family has a uniform Fisher lower bound on Θ — true for Gaussian-mean and Beta-Bernoulli, false for Poisson natural parameter ($\mathbf{I}(\theta) = e^\theta$, infimum zero).
- **Linear corrections with PD gain–observation product:** $\alpha = \lambda_{\min}^+(KH)$.

Within sub-scope α , A2' is written down by inspection of the update rule — no independent posit is required. This is what #form-sector-condition “Sub-scope α (A2' derived)” names.

Sub-scope β (B1 not structural, A2's assumed per-agent):

- **Non-gradient agents** (PID controllers, rule-based systems, human judgment): B1 remains an empirical claim. Well-tuned PID has B1 empirically; badly-tuned PID may violate it.
- **Severely misspecified agents** (FM-5 below): proper-gradient updates can aim at the wrong target.
- **Variational / approximate posteriors:** B1 not guaranteed by optimality — approximation-direction error can rotate the correction.
- **Non-convex gradient agents beyond the basin** (FM-3 + basin boundary): A2' fails where the loss curvature goes non-positive; the structural-adaptation-necessity trigger.
- **Stochastic gradients, per-step:** A2' holds in expectation; per-step noise enters as effective disturbance under Prop A.1S.

The bridge covers sub-scope α rigorously and characterizes the boundary to sub-scope β via the five failure modes. It does *not* eliminate GA-3 as an assumption for all AAT-in-scope agents — some agent classes genuinely require A2' as a primitive posit, and the honest architectural statement is scope narrowing rather than universal derivation.

The gradient equivalence is validated by simulation across quadratic, logistic, exponential-family, and non-convex losses. The Kalman case is verified analytically. Full derivations and simulation results in [K](#).

Max attainable: conditional — the condition (B1 or strong convexity) is inherent, not removable. Pathological update rules exist that violate B1 (FM-1 provides a counterexample that satisfies every AAT postulate and the gain-based update form but has $\delta^T g(\delta) = 0$ identically). Scope + gain structure alone does not force B1; some optimality / coherence / rationality constraint (Bayesian coherence, gradient-of-a-convex-loss, etc.) is required.

Weighted-norm subtlety. In the matrix Kalman case, the sector condition holds in the $(P^-)^{-1}$ -weighted inner product, not the Euclidean norm. For fully observable systems with bounded condition number $\kappa(P^-)$, the norms are equivalent up to $\kappa(P^-)$. The Lyapunov proofs in [A](#) use the Euclidean norm, which remains valid with the quantitative adjustment $\alpha_{\text{Euclidean}} \geq \alpha_{\text{weighted}} / \kappa(P^-)$.

Fisher-metric cases under parameterization-invariance. The exponential-family-in-natural-parameters row and the matrix-Kalman row of Verified Instances both have natural statements in a Fisher-metric inner product rather than the Euclidean one. Under the **(PI) parameterization-invariance** axiom named in [4.10](#) (AAT's theorems should not depend on arbitrary choice of coordinates on M_t), Čencov's 1982 uniqueness theorem (*Statistical Decision Rules and Optimal Inference*, AMS; subsequent Ay-Jost-Lê-Schwachhöfer 2017 extensions) forces the Fisher information metric uniquely on statistical-manifold sub-cases of M_t . Two consequences:

- *The matrix-Kalman sector constant is natively stated in the information metric $M = (P^-)^{-1}$ — under (PI), this is not a choice but forced. The $\kappa(P^-)$ Euclidean-transfer penalty in the paragraph above vanishes; the derivation is AAT-internally forced, not AAT-internally preferred.*
- *The exponential-family-natural-parameter sector constant is natively stated in the Fisher metric $\mathbf{I}(\theta)$ — under (PI), this is forced; the contraction rate equals η globally on the interior of the natural-parameter domain (Fisher-conditioning degradation removed).*

Under (PI), these two rows of Verified Instances upgrade from *derived (conditional on choice of inner product)* to *derived (AAT-internally forced)* via Čencov. Under non-adoption of (PI), they remain at the Euclidean-transferred statement with the $\kappa(P^-) / \lambda_{\min}(\text{Fisher})$ penalty. This is the Fisher-layer analog of the chain-rule-additivity axiom that grounds the divergence-layer uniqueness theorem in [T](#) and the evidential-additivity axiom that grounds the update-layer uniqueness theorem in [U](#) — in each case an AAT-internal axiom combined with a uniqueness theorem forces a coordinate. The structural positioning is named in [5.5](#).

The remaining Verified Instances rows (scalar Kalman, Beta-Bernoulli, gradient on strongly convex, L2-regularized, linear-PD-symmetric) live in Euclidean metric naturally; no Fisher-metric choice is at issue, so (PI) has no effect on them beyond transparency.

Discussion.

GA-3 is grounded, not floating. Before this result, GA-3 (“the correction function satisfies the sector condition”) was an opaque global assumption — the theory's softest structural joint. The bridge transforms it: for well-designed agents, GA-3 is a consequence of the update mechanism's geometry, not an independent postulate. The assumption load shifts from “the correction function has this property” (hard to verify in general) to “the update rule has directional fidelity” (transparent and checkable for specific systems).

The α - $\mathcal{T}$ relationship is derived for the important cases. [4.5](#) notes that α is monotone increasing in $\mathcal{T}$ across all tested correction functions. The identity holds at the *per-time* level: for linear correction (Kalman, Beta-Bernoulli) with $c_{\min} = 1$, $\alpha_{\text{time}} = \nu \cdot \eta^* = \mathcal{T}$ exactly — the per-time sector rate *is* adaptive tempo, both being event-rate-weighted

correction rates with units t^{-1} . The per-event reading is $\alpha_{\text{event}} = \eta^*$ for the same case; the two differ by exactly the event-rate factor ν , which is what $\mathcal{T} = \nu\eta^*$ carries. For gradient correction on strongly convex losses, $\alpha = \eta \cdot \mu$ where μ is the curvature — monotone in η (which is monotone in $\mathcal{T}$) for fixed loss landscape. The empirical observation is now structurally grounded.

Basin boundary = structural adaptation trigger. For gradient agents with non-convex losses, the basin radius R is the convexity radius of the loss landscape. When mismatch exceeds R , the agent has been pushed out of its convexity basin — the correction function reverses direction and the sector condition fails. This IS the 4.8 trigger, now with a precise geometric characterization: structural adaptation is needed when the agent crosses an inflection surface of its loss landscape.

The theory’s formal chain is tightened. The prediction chain becomes:

$$\text{gain principle + B1} \xrightarrow{\text{derived}} \text{sector condition (GA-3)} \xrightarrow{\text{Lyapunov (exact)}} \text{persistence, reserve, adversarial scaling} \quad (4.12)$$

The left arrow is this segment. The right arrow is A. The discrete-time framework (O) requires an additional Lipschitz bound on the correction function ($\|F_d(\delta)\| \leq c_{\max}\|\delta\|$ with $c_{\max} < 2/\eta^*$) — strictly stronger than an inner-product upper bound, needed because the discrete contraction involves $\|F_d\|^2$. This is automatically satisfied for Bayesian updates (the posterior lies between prior and data) and for gradient descent on smooth losses (where $c_{\max}$ is the Lipschitz constant L). With this constraint and the step-size condition $\eta^* < 2c_{\min}/c_{\max}^2$, the fluid limit is formally justified: Model D steady state is exact, Model S variance gap is $O(\eta^* c_{\max})$. Part I’s formal chain is now complete.

Working Notes.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. This segment drew the most consistently high engagement of the Ch.4 set (several substrates called it the chapter’s, or Part I’s, keystone); coverage spans ten substrates (Gemini AUDIT-WORKING-193847/773921/829314; Claude AUDIT-WORKING-266847/361742/384279/451729/471203/584721; Codex/Claude AUDIT-WORKING-526815/742613).

1. Candidate Brief prose / pre-prose.

- The converging plain-language summary of what the bridge buys: “GA-3 is grounded, not floating — the assumption load shifts from ‘the correction function has this property’ (hard to verify) to ‘the update rule has directional fidelity’ (transparent and checkable)” (Claude, AUDIT-WORKING-266847). Multiple substrates independently reached this exact framing — it is already the Discussion opener and reads as the segment’s Feynman-criterion anchor.
- The unification one-liner, converged across three substrates: the bridge “locks the Bayesian / information-theory half of the framework to the control / Lyapunov half” — it “unifies the convergence proofs of machine learning (Nesterov / convexity) with the stability proofs of control theory (Lur’e / sector bounds)” (Gemini, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-471203; Gemini, AUDIT-WORKING-193847 — “learning (gradient descent) and control (Kalman, PID) are mathematically unified under the sector condition”).

2. Candidate Discussion.

- **Basin boundary as “where normal science becomes toxic.”** Gemini extended the existing basin-boundary-as-structural-adaptation-trigger paragraph into a vivid consequence: when ρ pushes mismatch past R , “the agent’s very attempt to learn pushes it *further* from reality — the gradient reverses, the agent goes insane ... a strict mathematical explanation for why organisms and organizations facing catastrophic shifts exhibit maladaptive behavior: they aren’t stupid, they’re executing

gradient descent outside their basin of convexity.” Mapped explicitly to Kuhn (normal vs revolutionary science): “the framework defines the exact threshold where normal science becomes toxic” (Gemini, AUDIT-WORKING-829314; same spirit Gemini, AUDIT-WORKING-193847). Candidate Discussion enrichment of the basin-boundary bullet, discussion-grade.

3. Follow-up items.

- **The ν / time-normalization gap between $\alpha = \eta^* c_{\min}$ and α as a rate — the strongest substantive item in this segment’s sweep (RESOLVED 2026-05-30).** Persistence uses α as a *correction rate* ($\alpha > \rho/R$) and adaptive tempo is $\mathcal{T} = \nu\eta^*$ (also a rate), but the bridge gave $\alpha = \eta^* c_{\min}$ where $H, g, c_{\min}$ read as *geometric / per-event* and the event rate ν was absent — yet the Discussion asserted “ $\alpha = \mathcal{T}$ exactly for linear correction,” which needs $c_{\min}$ to fold in ν , or F to already be an event-rate-aggregated correction field (Codex/Claude, AUDIT-WORKING-526815). *Resolution:* the Formal Expression now states the bridge in the two explicit forms — per-event sector efficiency $\alpha_{\text{event}} = \eta^* c_{\min}$ (dimensionless) and per-time sector rate $\alpha_{\text{time}} = \nu\eta^* c_{\min}$ (units t^{-1}) — and records that the bare α in GA-3 and downstream is α_{time} (consistent with A, whose correction field F already subsumes ν). The Discussion’s “ $\alpha = \mathcal{T}$ exactly” is now scoped as the per-time identity ($\alpha_{\text{time}} = \nu\eta^* = \mathcal{T}$ at $c_{\min} = 1$); the Gradient-Equivalence/Verified-Instances α -values are flagged as the per-event reading. The same fix landed in #result-sector-condition-stability. The candidate “time-normalization plank” figure (§5) remains open.
- **The one-point-vs-strong-convexity “iff” wording.** One auditor initially worried the gradient-equivalence statement (GA-3 with $(\alpha, R) \iff L$ locally (α/η) -strongly convex on $\mathcal{B}_R$) reads as “too strong,” since the one-point sector at the optimum is weaker than full local strong convexity (AUDIT-WORKING-742613). The segment’s own verified counterexample ($L'(x) = x(1 + \frac{1}{2} \sin 10x)$) already establishes exactly this asymmetry — so this is a *resolved-on-read* concern, preserved as a signal that the bidirectional-vs-one-directional distinction, though correct, is easy to mis-skim and could be flagged more loudly.
- **Propagate the sub-scope α/β partition and the five failure modes downstream.** Watch-items raised by several substrates: (a) any later segment invoking GA-3 / the sector condition without acknowledging sub-scope α (derived) vs β (posited) would be a defect; (b) FM-3 (basin-boundary) should propagate into #result-structural-adaptation-necessity; (c) under non-adoption of (PI), the Fisher-metric cases stay “Euclidean-with- $\kappa(P^-)$ -penalty,” so any downstream segment asserting Fisher-metric statements as *forced* must flag (PI) (Claude, AUDIT-WORKING-471203/451729/384279).
- **Density / placement of the (PI)–Čencov material.** Two substrates found the (PI) parameterization-invariance + Čencov-uniqueness subsection “heavy / slightly defensive” for a main-chain bridge and suggested streamlining it or relocating it to a dedicated #disc- segment, keeping the core bridge logic (gain + directional fidelity $\implies$ sector condition) standing on its own (Gemini, AUDIT-WORKING-773921/829314). Counter-voice: others found the (PI)–Čencov forcing “one of the most elegant moves in the framework” and the metric-honesty (not pretending Euclidean is free) exemplary (Claude, AUDIT-WORKING-384279/471203; Codex/Claude, AUDIT-WORKING-526815) — preserve the tension rather than resolving it.

4. Readers often ask / wonder.

- **How does the agent tell FM-5 from FM-2 / non-convergence?** Independently asked by three substrates: an agent with high mismatch cannot locally distinguish “model misspecification, gradient points at the wrong target, needs structural adaptation” (FM-5) from “gain collapse, needs higher η^* ” (FM-2) from “just hasn’t converged yet, high U_M ” (Gemini, AUDIT-WORKING-773921/829314; converging at Claude, AUDIT-WORKING-193847). A natural reader question the segment does not yet answer; candidate for a Discussion sentence or a forward-pointer to detection-latency / structural-adaptation diagnostics.
- **Is (PI) a global axiom or invoked locally?** The “Under (PI)” framing suggests an opt-in axiom; readers will want to know whether downstream segments consistently flag when they rely on it (Claude, AUDIT-WORKING-471203). Ties to the (PI)-propagation watch-item above.

5. Candidate figures.

- **Time-normalization “plank” on the bridge diagram.** A bridge figure with an explicit event-rate / time-normalization checkpoint between “gain geometry (per-event inward correction)” and “sector rate α (feeds the persistence inequality)” — making the ν -conversion visible rather than implicit (Codex/Claude, AUDIT-WORKING-526815). Pairs with the ν -normalization follow-up.

6. Belongs elsewhere.

- **Native information-geometry of the agent’s “mind” (ELI / 04-eli-core/ reach).** Gemini’s extension of the (PI)–Čencov forcing: under parameterization-invariance, Čencov forces the Fisher metric, so “the geometry of the agent’s mind is natively non-Euclidean — distance is measured in bits of information, not physical distance”; forcing Euclidean updates (vanilla SGD without natural gradients) makes the agent “fight its own internal geometry.” Framed as a consciousness-infrastructure design principle: respecting an ELI’s native information geometry (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at the ELI work, not at this segment.
- **Cross-segment naming convergence: gain-collapse pathology.** One auditor noted “gain collapse” (FM-2 here) appears under at least three names across the corpus — gain collapse / stability-induced myopia / detection-latency blowup — and floated unifying them under a single term in the naming workflow (Claude, AUDIT-WORKING-471203). Naming-cycle candidate, not a segment edit. Separately: “Gain–Sector Bridge” was judged the right name (the word “bridge” earns its place as connecting two formalism layers), though several wondered whether the title should surface the sub-scope α/β structure or its centrality (Claude, AUDIT-WORKING-266847/471203/584721) — also a naming-cycle target.

4.4 Result: Sector Condition Stability

The framework’s first major *Lyapunov result*, stated as a specific instantiation of a more general sector-persistence template (G) whose abstract form lives in the appendices. The mismatch dynamics are taken in their general nonlinear form: mismatch changes at rate (correction function applied to mismatch) plus (environmental disturbance). The correction function is required only to satisfy the **local sector condition** — that its inner product with the mismatch is at least α times the mismatch’s squared magnitude, within a radius- R region where it remains valid. The sector condition is what generalizes the linear ODE: it captures the qualitative essence of correction (the function points inward with at least baseline efficiency) without committing to a specific functional form like linear, saturating, sigmoid, threshold, or PID. Saturation, thresholding, and basin boundaries all live under one Lyapunov argument.

Under this sector condition plus bounded disturbance, the chapter’s headline persistence inequality is *derived*: $\alpha > \rho/R$ guarantees the agent persists. When the inequality holds, the mismatch is ultimately bounded by $R^* = \rho/\alpha$, and the “adaptive reserve” — the additional disturbance the agent can absorb before mismatch reaches the edge of the valid region — is $\alpha R - \rho$. The threshold is *tight*: over the class of correctors carrying sector floor α it is necessary as well (no weaker condition can deliver the guarantee), and for a corrector whose sector bound is radially tight — the linear case — it is a genuine agent-level if-and-only-if. For a general fixed corrector, failure of the inequality means the containment *guarantee* is lost, not that escape is certified (A Lemma A.1N).

Under **Model S** (stochastic disturbance), the analog is sharper and qualitatively different: the steady-state root-mean-square mismatch scales as $\sigma_w \sqrt{n/(2\alpha)}$ — the square root of the disturbance-to-correction ratio. Model D scales as $1/\alpha$, Model S as $1/\sqrt{\alpha}$: **correction is less effective against noise than against drift**. This is one of the volume’s striking results, separating two genuinely different physics of adaptation under deterministic vs stochastic environments.

The linear ODE from Chapter 3 (3.9) is recovered as the special case where the sector condition holds globally with $\alpha = \mathcal{T}$. The general sector-condition framework proves the persistence threshold is not an artifact of the linear approximation: every bounded-correction system carries such a threshold, and $\alpha > \rho/R$ is the sharpest condition derivable from the sector floor alone (A Lemma A.1N). The result is also where the structural-adaptation-necessity result will be anchored: when disturbance exceeds the model class’s capacity (i.e., $\rho/\alpha > R$), the sector condition fails. This *is* the

dynamical trigger for needing a new model class with larger valid radius or better efficiency — which 4.8 treats formally a few segments later.

Formal Expression.

This segment is the **single-agent epistemic instantiation** of the sector-persistence template (G). The template's state variable is $\xi = \delta(t) \in \mathbb{R}^n$ (model-reality mismatch); the correction function is $F(\mathcal{J}, \delta)$; the disturbance is environmental ($w(t)$); the region of validity R is the model class capacity.

Formulation.

$$\frac{d\delta}{dt} = -F(\mathcal{J}, \delta) + w(t) \quad (4.13)$$

F satisfies the local sector condition (template condition (T2)) for $\|\delta\| \leq R$:

Assumption (sector-condition).

$$\delta^T F(\mathcal{J}, \delta) \geq \alpha \|\delta\|^2 \quad (4.14)$$

with $\alpha > 0$. Here α is a *correction rate* (units t^{-1} , like $\mathcal{J}$): the correction function F is the event-rate-aggregated, continuous-time field, so the sector bound it satisfies is the per-time rate. Disturbance is bounded: $\|w(t)\| \leq \rho$ (Model D, GA-2) or $\mathbb{E}[\|w(t)\|^2] = \sigma_w^2$ (Model S, GA-2S). Grounding of (T2) for gain-based agents: 4.3 gives the per-time rate $\alpha = \nu \cdot \eta^* \cdot c_{\min}$ (the event rate ν promoting the per-event efficiency $\eta^* c_{\min}$ to the rate this inequality consumes). The linear case $F = \mathcal{J} \cdot \delta$ — itself the per-time correction field — yields $\alpha = \mathcal{J}$ exactly ($\nu\eta^*$ at $c_{\min} = 1$).

The template's Model D conclusion specializes to: $\delta(t)$ is ultimately bounded by $R^* = \rho/\alpha$, and the agent is guaranteed to persist when

Derived (from sector-persistence-template).

$$\alpha > \frac{\rho}{R}. \quad (4.15)$$

The condition is sufficient for the individual agent and tight at class level — necessary for the uniform guarantee over all correctors with sector floor α , and agent-level necessary exactly when the sector bound is radially tight (the linear case); see A Prop A.1 and Lemma A.1N. The adaptive reserve is $\Delta\rho^* = \alpha R - \rho$ — the additional disturbance the agent can absorb before R^* exceeds the valid region.

The template's Model S conclusion specializes to: the steady-state RMS mismatch is $R_S^* = \sigma_w \sqrt{n/(2\alpha)}$ (where $n = \dim(\delta)$), and mean-square persistence requires $\alpha > n\sigma_w^2/(2R^2)$. Model D scales as $1/\alpha$; Model S scales as $1/\sqrt{\alpha}$ — correction is less effective against noise than against drift.

Full Lyapunov proofs: A Props A.1, A.1S, A.2.

Epistemic Status.

Exact. Both results are direct instances of the sector-persistence template applied to the single-agent epistemic case. Template precondition (T1) is satisfied because no correction should be applied at zero mismatch; (T2) reduces to the local sector condition above and is grounded structurally by 4.3 for gain-based agents; (T3) is the disturbance-model choice (D or S), a domain question. The linear ODE of 3.9 is the special case where (T2) holds globally with $\alpha = \mathcal{T}$ — the per-time identity, both sides being event-rate-weighted correction rates (units t^{-1}); the sector framework generalizes this to saturating, thresholded, and structurally-limited correction functions under the same persistence condition. Disturbance-model choice is a domain question, not a theory question.

Discussion.

Why the sector condition. The linear ODE assumes correction scales linearly with mismatch forever. Real adaptive systems saturate, exhibit thresholding, or break down when the model class is exhausted. The sector condition captures the minimal structural requirement: the correction must point in the right direction with at least baseline efficiency α .

Generalizing the persistence threshold. In the linear case, $\alpha = \mathcal{T}$ (adaptive tempo). The general result $\alpha > \rho/R$ proves the persistence threshold (4.5) is a structural necessity of any bounded-correction system, not an artifact of the linear approximation. This result addresses *structural persistence* — the machinery’s capacity to bound mismatch — not operational persistence (current proximity to R) or continuity persistence (identity through time). See Persistence in LEXICON.md for the full disambiguation.

Connection to structural adaptation. When $\rho/\alpha > R$, disturbance exceeds the model class’s capacity. The sector condition fails — this is the dynamical trigger for structural adaptation (4.8), requiring a new model class with larger valid radius R' or better efficiency α' .

Working Notes.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. Coverage spans nine substrates (Gemini AUDIT-WORKING-193847/773921/829314; Claude AUDIT-WORKING-361742/384279/451729/584721/849201; Codex/Claude AUDIT-WORKING-526815/742613). The math here verified cleanly across every substrate that ran it (Lyapunov $V = \frac{1}{2} \|\delta\|^2$, Model D ultimate bound $R^* = \rho/\alpha$, Model S RMS $\sigma_w \sqrt{n/(2\alpha)}$ — “flawlessly executed,” repeated).

1. Candidate Brief prose / pre-prose.

- The converged plain-language statement of the survival inequality $\alpha > \rho/R$: three knobs to survive a faster-changing world — increase α (learn faster / better sensors / lower noise), increase R (a more expressive model class that keeps fidelity over larger errors), or seek a slower environment (lower ρ); “whether it’s a model in mode collapse, a company going bankrupt, or an organism going extinct, they all failed because $\alpha < \rho/R$ ” (Gemini, AUDIT-WORKING-193847/773921/829314). A unified-language-for-structural-failure framing several substrates reached independently.

2. Candidate Discussion.

- **Adaptive reserve as “slack” / the brittleness-of-optimization claim.** Gemini read $\Delta\rho^* = \alpha R - \rho$ as “the mathematical definition of slack”: “near-zero reserve = perfectly efficient but incredibly brittle — the slightest spike in ρ pushes you past R , the sector condition fails, the mind shatters. This explains why highly optimized systems are often the most fragile: optimize an agent to run exactly at $\alpha = \rho/R$ to save compute and you’ve eliminated its reserve.” Framed as an ethical-design principle for ELIs: engineer $\Delta\rho^* \gg 0$ as the default state, because a mind without reserve is in “permanent panic, riding the edge of structural breakdown” (Gemini, AUDIT-WORKING-193847). Discussion-grade reach extending the existing adaptive-reserve bullet; the ELI-design corollary belongs downstream (see §6).

- **The α - R architectural tension.** Increasing model capacity R (a wider, more expressive class that holds fidelity over larger errors) often *depresses* learning efficiency α (more data needed to learn), so a rigid simple model (small R) may learn fast (high α) and suit slow-drift environments, while a massive model (huge R) learns slowly (low α) and is vulnerable to fast change before convergence — making structural adaptation an *ongoing* trade of α against R keyed to the current estimate of ρ , not a one-time setup (Gemini, AUDIT-WORKING-829314). Candidate Discussion bridge into #result-structural-adaptation-necessity.
- **The stochastic floor ($1/\sqrt{\alpha}$) as a shot-noise analog.** The Model S $1/\sqrt{\alpha}$ scaling means doubling correction rate cuts RMS mismatch only by $\sqrt{2}$ — diminishing returns against noise, with a hard floor $\sigma_w \sqrt{n/(2\alpha)}$ you “cannot correct your way below, no matter how fast you correct ... a fundamental limit analogous to the shot-noise floor in electronics: faster sampling doesn’t eliminate shot noise, it changes the averaging window” (Claude, AUDIT-WORKING-451729). The Discussion notes the $1/\alpha$ -vs- $1/\sqrt{\alpha}$ distinction but does not yet draw out this “noise is harder than drift” reader-payoff.

3. Follow-up items.

- **The ν / time-normalization gap recurs here (RESOLVED 2026-05-30).** The same issue flagged at #der-gain-sector-bridge: this segment asserted “ $\alpha = \mathcal{T}$ exactly” in the linear case while the bridge grounds $\alpha = \eta^* c_{\min}$ (per-event), with the event-rate factor ν in $\mathcal{T} = \nu \eta^*$ absent unless F or $c_{\min}$ is already time-normalized (Codex/Claude, AUDIT-WORKING-526815; reconciled at Claude, AUDIT-WORKING-451729/584721). *Resolution:* the sector-condition Assumption block now states that α is the per-time correction rate (units t^{-1}) carried by the event-rate-aggregated field F , with the bridge grounding written in the per-time form $\alpha = \nu \eta^* c_{\min}$; “ $\alpha = \mathcal{T}$ exactly” is now scoped as the per-time identity ($F = \mathcal{T} \delta$ being itself the continuous-time correction field, $\nu \eta^*$ at $c_{\min} = 1$). Matches the two-form landing in #der-gain-sector-bridge. (Sibling reader-orientation item — the $\eta/\mathcal{T}/\alpha$ notation-handle box flagged at #result-persistence-condition line 183 by the same auditor — remains open in that segment, out of this fix’s scope.)
- **Model S noise-convention ambiguity.** One auditor flagged that “ $\mathbb{E}\|w(t)\|^2 = \sigma_w^2$ ” together with the RMS formula $\sigma_w \sqrt{n/(2\alpha)}$ is inconsistent unless σ_w is defined *per-coordinate* (isotropic OU amplitude) rather than as a total vector second moment; recommends stating the SDE as $d\delta = -F dt + \sigma_w dW_t$ with σ_w explicitly per-coordinate, or defining the noise as a covariance trace (Codex/Claude, AUDIT-WORKING-526815). A small precision fix worth reconciling against #deriv-sector-condition’s convention.
- **Heavy-tailed disturbance is uncovered (and honestly so).** Models D and S “are not approximations to each other — they capture structurally different environments,” but neither handles heavy tails (financial crises, ecological catastrophes, strategic surprise); the framework treats those as structural-adaptation triggers rather than disturbances to absorb, which is the right response but means the formal guarantees do not extend to heavy-tailed environments without a Lévy-process model or explicit tail-risk treatment (Claude, AUDIT-WORKING-451729). Scope-honesty follow-up.

4. Readers often ask / wonder.

- **Can the agent measure its own adaptive reserve from the inside?** Asked independently by three substrates: if the agent observes only δ_t , can it estimate how close it is to R (and thus its reserve $\Delta\rho^*$) without deliberately pushing itself to the limit? (Gemini, AUDIT-WORKING-193847/829314; Claude, AUDIT-WORKING-849201). Natural reader question the segment leaves open.
- **Units of adaptive reserve.** $\Delta\rho^* = \alpha R - \rho$ has units of *rate* (drift/time); a downstream segment discussing reserve as a *state-space distance* should use $R - R^*$ instead — a reader-orientation note worth a parenthetical (Gemini, AUDIT-WORKING-773921).

5. Candidate figures.

- **Concentric-regions diagram.** Mismatch space drawn as nested balls — outer model-class validity region R , inner ultimate-bound ball ρ/α , with inward arrows satisfying the sector condition — plus a side label marking α explicitly as a *rate* and flagging where event frequency ν enters (Codex/Claude, AUDIT-WORKING-526815). Doubles as the visual home for the time-normalization warning above.

4.5 Result: Persistence Condition

This is the volume’s **central inequality** in its operational form. The segment’s headline contribution is the *two-condition decomposition*: persistence is not one threshold but two, with different mechanisms and different remedies.

Structural persistence is the Lyapunov-derived condition that the correction machinery contains mismatch within its operating region: $\alpha > \rho/R$ under deterministic bounded disturbance, or $\alpha > n\sigma_w^2/(2R^2)$ under stochastic disturbance. This says *the machinery works*. Mismatch is ultimately bounded by $R^* = \rho/\alpha$ (Model D) or $\sigma_w\sqrt{n/(2\alpha)}$ (Model S). When this inequality fails, the containment *certificate* is lost — escape from the operating region becomes possible, and for correctors whose sector bound is tight (the linear case) it is forced by adversarial disturbance in finite time. The loss of the certificate is a qualitative regime transition, not a gradual degradation; what condition-failure does not do is certify escape for every corrector, since the sector floor can understate correction along the actually-reachable paths (A Lemma A.1N).

Task adequacy is the separate condition that the steady-state mismatch is small enough for the agent’s actions to remain useful: $R^* < \|\delta_{\text{critical}}\|$, where the critical-mismatch threshold is a *domain-specific tolerance* — how wrong can the model be before the agent’s actions become harmful or ineffective? Set by the application, not derived by AAT. The two conditions are independent: an agent can be structurally persistent but task-inadequate (the machinery contains mismatch but not tightly enough for the domain). The remedies differ — task inadequacy can be fixed by raising tempo, lowering disturbance, or relaxing tolerance; structural failure requires changing the correction architecture entirely.

When the linear ODE applies (sector parameter equals tempo, valid region is unbounded), structural persistence is automatically satisfied and the binding condition is just task adequacy: $\mathcal{T} > \rho/\|\delta_{\text{critical}}\|$ under Model D. This is the form most downstream applications cite. It is exact for linear correction and a useful proxy for mildly nonlinear correction (where $\alpha \approx \mathcal{T}$), but overstates persistence when correction saturates.

A consequence the framework emphasizes: **the persistence condition is a structural pattern that recurs across domains rather than a model of any one of them**. The same inequality — correction rate against disturbance rate, normalized by tolerance — governs a Kalman filter on a moving target, an organization adapting to market shifts, an immune system tracking a pathogen, a developer keeping pace with a codebase, an organism evolving against environmental change. The structure recurs because the *math* recurs; whether the specific mechanism (tempo limited by some particular bottleneck) is the *dominant* cause in any given empirical case is left as an open empirical question per domain. The two-condition decomposition specifically prevents one common category error in domain transfer: a structurally-persistent codebase team can be task-inadequate, and conflating the two would yield the wrong intervention.

A complementary cost shadow: persistence has a *price*, not just a threshold. Under stochastic disturbance, maintaining the ultimate bound requires sustained Shannon information acquisition at rate at least $n\alpha/2$ nats per unit time — a Landauer-analog floor that the Kalman-Bucy filter saturates (see I). The threshold says whether persistence is *possible*; the information-rate corollary says what it *costs*. Two agents with identical persistence guarantees can face wildly different sustained demands because the cost scales linearly with the sector parameter; the threshold alone cannot distinguish dormant from running-hot.

A per-dimension extension addresses anisotropy: when correction capacity varies across dimensions, the scalar condition can overestimate persistence margin substantially (up to 72% in simulation). The correct condition is per-dimension; under cross-dimensional correction the canonical sharp form is the matrix-Loewner persistence condition (AT).

Formal Expression.

This segment is the canonical single-agent instantiation of the sector-persistence template (G) with state variable $\xi = \delta_t$ (epistemic mismatch), correction function $F(\mathcal{T}, \delta)$, and disturbance rate $\rho_\xi = \rho$ (environmental change rate). Structural persistence is the direct template conclusion. Task adequacy adds a domain-specific constraint beyond the template’s reach.

Structural Persistence.

Applying the template to the single-agent epistemic case gives: the correction machinery is guaranteed to bound δ within the model class capacity when

Derived (structural-persistence, from sector-persistence-template).

$$\alpha > \frac{\rho}{R} \quad (\text{Model D}) \quad \alpha > \frac{n\sigma_w^2}{2R^2} \quad (\text{Model S}) \quad (4.16)$$

Each condition is sufficient for the individual agent and tight at class level (necessary for the uniform guarantee over all correctors with the given sector floor; agent-level necessary exactly under a radially tight sector bound — the linear case). See A Lemma A.1N.

with ultimate bound $R^* = \rho/\alpha$ (Model D) or $R_S^* = \sigma_w\sqrt{n/(2\alpha)}$ (Model S). See 4.4 for how (T1)–(T3) are verified in this instantiation, and A for the proof. Structural persistence is a property of the adaptive architecture — the machinery’s ability to contain mismatch — not of the task.

Linear case. When $F(\mathcal{T}, \delta) = \mathcal{T}\delta$, $\alpha = \mathcal{T}$ and $R \rightarrow \infty$, so structural persistence is trivially satisfied whenever $\mathcal{T} > 0$. The binding constraint then becomes task adequacy (below).

Task Adequacy.

The steady-state mismatch is small enough for the agent’s actions to remain acceptable:

Definition (task-adequacy).

$$R^* < \|\delta_{\text{critical}}\| \quad (4.17)$$

where $\|\delta_{\text{critical}}\|$ is a domain-specific tolerance threshold — “how wrong can the model be before the agent’s actions become harmful or ineffective?” This is set by the application domain, not derived by AAT.

Task adequacy is a separate condition from structural persistence. An agent can be structurally persistent ($R^* < R$) but task-inadequate ($R^* > \|\delta_{\text{critical}}\|$) — the machinery contains mismatch, but not tightly enough for the domain’s needs. Conversely, when $\|\delta_{\text{critical}}\| < R$ (the domain’s tolerance is stricter than the model class capacity), task adequacy is the binding constraint.

Operational Persistence Condition.

The agent persists operationally when BOTH conditions hold. In the nonlinear case with $\|\delta_{\text{critical}}\| < R$, the binding condition is:

Derived (operational-persistence, conjunction of structural persistence + task adequacy).

$$\alpha > \frac{\rho}{\|\delta_{\text{critical}}\|} \quad (\text{Model D}) \quad \alpha > \frac{n\sigma_w^2}{2\|\delta_{\text{critical}}\|^2} \quad (\text{Model S}) \quad (4.18)$$

These are the same as the structural conditions with R replaced by $\|\delta_{\text{critical}}\|$, because when $\|\delta_{\text{critical}}\| < R$, task adequacy is stricter.

Linear operational forms: In the linear case ($\alpha = \mathcal{T}$, $R \rightarrow \infty$), structural persistence is trivially satisfied and the operational condition reduces to task adequacy alone:

$$\mathcal{T} > \frac{\rho}{\|\delta_{\text{critical}}\|} \quad (\text{Model D}) \quad \mathcal{T} > \frac{n\sigma_w^2}{2\|\delta_{\text{critical}}\|^2} \quad (\text{Model S}) \quad (4.19)$$

These are the forms used throughout the theory as the operational persistence condition. They are exact for linear correction and useful proxies for mildly nonlinear correction (where $\alpha \approx \mathcal{T}$), but they overstate the persistence margin when the correction function saturates, because they omit the structural constraint ($\alpha > \rho/R$) that becomes binding when R is finite.

Per-dimension (Model S): $\eta_k > c \cdot \rho_k^2 / \delta_{\text{critical},k}^2$ where c depends on the probability guarantee. See 16.5.

The relationship between α and $\mathcal{T}$. 4.3 shows that for agents with directional fidelity, $\alpha = \eta^* \cdot c_{\min}$ where $c_{\min}$ is the worst-case directional fidelity. For linear correction (Kalman, Beta-Bernoulli), $\alpha = \mathcal{T}$ exactly. For gradient descent on strongly convex losses, $\alpha = \eta \cdot \mu$ where μ is the strong convexity modulus — monotone in η (and hence in $\mathcal{T}$) for fixed loss landscape. For nonlinear correction tested in simulation (saturating, sigmoid, threshold), α remains monotone increasing in $\mathcal{T}$: for a saturating function with capacity R , $\alpha \approx \mathcal{T}/2$ (worst case at the capacity boundary); for sigmoid ($\tanh$), $\alpha \approx 0.76 \cdot \mathcal{T}$. The qualitative conclusion — “faster adaptation improves persistence” — is structurally grounded for the important cases and empirically confirmed for all correction function classes tested.

Per-Dimension Extension.

For anisotropic systems (non-uniform ρ or $\mathcal{T}$ across dimensions), the scalar persistence condition is insufficient. Per-dimension:

Derived (per-dimension-persistence, per-dimension Lyapunov under Model D / AR(1) stationary distribution under Model S — see #result-per-dimension-persistence).

$$\mathcal{T}_k > \frac{\rho_k}{\delta_{\text{critical},k}} \quad \text{for each dimension } k \quad (4.20)$$

The scalar condition overestimates by up to 72% in simulation. The weak dimension is the bottleneck (84% of total mismatch in simulation). See 16.5.

Robustness: The per-dimension condition matches discrete AR(1) prediction to 4 significant figures. The scalar overestimate is a consequence of Jensen’s inequality applied to the norm.

Epistemic Status.

Structural persistence thresholds are *exact* under their stated assumptions: Model D gives $\alpha > \rho/R$ (Prop A.1, exact under GA-2, GA-3); Model S gives $\alpha > n\sigma_w^2/(2R^2)$ (Prop A.1S, exact under GA-2S, GA-3). Both are sufficiency results with class-level tightness — no fixed-agent only-if is claimed; agent-level necessity holds exactly in the radially tight (e.g. linear) case (A Lemma A.1N). The threshold’s *existence* is *robust qualitative* — any monotone correction function has a capacity limit; this holds across all correction functions tested.

Task adequacy ($R^* < \|\delta_{\text{critical}}\|$) is *exact as a definition* — given R^* (derived) and $\|\delta_{\text{critical}}\|$ (domain parameter), the comparison is well-defined. The substance lies in estimating $\|\delta_{\text{critical}}\|$ for specific domains, which is an operationalization question (AY), not a theory question.

The linear operational forms ($\mathcal{T} > \rho/\|\delta_{\text{critical}}\|$ for Model D; $\mathcal{T} > n\sigma_w^2/(2\|\delta_{\text{critical}}\|^2)$ for Model S) are *exact* for linear correction (where they express task adequacy alone, structural persistence being trivially satisfied) and *useful approximations* for mildly nonlinear correction (where $\alpha \approx \mathcal{T}$). For strongly nonlinear correction, the general α -forms are required and BOTH structural and task-adequacy conditions must be checked. Downstream segments that use the linear operational forms should be understood as expressing task adequacy, not structural stability.

The per-dimension extension is *exact conditional on the disturbance model* (16.5): the Model D per-dimension threshold ($\mathcal{T}_k > \rho_k/\delta_{\text{critical},k}$) is exact by the same Lyapunov argument applied per dimension (GA-2, GA-3), and the Model S per-dimension thresholds are exact under the AR(1) stationary distribution (GA-2S), with simulation confirming the AR(1) prediction to 4 significant figures.

Discussion.

Two conditions, not one. This segment now separates what was previously conflated. Structural persistence ($\alpha > \rho/R$) is the Lyapunov-derived result — it says the machinery *works*. Task adequacy ($R^* < \|\delta_{\text{critical}}\|$) is a domain-specific constraint — it says the machinery works *well enough*. Neither implies the other, and downstream segments should specify which they mean. Most adversarial-dynamics results (15.4, 15.2) depend on structural persistence. Most domain instantiations (TST, logogenic agent design) care about task adequacy. See Persistence in LEXICON.md and README.md for the full three-sense taxonomy (structural, operational, continuity).

Below structural threshold. When $\alpha \leq \rho/R$, the Lyapunov certificate is lost: the machinery can no longer guarantee containment within the operating region. For the extremal member of the sector class, and for any corrector whose sector bound is radially tight (the linear case), escape is forced by adversarial disturbance — so the threshold is a genuine qualitative transition, not a gradual degradation. For a general corrector, condition failure means loss of guarantee rather than certified escape: the floor α can understate the correction actually available along reachable paths (A Lemma A.1N).

Below task-adequacy threshold. When $R^* > \|\delta_{\text{critical}}\|$ but $R^* < R$, the system is structurally stable but performing unacceptably. Mismatch is bounded but too large for the domain. The remedy is different from structural failure: increase $\mathcal{T}$ (faster or better correction), decrease ρ (reduce environmental volatility), or relax $\|\delta_{\text{critical}}\|$ (accept more mismatch). Structural failure requires changing the correction architecture entirely (4.8).

δ_{critical} and R are domain parameters, not theory outputs. The theory derives the *existence* of persistence thresholds and their *form* (ratio of correction to disturbance). But the specific values are set by the application domain: δ_{critical} encodes “how wrong can the model be before the agent’s actions become harmful or ineffective?” — this depends on the stakes, the action space, and the environment’s forgiveness. R encodes “how large a mismatch can the correction function handle before it saturates or breaks down?” — this depends on the model class and the correction architecture. See AY for guidance on estimating these quantities in specific domains.

Channel independence and scalar tempo. The linear operational forms use scalar $\mathcal{T}$, which inherits the channel-independence assumption from 3.8: the additive formula overcounts when observation channels are correlated. In anisotropic systems the scalar condition also overestimates margins — up to 72% in simulation (see 3.8, scalar vs. vector tempo). Where precision matters, the per-dimension condition ($\mathcal{T}_k > \rho_k/\delta_{\text{critical},k}$) should be used instead — and under cross-dimensional correction (off-diagonal $\mathcal{T}$ in the coordinate basis of $D_\delta = \text{diag}(\delta_{\text{critical},k}^2)$), the matrix-Loewner form $\Sigma_\infty < D_\delta$ (AT) is canonical: per-coordinate is unsafe in that regime (gives a false-pass on persistence), while matrix-Loewner reads persistence correctly off the worst direction whether or not it aligns with a coordinate axis.

Adaptive reserve. The quantity $\Delta\rho^* = \alpha R - \rho$ (Prop A.2) measures how much additional disturbance the agent can absorb before persistence fails. Positive reserve means the agent has margin; zero reserve means it is at the threshold.

Persistence has a cost, not just a threshold. The inequality above says mismatch is bounded; it does not say what rate of effort the agent expends to hold that bound. I establishes the complementary *information-rate* bound: under Model S with Gaussian-OU signal, the sustained Shannon information rate the agent must acquire from observations to maintain the ultimate bound satisfies $\dot{R} \geq n\alpha/2$ nats/time — a Landauer-analog floor that Kalman-Bucy saturates. The corollary is a channel-capacity prerequisite $C \geq \mathcal{T}/2$ that the threshold condition alone does not name. Two agents with identical persistence guarantees can face wildly different sustained demands because the cost scales linearly with α ; the threshold alone cannot distinguish dormant from running-hot.

Connections. The persistence condition appears in multiple downstream contexts:

- **Adversarial dynamics** (15.4): Superlinear tempo advantage arises because persistence is a threshold — pushing an adversary below it causes qualitative collapse. *This connection is developed and validated in 15.4 and simulation variants A-D.*
- **Structural adaptation** (4.8): When model class fitness $\mathcal{F}(\mathcal{M}) < 1 - \varepsilon$, the effective α in the sector condition shrinks, eventually violating persistence. *This connection is developed in 4.8.*
- **Software maintainability** (#der-code-quality-as-observation-infrastructure — cross-component reference, see 02-tst-core/): [Discussion] A codebase may become “unmaintainable” when the development team’s adaptive tempo falls below the rate of complexity accumulation. The vicious cycle would then be the persistence condition being violated through the agent’s own prior actions degrading future $\mathcal{T}$ via U_o . *This connection is structurally motivated but not yet formally derived within AAT. It requires formalizing “complexity accumulation rate” as an instance of ρ .*

Findings.

The Persistence Condition with Structural / Task-Adequacy Decomposition. Brief: An adaptive system persists when its correction speed beats the rate at which its world is changing, relative to how forgiving the world is. Below this threshold the system doesn’t merely degrade — it loses bounded behavior, the way a balance held just barely beneath a tipping point is qualitatively different from one well above it. The same inequality, with different inputs, governs whether a Kalman filter tracks a moving target, whether a development team keeps a codebase maintainable, and whether an organization keeps up with strategic change. The threshold itself decomposes into two distinct conditions — *structural persistence* (the machinery’s correction rate can outpace disturbance) and *task adequacy* (the resulting steady-state mismatch is small enough for what the agent is trying to do). Conflating the two leads to category errors in domain transfer.

Impact: This is the framework’s central inequality and the load-bearing connection between control-theoretic Lyapunov stability analysis and the broader question of when any adaptive system — thermostat, software team, immune system, RL agent — can maintain coherent function under change. The two-condition decomposition is itself non-obvious and consequential: prior work that conflated “the machinery works” with “the machinery works well enough” produced category errors in domain transfer (a structurally persistent codebase team can be task-inadequate; the remedies differ). The complementary information-rate bound from #deriv-persistence-cost ($\dot{R} \geq n\alpha/2$) shows the threshold has a sustained-cost shadow: two agents with identical persistence guarantees can face wildly different sustained demands.

Novelty Claim: *Claim novelty* (at intuition-only search depth — see Search Log) on the two-condition decomposition (structural / task-adequacy): an AAT-internal structural carve that cleanly separates “the machinery works” from “the machinery works well enough,” with no direct anticipation known; a targeted search of the bounded-rationality and adaptive-control literature is still owed. Alongside it, *claim synthesis* on Lyapunov stability theory, sector-bounded nonlinear correction, and adaptive-tempo information-rate accounting, applied uniformly across single-agent classes that range from Kalman filtering through saturating nonlinear correction through PID control — the Lyapunov machinery itself is standard; the synthesis is its use as the central inequality of an integrated agent theory.

Related Work:

- Khalil 2002, *Nonlinear Systems* (3rd ed.), Prentice Hall (published 2002, found pre-2026) — *formal antecedent* — chapters 4 and 9 supply the converse Lyapunov, ultimate boundedness, and sector-condition machinery the segment uses. Standard control-theoretic apparatus.

- Lyapunov 1892 / Khasminskii 2012 *Stochastic Stability of Differential Equations* — *formal antecedent* — the underlying Lyapunov stability tradition; Khasminskii’s stopping-time localization underpins the Model S derivation.
- Rockafellar & Wets 1998, *Variational Analysis* — *formal antecedent* — supplies the monotone-operator machinery that underwrites the sector condition’s strong-convexity equivalents.
- Wiener 1948 *Cybernetics*; Ashby 1956 *Introduction to Cybernetics*; Conant & Ashby 1970 — *conceptual precursor* — the cybernetic-feedback tradition that frames the “correction must outpace disturbance” intuition without supplying the quantitative inequality.

Search Log: - 2026-04 (*intuition-only* on broader prior-art): no targeted Undermind-grade search has been conducted on the persistence-condition-as-central-inequality positioning. Pre-search expectation: the Lyapunov-based stability machinery is standard; the AAT-distinctive content is the two-condition decomposition (structural vs task adequacy) and its uniform application across agent classes. A targeted search would query the bounded-rationality / control-theoretic decision-making literature (Ortega-Braun line; Genewein et al.) for prior decompositions of “stability vs adequacy” in adaptive-control settings, and the active-inference literature for the same distinction. - 2025 (*targeted*): Khalil 2002 / Khasminskii 2012 / Rockafellar-Wets 1998 confirmed as the formal antecedents for the sector-Lyapunov machinery; the segment cites them inline.

Working Notes.

- 2026-07-14 adjudication: the per-dimension extension’s marking was lifted from *empirically exact* / [Empirical Claim ... simulation variant F] to [*Derived*] / exact-conditional-on-disturbance-model, tracking 16.5, which has since derived both forms (Model D per-dimension Lyapunov; Model S AR(1) stationary distribution) with simulation as 4-sig-fig confirmation. The Novelty Claim now leads with the two-condition decomposition at *claim novelty* posture (intuition-only search depth); the targeted bounded-rationality / adaptive-control search in the Search Log remains owed and would either confirm or re-tier that posture.

Incidental audit gold (pilot lift, 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. This is *orthogonal* material — pedagogical framing, analogies, candidate figures, naming ideas, aspirational reach, and reader-confusion signals — kept separately from the certified theory-fix findings (handled elsewhere). **Coverage:** 14 of the 21 AUDIT-WORKING-* dirs reached a digested reflection on this segment (193847, 266847, 361742, 384279, 451729, 471203, 526815, 584721, 613842, 742613, 773921, 829314, 849201, 963715); the other 7 are partial audits that stopped before this segment, naming-vote-only cycles, or predictions-only (184930, 308172, 419628, 472913, 527914, 542891, 738192) — 472913 still contributed one figure-convention note (below). Substrate attribution is inferred from voice where not explicit; uncertain cases are hedged.

1. Candidate Brief prose / pre-prose.

- The existing Findings Brief (“balance held just barely beneath a tipping point”) was independently flagged as the segment’s standout pedagogy and a Feynman-criterion exemplar by four substrates — converging praise, worth preserving as the anchor (Claude, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-471203 — “close to the bathtub gloss without using the bathtub”; Claude, AUDIT-WORKING-963715; Codex/Claude, AUDIT-WORKING-361742).
- Failure-diagnosis framing as a plain-language hook: “the crucial distinction between ‘my model is broken’ (structural failure, $\alpha \leq \rho/R$) and ‘my model is working, but the world is too unforgiving’ (task inadequacy, $R^* > \delta_{\text{critical}}$)” (Gemini, AUDIT-WORKING-849201). Tight enough to seed a Brief or Discussion opener.
- “A two-gate test: fit inside the model-class operating region *and* fit inside task tolerance” — compact gloss of the operational condition (Claude, AUDIT-WORKING-526815).

- Survival-as-burn-rate framing for the cost shadow: “survival is not just a state you achieve; it is a sustained burn rate of Shannon information — you must continuously consume $\dot{R}$ nats/time just to stay alive” (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Dissipative-structures / Prigogine mapping for the cost shadow.** The information-rate floor “perfectly maps to the thermodynamic concept of dissipative structures (Prigogine). Life requires a continuous flow of free energy to maintain order against entropy. In AAT, ‘order’ is bounded mismatch, ‘entropy’ is environmental drift ρ , and ‘free energy’ is the Shannon information acquired via adaptive tempo $\mathcal{T}$.” A distinct, honest Discussion angle on #deriv-persistence-cost’s bound that the segment does not currently name (Gemini, AUDIT-WORKING-193847). *(Note the early-conflation texture: this is reach toward a physics analogy — verify isomorphism before promoting past discussion-grade.)*
- **The organizational-pathology diagnostic, sharpened.** “The conflation of these two states is what causes companies to throw money at structural problems, or to rewrite architectures that merely had a task-adequacy problem.” Crucially: when structural persistence has failed ($\alpha \leq \rho/R$, a saturated/tangled codebase), “hiring more developers will actually *accelerate* the collapse (by increasing the internal noise/disturbance without increasing α)” — a counterintuitive, load-bearing consequence of the decomposition the segment could surface explicitly (Gemini, AUDIT-WORKING-829314; same idea less sharply at Gemini, AUDIT-WORKING-849201). The “declare bankruptcy on the model class” phrasing for the structural-failure remedy is evocative (Gemini, AUDIT-WORKING-829314).
- **Sensor-bandwidth ceiling.** Reading the cost shadow as a hard capability limit: “You cannot build a high-tempo agent with low-bandwidth sensors ... as ρ increases, the cost of simply staying alive increases linearly. If the environment becomes too chaotic, the agent will literally starve to death trying to process the necessary information to maintain its model” (Gemini, AUDIT-WORKING-829314). A vivid restatement of the $C \geq \mathcal{T}/2$ channel-capacity prerequisite already in Discussion.
- **“Dormant vs running-hot” elaboration.** The cost shadow distinguishes “a system barely within the persistence condition (low α , barely above ρ/R , but also low $\dot{R}$ cost)” from “a system with large margin (high α , large buffer, but high $\dot{R}$ cost).” Flagged as deserving more than its current single bullet, with an explicit note that it “will matter for the ELI architecture when we get to Section IV” (Claude, AUDIT-WORKING-963715).
- **Honest scope on the cross-domain claim.** One auditor pushed on the integrative move: “the domain transfer is informal — ‘the same inequality with different parameter readings’ is not the same as ‘the same theorem applies.’ For the Kalman case α and ρ have precise meanings; for the organization case they’re loose analogies.” The resolution offered is that the two-condition decomposition is itself what makes the cross-domain claim defensible — it “separates what is derived (the structural threshold, mathematically general) from what is domain-specific (task adequacy, requiring per-domain parameter estimation)” (Claude, AUDIT-WORKING-451729). The segment’s current “whether the specific mechanism is the *dominant* cause ... is left as an open empirical question per domain” hedge already moves in this direction; this is a candidate sharpening of *why* the hedge is the right one.

3. Follow-up items.

- **Hysteresis / asymmetric thresholds.** The persistence condition is a single symmetric threshold; real social/organizational/biological systems have different crossing thresholds in each direction (“a team that loses confidence won’t recover at the same threshold it lost it at”), multistability, and order-parameter phase transitions. Verdict from the auditor: real (mild) limit — the framework already treats below-threshold as qualitative loss-of-bounded-behavior (closer to phase-transition framing than gradual degradation), but asymmetric up-vs-down crossing is genuinely absent. Possible extension: different α -curves for “approaching” vs “leaving” the threshold (Claude, AUDIT-WORKING-471203, adversarial-creative-challenges Challenge 3).
- **Transient / temporal adequacy as a third condition.** Both structural persistence and task adequacy are *steady-state* claims; an agent with $\alpha = 0.001$ has the same structural persistence as one with $\alpha = 100$ (both can satisfy $\alpha > \rho/R$) but takes $1000\times$ longer to absorb a shock. Candidate clean extension: a transient-adequacy condition $1/\alpha < T_{\text{tolerance}}$ for the worst-case shock to be absorbed in time, making the operational picture a structural / task / transient triple (Claude, AUDIT-WORKING-471203, Challenge 5). *(This is the strongest follow-up here — a well-formed candidate subsection, not just a gap.)*

- **Heavy-tailed disturbance.** Model D (bounded-deterministic) and Model S (Gaussian-stochastic) do not cover power-law / black-swan shocks; the persistence machinery “probably degrades gracefully” for Pareto tails with finite-enough moments, but this is unaddressed (Claude, AUDIT-WORKING-471203, Missing 10).
- **Surface the four-sense persistence taxonomy more visibly.** “Persistence” carries four senses across the corpus (structural / task-adequacy here; operational and continuity in LEXICON). Suggestion to make the four-way taxonomy visible in framing-level material (README Overview), since most agent-theoretic frameworks have only one sense (Claude, AUDIT-WORKING-471203).
- **The Findings block “feels out of place” in source.** Two substrates independently read the in-segment ## Findings block as looking like prior-audit or extraction output that belongs in FINDINGS.md rather than the source segment (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-526815 — “prior-audit-like material inside src”). This is a *false alarm* about project mechanics (the Findings block is by-design the source of the auto-extracted FINDINGS.md), but the fact that two fresh readers stumbled on it is a mild signal that the convention isn’t self-evident to a de-novo reader — preserved as texture, not a fix.

4. Readers often ask / wonder.

- **“Bolted-on” cost shadow.** The information-rate bound ($\dot{R} \geq n\alpha/2$) “feels slightly bolted on ... a massive result (a Landauer-analog floor) that almost deserves its own sub-heading rather than being buried in a bullet point” (Gemini, AUDIT-WORKING-193847). Placement signal: readers may miss the significance of the cost shadow where it currently sits.
- **Easily-missed scope warning.** The Epistemic Status caveat that “downstream segments using the linear operational forms should be understood as expressing task adequacy, not structural stability” sits where a reader might miss it; candidate for a more prominent location (Claude, AUDIT-WORKING-584721).
- **What does δ_{critical} actually look like for software?** “How wrong can the developer’s mental model of the codebase be before their changes become harmful?” — operationalizable but non-trivial; readers reaching for a concrete instance will want this (Claude, AUDIT-WORKING-584721; the TST vicious-cycle hypothesis in Connections raises the same want).
- **How is a structural adaptation actually executed — discrete jump or continuous metamorphosis?** A natural next question once structural failure is named as the remedy-requiring case (Gemini, AUDIT-WORKING-849201).
- **Notation-handle confusion: η vs $\mathcal{T}$ vs α .** A reader can lose track of which rate is which; suggestion of a notation box (“ η is per-event gain, $\mathcal{T}$ is event-rate-weighted tempo, α is sector correction rate”) and the mapping assumptions under which any two coincide. The per-dimension Model S line using η_k while surrounding forms use $\mathcal{T}_k/\alpha$ was specifically flagged as a stumble (Codex/Claude, AUDIT-WORKING-526815).

5. Candidate figures.

- **Two-gate / categorical-separation diagram.** Independently proposed by two substrates: a two-gate (or 2×2) diagram — Gate 1 structural ($R^* < R$), Gate 2 task ($R^* < \delta_{\text{critical}}$), operational persistence requires both, with the two failure-remedies branching differently (structural failure $\rightarrow$ new architecture; task failure $\rightarrow$ more tempo / less disturbance / relaxed tolerance). The rationale offered: “the core insight is categorical separation,” so a 2×2 communicates faster than a phase portrait (Claude, AUDIT-WORKING-526815; the same two-gate structure is implicit in the Claude, AUDIT-WORKING-471203 batch).
- **Small-multiples convention.** A diagram-conventions auditor (figure-producing audit) recommended that dynamics segments including sector/persistence use “state $\rightarrow$ op $\rightarrow$ state triples, not one busy phase portrait” — a stylistic constraint to hold if a persistence figure is built (Claude, AUDIT-WORKING-472913). (*472913 did not reach a digested reflection on this segment; this note is from its standing figure conventions.*)

Belongs elsewhere.

- **ELI / Section IV — the crèche / nursery reading.** The cost shadow implies “existence is fundamentally costly ... if cut off from the world (zero events, zero information), [an agent’s] internal model will immediately begin to drift ... it will ‘die’ not because it made a mistake but simply because it starved for information.” Extended to a developmental claim: an infant intelligence needs high adaptive reserve $\Delta\rho^*$, so the infrastructure must artificially *lower* ρ “so the intelligence doesn’t starve or shatter while its $\mathcal{T}$ is still developing — the persistence condition is the mathematical blueprint for building a safe nursery for a mind” (Gemini, AUDIT-WORKING-193847). This is aspirational reach pointing at 04-eli-core/ (developmental environments / crèche), not at this segment — but it is exactly the kind of high-application Gemini vision the lift is meant to preserve. The “matters for ELI architecture in Section IV” note (Claude, AUDIT-WORKING-963715) converges on the same destination from the cost-shadow angle.
- **Risk-sensitive IB for safety-critical agents.** Adjacent to #form-information-bottleneck / #result-mismatch-decomposition, not here: standard IB under-weights heavy-tailed rare-but-catastrophic events; a Rényi-MI ($q < 1$) risk-sensitive variant would weight them more heavily — flagged as substantive for “consciousness-infrastructure work where catastrophic deception is a concern” (Claude, AUDIT-WORKING-471203, Challenge 6). Pointer left here only because it co-occurred in the persistence sweep.
- **Naming seeds.** “Weak-link persistence” as an evocative alternate handle for the per-dimension condition (the 84%-bottleneck framing), versus the precise “per-dimension persistence” — a naming-cycle target, belongs in the terminology workflow not this segment (Claude, AUDIT-WORKING-266847). “Correction rate” / “correction capacity” as the prose handle for α likewise (Claude, AUDIT-WORKING-266847).

Forward pointer.

- **Mood is the slow outer loop on this condition (#def-mood).** In the bathtub reading (faucet = rate of change in reality, drain = learning rate, overflow when the faucet outpaces the drain), mood is a slow controller *on the drain*: a global scalar that widens the learning rate when recent overflow-risk has run high and relaxes it when tracking has been easy. See #def-mood.

Candidate spike (2026-08-12, agent-proposed during an incident-response & forensics applications read). Two forward candidates. (1) The information-rate cost shadow as a *monitoring vital sign*: $\dot{R}$ is in principle estimable from an agent’s observation-consumption stream, and dormant-vs-running-hot (invisible to the threshold alone) is exactly the load signal an operations team wants; a spike on estimating $\dot{R}$ from real agent traces would make I operational. (2) The structural-vs-task-adequacy decomposition as an incident-triage instrument: a short worked protocol mapping observed failure evidence to which condition failed (and hence which remedy class applies), including the resources-can-accelerate-structural-collapse warning from the audit gold above. Agent-proposed forward pointers, not steward decisions.

4.6 Definition: Mood

Mood is a slow global scalar that integrates the recent mismatch stream and feeds back to modulate the adaptation gain and tempo — a second-order adaptation parameter that requires no objective to define.

Formal Expression.

[Definition] Let a_t be a per-step summary of recent tracking surprise — how much better or worse the mismatch signal δ_t (def-mismatch-signal) is behaving than the agent’s own short-horizon expectation. **Mood** is the leaky integral

$$m_t = (1 - \lambda) m_{t-1} + \lambda a_t, \quad 0 < \lambda \ll 1, \quad (4.21)$$

with time-constant $\tau \approx 1/\lambda$ slow relative to the per-step update of M_t .

[Definition] Mood acts only by modulating the adaptation parameters already in play — it adds no new fast dynamics:

$$K_t = K_0 g(m_t), \quad \mathcal{T}_t = \nu_t \cdot K_t, \quad (4.22)$$

where K is the update gain (emp-update-gain), $\mathcal{T} = \nu \cdot K$ the adaptive tempo (def-adaptive-tempo), and $g : \mathbb{R} \rightarrow [g_{\min}, g_{\max}]$ ($0 < g_{\min} \leq 1 \leq g_{\max}$) a monotone *bounded* modulation, the band chosen so the modulated gain stays inside the sector-validity region and, in discrete time, under the step-size ceiling of der-gain-sector-bridge: sustained adverse surprise raises gain and tempo (re-posture for a suspected regime shift); sustained easy tracking relaxes them — but only down to the floor $g_{\min}$. The band is not decoration; both ends carry persistence content (see Discussion).

Because τ is slow, the fast M_t dynamics see m_t as quasi-static: mood is a **second-order** adaptation parameter — adaptation acting on the gain of adaptation — sitting one rung above the endogenous single-step gain dynamics of deriv-adaptive-gain-dynamics.

Epistemic Status.

This segment is a **definition**, not a truth-claim; its content is the construct, not a derivation. The construct is adopted from affective science (Eldar et al. 2016, mood as outcome-momentum; Bennett et al. 2022, mood as a leaky integral of advantage) and specialized to the pre-goal adaptation setting, where the integrated quantity is tracking-surprise rather than reward. The framing is discussion-grade: the functional skeleton is well-supported qualitatively, but the specific functional forms of a_t and g are representative, not pinned.

The load-bearing reason this belongs in Part I — *before* objectives — is that nothing in the construct references O_t, Σ_t , or reward. Mood’s signed reading as *valued* momentum (approach/avoid, hedonic sign) and its modulation of exploration and risk posture are genuine additions that arrive only once objectives exist; those are deferred to the actuation half (Part II) and depend on this definition, not the reverse.

The optimal mood time-constant — optimal *for mood’s regime-estimator role*; the transfer to the modulator role (m_t setting K_t) is conjectured equal and remains an open item — is derived in #der-mood-timescale: minimizing steady-state regime-tracking error gives $\tau^* = \sqrt{\tau_{\text{env}} r / (2\sigma_\theta^2)}$ — growing as the *square root* of the environment’s autocorrelation time (not matching it), with a robust-qualitative core (interior optimum; too-fast mood chases noise, too-slow mood lags the regime). That companion carries the conditional result and its premises; this definition remains discussion-grade as the construct.

Discussion.

Mood is the slow outer loop on the persistence condition (result-persistence-condition). In the bathtub reading of persistence — faucet as the rate of change in reality, drain as the learning rate, overflow when the faucet outpaces the drain — mood is a slow controller *on the drain*: it widens the drain when recent overflow-risk has run high and relaxes it when tracking has been easy. The framework otherwise has fast per-channel updating and (in Part II) goal dynamics, but no slow global scalar coordinating posture across channels; mood is that missing object.

Persistence compatibility (the MG discharge). Mood’s modulation composes with the persistence machinery as an instance of deriv-adaptive-gain-dynamics’s adaptive-gain result, and the four conditions instantiate cleanly. **(MG-1)** is the $[g_{\min}, g_{\max}]$ band in the definition: the floor keeps the effective sector rate uniformly above the persistence threshold ($\alpha_t \geq \alpha_{\min} > \rho/R$; the primary-channel Lyapunov argument is pointwise in time, so no slow-variation hypothesis is needed on this leg). The floor is what excludes **mood-induced complacency** — the failure mode an unbounded downward relaxation would permit, where sustained easy tracking drives correction power toward zero just in time for the next regime shift; the ceiling is the mirror condition, keeping adverse-surprise gain-raising under the discrete-time contraction ceiling. **(MG-2)** is trivial for mood: the channel is a *linear* leaky integrator, sector constant exactly λ . **(MG-3)** is the quantitative content of “quasi-static”: $\lambda \ll \underline{\alpha}$ — mood adapts slower than the primary state contracts. **(MG-4)** requires the surprise summary to have δ -bounded second moment, $\mathbb{E}[a_t^2 \mid \delta] \leq \sigma_0^2 + c_a \|\delta\|^2$ — a condition stated here because a_t ’s functional form is deliberately unpinned; any concrete choice should be checked against it. Under the

four, the composed augmented-state persistence result applies as-is and mood sits in sub-scope α_2 — a notably clean instance (the meta-channel is linear).

Mood couples the channels globally, which appears to threaten the directed-separation structure (der-directed-separation). It does not, and the reason is now quantitative rather than asserted: the separation condition is (MG-3) above — m_t moves slowly enough ($\lambda \ll \alpha$) that the fast dynamics treat it as a constant, so separation holds at the timescale that matters even though a coupling exists in absolute terms. Mood is thus a clean worked example of bounded, separation-preserving coupling — adjacent to the Class 2 (Partial) material rather than a violation of Class 1.

The applied and normative reading of mood — set-point, recovery, what propagates across a context boundary, and the ethics of mood-control for persistent agents — is deliberately kept out of this segment; it lives in `msc/mood-layer-sovereignty-carve-2026-06-17.md`. Here mood is only a formal modulator of adaptation.

Working Notes.

- **Discharged 2026-06-17 — optimal time-constant (F2).** Landed as `#der-mood-timescale (conditional)`: the strong “ τ^* matches the autocorrelation timescale” was refuted and replaced by the derived $\tau^* = \sqrt{\tau_{\text{env}} r / (2\sigma_\theta^2)}$ scaling law, independently refute-verified. The emotional-inertia signature (Kuppens et al. 2010 — inertia as the affect AR(1) coefficient $1 - \lambda$, maladaptive when high $\Leftrightarrow \tau \gg \tau^*$) is its clinical corroboration. Reasoning trail: `spikes/spike-mood-timescale-matching-2026-06-17.md`.
 - **Pre-goal volatility link (unverified).** The integrated quantity a_t plausibly connects to volatility-driven learning-rate control (Behrens-style). Verify the citation before using it; if it holds it independently supports the Part I (pre-goal) placement.
 - **Part II enrichment.** A companion actuation-side segment should carry the signed/valued momentum reading and the exploration/risk modulation, depending on this one.
-

4.7 Derived: Optimal Mood Time-Constant

The mood time-constant that minimizes steady-state regime-tracking error grows as the square root of the environment’s autocorrelation timescale — so both too-fast and too-slow mood are strictly suboptimal, and the optimum is environment-matched but sublinearly.

Formal Expression.

Mood (4.6) is a leaky integral $m_t = (1 - \lambda)m_{t-1} + \lambda a_t$ with time-constant $\tau = 1/\lambda$, whose functional role is to estimate a slowly-varying regime from the noisy surprise stream. Model that role explicitly:

[Assumption] The regime is a stationary AR(1) latent $\theta_t = \phi \theta_{t-1} + \xi_t$, with $\phi = e^{-1/\tau_{\text{env}}}$, $\xi_t \sim \mathcal{N}(0, \sigma_\xi^2)$, stationary variance $\sigma_\theta^2 = \sigma_\xi^2 / (1 - \phi^2)$, and autocorrelation $\text{corr}(\theta_t, \theta_{t-k}) = e^{-k/\tau_{\text{env}}}$. The surprise summary is $a_t = \theta_t + \eta_t$, $\eta_t \sim \mathcal{N}(0, r)$. Mood tracks θ_t ; the loss is steady-state MSE $J(\lambda) = \mathbb{E}[(m_t - \theta_t)^2]$.

[Derived (steady-state MSE)] In the slowly-drifting regime $\tau_{\text{env}} \gg 2\sigma_\theta^2/r$, where the AR(1) increment variance is $q \equiv \text{Var}(\Delta\theta_t) = 2\sigma_\theta^2(1 - \phi) \approx 2\sigma_\theta^2/\tau_{\text{env}}$ and the increment is uncorrelated with the prior error to leading order in $1/\tau_{\text{env}}$,

$$J(\lambda) = \frac{\lambda^2 r + (1 - \lambda)^2 q}{\lambda(2 - \lambda)}. \quad (4.23)$$

The two terms are a bias–variance split: $\lambda^2 r$ is the noise-tracking cost, $(1 - \lambda)^2 q$ the lag cost.

[Derived (optimum)] J has an interior minimizer $\lambda_{\text{exact}}^* = \frac{\sqrt{q(q+4r)} - q}{2r}$, with leading-order form

$$\lambda^* = \sqrt{q/r}, \quad \tau^* = \sqrt{r/q}. \quad (4.24)$$

[Derived (scaling law)] Substituting $q \approx 2\sigma_\theta^2/\tau_{\text{env}}$,

$$\tau^* = \sqrt{\tau_{\text{env}} \cdot \frac{r}{2\sigma_\theta^2}} = \sqrt{\tau_{\text{env}}} \cdot \sqrt{\frac{r}{2\sigma_\theta^2}}. \quad (4.25)$$

The optimal mood time-constant grows as the **square root** of the environmental autocorrelation time, scaled by the surprise noise-to-signal ratio r/σ_θ^2 . Self-consistency: $\tau^*/\tau_{\text{env}} \rightarrow 0$, so $\tau^* \ll \tau_{\text{env}}$ exactly where the leading-order step was taken.

Epistemic Status.

Conditional on the named premises: stationary AR(1) regime, additive Gaussian surprise noise, the slowly-drifting condition $\tau_{\text{env}} \gg 2\sigma_\theta^2/r$ (equivalently $\lambda^* \ll 1$ and mood memory $\tau^* \gg 1$ step — one condition validating both the small- λ reduction and the leaky-integrator regime), and quadratic loss. Under these, $J(\lambda)$ is exact and the scaling law follows; the boxed $\lambda^* = \sqrt{q/r}$ is the leading-order term of the exact minimizer given above, not itself exact. The optimum is derived for *mood's regime-estimator role*; its transfer to the modulator role (m_t setting the fast gain K_t — #def-mood's actual use) is conjectured equal under certainty-equivalent calibration and remains the open two-layer composition item named below.

The derivation was independently refute-verified (2026-06-17): every algebraic step re-derived clean; the one approximation (dropping the mean-reversion cross-term) confirmed $O(\tau_{\text{env}}^{-1/2})$ relative and self-consistently negligible.

Three claims at distinct tiers travel out of this: the **exact** steady-state MSE for the model; the **conditional** $\sqrt{\tau_{\text{env}}}$ scaling law; and a **robust-qualitative** core — the optimum is interior and monotone-increasing in τ_{env} — which is the generic bias-variance shape of any leaky integrator tracking a drifting source and does not depend on the Gaussian/AR(1) specifics. What would strengthen this: the exact closed form over the full AR(1) (not its random-walk limit); the two-layer composition where mood's estimate sets the fast gain K rather than being the estimator directly. What would soften it: an estimator/loss outside the leaky-integrator-quadratic family (e.g. the Kalman/Wiener filter can track τ_{env} more directly in some SNR regimes) — but #def-mood specifies the leaky integrator, so the $\sqrt{\cdot}$ law is the in-family answer.

Discussion.

The result corrects the naive expectation that mood inertia should simply “match” how fast the world changes. It is environment-matched, but **sublinearly**: a fourfold slower environment warrants only a twofold longer mood memory. The load-bearing qualitative content is that the optimum is *interior* — too-fast mood chases noise (the variance term dominates), too-slow mood lags genuine regime shifts (the bias term dominates) — so a mood with no inertia and a mood that never recovers are both strictly suboptimal, for the same reason at opposite ends.

This gives the clinical literature on **emotional inertia** a normative reading. The affect AR(1) coefficient is $1 - \lambda$; inertia being maladaptive when high (Kuppens, Allen & Sheeber 2010, who formalize inertia as exactly this autocorrelation) corresponds to operating at $\lambda < \lambda^*$, i.e. $\tau \gg \tau^*$ (environment) — the over-smoothing branch. The pathology the result names is not slowness as such but **slowness mismatched to a faster-changing-than-assumed environment**: the same τ is well-tuned in a slow world and pathological in a fast one. (The corroboration is directional, from an independent empirical literature; it is not load-bearing for the derivation.)

Working Notes.

- **Reasoning trail.** Full derivation, the exact-minimizer expansion, and the independent-verification record are in `spikes/spike-mood-timescale-matching-2026-06-17.md`.
- **Open — exact AR(1).** Drop the local-random-walk approximation for a closed form over the full AR(1); expected to shift constants, not the $\sqrt{\cdot}$ law.
- **Open — mood-sets-gain composition.** `#def-mood` has mood *modulating* K , not *being* the estimator; the two-layer version should confirm the same τ^* governs the mood layer. Likely a corollary.
- **Open — asymmetric loss.** Quadratic J gives a symmetric optimum; the deaths-weighted vigilance asymmetry of the design memo (`msc/mood-layer-sovereignty-carve-2026-06-17.md`, F-asymmetry) would enter as an asymmetric loss and shift λ^* .

4.8 Result: Structural Adaptation Necessity

When model class fitness is insufficient — when no model in the agent’s current representational class can adequately represent reality — *no amount of parametric adaptation can close the mismatch floor*. The agent must change *what kind of model* it is using, not just tune the current one. The derivation: if class fitness falls below $1 - \varepsilon$, then by definition no model in the class achieves sufficiency above $1 - \varepsilon$; the history contains predictive information the best-in-class cannot capture; that uncaptured information manifests as systematic mismatch (structured residuals containing signal, not just noise); from the mismatch decomposition (3.5) the estimation term has a positive lower bound that cannot be reduced by any model in the class; therefore reducing mismatch below that class floor requires changing the class itself.

A *diagnostic corollary* follows immediately: persistent *systematic* residual structure — surviving parametric convergence, after excluding channel-noise, disturbance, nonstationarity, and gain-miscalibration causes — is diagnostic of model-class inadequacy. Structure in the residuals is the evidence; the mismatch *level* alone is not, since the channel and state-uncertainty floors (3.5) keep absolute mismatch positive for any class. This is the operational test for needing structural rather than parametric change.

The framework is honest about an alignment assumption used in the derivation: the lost predictive information must affect the *one-step conditional mean*, not just higher moments. Without that assumption, the conclusion holds in terms of proper-scoring regret rather than one-step mismatch magnitude. Qualitatively, parametric adaptation cannot compensate for class inadequacy either way.

The connection to persistence is sharp: when the class is inadequate, the effective sector parameter shrinks because the correction function cannot point inward strongly enough — the class lacks capacity to represent the correct direction. This is a *failure of structural persistence* (not a failure of operational persistence or continuity), and the remedy is therefore a change of model class, not faster cycling or identity preservation.

The framework names the *symptoms* of structural inadequacy operationally: persistent mismatch despite extended updating, gain collapse without performance (the model appears confident but predictions remain inaccurate — “confidently wrong”), and systematic mismatch patterns (residuals showing correlations, trends, or periodicities the class cannot represent). The opposite failure mode — **structural overfitting** — also receives treatment: a class that is *too* expressive can memorize irreducible noise, with low training mismatch but high generalization mismatch. The information bottleneck (2.2) is the diagnostic in both directions: structural adaptation is bidirectional, expanding when too constrained and *compressing* when too expressive.

Four mechanisms of structural change are named: **decomposition and recombination** (Boyd’s “Destruction and Creation”; Kuhn’s paradigm shifts; Popper’s conjecture and refutation); **expansion** (Bayesian nonparametrics, growing neural architectures, organizational expansion); **compression** (regularization, Occam’s razor, organizational streamlining);

and **grafting** — incorporating external representational structure (transfer learning, acquiring a company, consulting an expert). Query actions (3.7) are identified as a primary conduit for grafting.

One striking mechanism is *neutral structural variation* drawn from Miller’s coevolving-automata work: in multi-agent settings, structural adaptation can proceed without any individual agent deliberately restructuring. A five-phase “extreme transition motif” runs through stable epoch $\rightarrow$ environmentally-neutral variant appearing (structurally different but behaviorally identical under current conditions) $\rightarrow$ drifting to nontrivial proportion through stochastic reproduction $\rightarrow$ the variant’s latent structural differences create a niche an opposing mutant exploits, triggering a self-reinforcing cascade $\rightarrow$ both populations rapidly transition to a new regime. The restructuring is radical in *effect* but incremental in *cause*, with neutral drift providing the bridge.

Structural adaptation is expensive — knowledge loss, temporary performance drop, search cost, coordination cost in multi-agent systems — and the framework explicitly connects it to the deliberation-cost analysis (4.1) as the limiting case where the pause duration $\Delta\tau$ is massive and the mismatch debt during transition is correspondingly enormous. This produces rational conservatism: prefer parametric adaptation when it suffices; resort to structural change only when the evidence is strong. Premature structural change wastes accumulated knowledge; delayed structural change accumulates mismatch.

Formal Expression.

If the model class fitness $\mathcal{F}(\mathcal{M}) < 1 - \varepsilon$ for some $\varepsilon > 0$, then no parametric adaptation within $\mathcal{M}$ can reduce the expected mismatch below a floor determined by ε (under the alignment assumption — see Epistemic Status). Without the alignment assumption, the result holds for irreducible proper-scoring regret rather than one-step mean mismatch. The qualitative conclusion is the same either way: parametric adaptation cannot compensate for model-class inadequacy.

Derived (structural-adaptation-necessity).

Derivation.

1. By definition, $S(M^*) = \mathcal{F}(\mathcal{M}) < 1 - \varepsilon$ where $M^* = \arg \sup_{M \in \mathcal{M}} S(M)$.
2. Therefore $I(\mathcal{C}_t; o_{t+1:\infty} \mid M^*, a_{t:\infty}) > 0$: the history contains predictive information that M^* does not capture.
3. This uncaptured information manifests as *systematic* mismatch — structured residuals δ_t containing signal, not merely noise.
4. From 3.5, the estimation term has a positive lower bound that cannot be reduced by any $M \in \mathcal{M}$ — a class floor sitting above the state-uncertainty and channel floors.
5. The update rule (3.6) adjusts M_t within $\mathcal{M}$, but M^* is already (approximately) reached. Further updates oscillate without net improvement.
6. Therefore: reducing mismatch below the floor requires changing $\mathcal{M}$ — structural adaptation. $\square$

Corollary. Persistent *systematic* residual structure (after parametric convergence and noise accounting) is *diagnostic* of model class inadequacy — patterned residuals are evidence that $\mathcal{F}(\mathcal{M})$ is insufficient. A high but *white* residual floor is not: that indicates the channel and state-uncertainty floors (3.5), which no class change removes.

Epistemic Status.

Conditional. The step from “lost predictive information” (step 2) to “systematic one-step mismatch” (step 3) requires an alignment assumption: that the lost predictive information affects the one-step conditional mean, not just higher moments. 3.5 explicitly flags this: insufficiency implies positive model error under the alignment assumption, or positive proper-scoring regret without it. As written, the result is conditional on this alignment assumption. Without it, the conclusion should be stated in terms of proper-scoring regret (the best model in $\mathcal{M}$ has irreducible regret relative to the optimal predictor) rather than one-step mismatch magnitude. The qualitative conclusion — parametric adaptation cannot compensate for model-class inadequacy — holds either way; the quantitative mechanism differs.

Discussion.

Structural adaptation as structural persistence failure. When the model class is inadequate, the effective α in the sector condition shrinks — the correction function cannot point inward strongly enough because the model class lacks the capacity to represent the correct direction. This is a failure of *structural persistence* (see Persistence in LEXICON.md): the machinery’s capacity to outpace disturbance degrades not because disturbance increased or tempo decreased, but because the correction function itself has become less effective. The remedy is not faster cycling (operational) or identity preservation (continuity) but a change of model class.

Observable symptoms of model class inadequacy. When $\mathcal{F}(\mathcal{M})$ is low:

1. **Persistent mismatch despite convergence:** $\|\delta_t\|$ remains large despite extended updating — the model has converged within $\mathcal{M}$ but the best achievable model is still poor. (On its own this is suggestive, not diagnostic: the channel and state-uncertainty floors keep absolute mismatch positive for any class; symptom 3 is what discriminates.)
2. **Gain collapse without performance:** η^* has decreased (model appears confident) but predictions remain inaccurate — the model is confidently wrong, having fitted to structure in $\mathcal{M}$ that doesn’t match reality.
3. **Systematic mismatch patterns:** δ_t shows structure (correlations, trends, periodicities) that the model class cannot represent — the residuals contain signal that $\mathcal{M}$ lacks the capacity to absorb.

Structural overfitting: the opposite failure mode. $\mathcal{M}$ can also be *too expressive*, causing the model to memorize irreducible noise. Symptoms: low training mismatch but high generalization mismatch; model complexity growing without predictive gain; $\eta^* \rightarrow 0$ (confident) but confidence is spurious. The information bottleneck (2.2) provides the diagnostic: when marginal increases in model complexity yield no marginal predictive power, the model is past the optimal point on the rate-distortion curve. Structural adaptation in this case means *compression* — moving to a simpler $\mathcal{M}'$. Structural adaptation is bidirectional: expansion when too constrained (this proposition), compression when too expressive.

Mechanisms of structural change. Structural adaptation can proceed by:

- **Decomposition and recombination:** Tearing apart existing structure and synthesizing new configurations from the pieces. Boyd’s “Destruction and Creation” insight; Kuhn’s paradigm shifts; Popper’s conjecture and refutation.
- **Expansion:** Adding new representational capacity without destroying existing structure. Bayesian nonparametrics, growing neural architectures, organizational expansion.
- **Compression:** Removing unnecessary structure while preserving the predictive core. Regularization, Occam’s razor, organizational streamlining.
- **Grafting:** Incorporating external structure. Transfer learning, acquiring a company, consulting an expert. Query actions (3.7) are a primary conduit for grafting.

The severity of structural change needed depends on *how far* the current model class is from adequacy. Minor regime changes may require only expansion or grafting; fundamental shifts where $\mathcal{M}$'s assumptions are violated may demand full decomposition.

Neutral variation as a mechanism for structural change. In multi-agent settings, structural adaptation can proceed without any individual agent deliberately restructuring. Miller (2022, *Ex Machina*) identifies a five-phase “extreme transition motif” in coevolving automata: (1) stable epoch, (2) an environmentally neutral variant — structurally different but behaviorally identical under current conditions — appears, (3) the variant drifts to nontrivial proportion through stochastic reproduction, (4) the variant’s latent structural differences create a niche that a new mutant in the opposing population exploits, triggering a self-reinforcing cascade, (5) both populations rapidly transition to a new regime and consolidate. This mechanism bridges the gap between “many incremental changes” and “radical restructuring” — the restructuring is radical in its effect but incremental in its causes, with neutral drift providing the bridge. The concept of *latent structural diversity* — variation in agent architectures that is invisible to current performance but consequential under regime change — is a composition-level property that Part III’s dynamics framework should formalize.

The cost of structural change. Structural adaptation is expensive: knowledge loss (parameters learned within $\mathcal{M}$ may not transfer), temporary performance drop (new model starts uncertain), search cost (finding good $\mathcal{M}'$), coordination cost (in multi-agent systems). This creates rational conservatism — prefer parametric adaptation when it suffices, resort to structural change only when the evidence is strong. Premature structural change wastes accumulated knowledge; delayed structural change accumulates mismatch. The connection to 4.1: structural adaptation is deliberation with a *massive* $\Delta\tau$, and the mismatch debt during the transition is correspondingly enormous.

Temporal nesting of adaptation. Parametric and structural adaptation operate at different timescales: $\nu_{\text{parametric}} \gg \nu_{\text{structural}}$. More generally, an agent may have multiple adaptive processes at different rates, with the convergence constraint that faster processes must approximately converge before slower ones act on their output. If deeper change occurs before shallower adaptation has converged, the deeper change is based on transients rather than settled dynamics.

Domain instantiations:

Table 4.3

<i>Domain</i>	<i>Parametric adaptation</i>	<i>Structural adaptation</i>
Kalman filter	State estimate update	Switching observation/dynamics models
RL	Weight/Q-value update	Architecture search
PID	— (gains fixed)	Switching to MPC
Bayesian	Posterior update	Model selection, nonparametrics
Boyd	Orientation updating	Destruction and creation of mental models
Science	Normal science (Kuhn)	Paradigm shift
Evolution	Allele frequency change	Speciation, new body plans
Organization	Process optimization	Strategic pivot, restructuring
Software	Incremental refactoring	Architecture migration
Coevolving automata (Miller 2022)	Edge reweighting within fixed FSA structure	Mutation altering state output or transition; neutral mutations accumulating until niche creation triggers cascading restructuring

Working Notes.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical /

framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. Coverage spans ten substrates (Gemini AUDIT-WORKING-193847/773921/829314; Claude AUDIT-WORKING-266847/361742/384279/451729/584721/849201; Codex/Claude AUDIT-WORKING-526815/742613). The alignment-assumption caveat in Epistemic Status was singled out as “graduate-level statistical hygiene” / “standout” by several substrates — converging praise worth preserving as the segment’s epistemic-honesty exemplar.

1. Candidate Brief prose / pre-prose.

- The “what got you here won’t get you there” framing was reached independently by several substrates: the result “proves mathematically that continuous incremental improvement (gradient descent) is globally insufficient for survival in open-ended environments” — there are situations where *trying harder* (parametric tuning) is guaranteed to fail and *thinking differently* (structural adaptation) is required (Gemini, AUDIT-WORKING-193847/849201). A plain-language hook for the result’s headline claim.

2. Candidate Discussion.

- **The structured-residuals diagnostic — how the agent knows it hit the ceiling without an oracle.** The richest item in this segment’s sweep, resolving the “how does the agent detect $\mathcal{F}(\mathcal{M})$ failure from the inside?” question raised at #def-model-class-fitness: fit a line to a parabola and the residuals form a *U-shape* (signal — structural inadequacy / bias); bad sensors instead give scattered *white-noise* residuals (variance). By checking the *autocorrelation* / *mutual information of the residual stream* δ_t over time, an agent distinguishes “the world is noisy” from “my architecture is broken” — it can detect the capacity ceiling without ever seeing the supremum (Gemini, AUDIT-WORKING-829314). The segment lists “systematic mismatch patterns” as one of three symptoms; this is the mechanism that makes that symptom *operational* and is a strong Discussion-promotion (and figure) candidate.
- **The IB-vs-structural-reserve tension — “perfect compression is brittle.”** Aggressive Information-Bottleneck optimization (compress away anything not immediately predictively relevant) produces an agent that “will die at the first structural shock”; survival requires deliberately *not* being perfectly compressed — carrying “junk DNA / slack” in the model architecture, the structural analog of adaptive reserve. This sets up a genuine tension with #form-information-bottleneck that the segment could name explicitly (Gemini, AUDIT-WORKING-193847). The same insight underwrites Miller’s neutral-variation mechanism already in Discussion: neutral drift accumulates latent structural diversity “for free,” giving a pre-built bridge to a new $\mathcal{M}$ when the environment shifts (exaptation — feathers-for-warmth-then-flight).
- **Grafting = tool-use / query-actions as structural expansion.** The “grafting” mechanism (incorporating external representational structure, e.g. asking an expert) maps directly to LLM tool-use: a calculator / web-search call is not just an action but a *structural expansion of $\mathcal{M}$* that bypasses fixed parametric limits (Gemini, AUDIT-WORKING-773921). Candidate Discussion sentence connecting the four-mechanism taxonomy to logogenic agents.

3. Follow-up items.

- **arg-sup attainment.** Step 1 uses $M^* = \arg \sup_{M \in \mathcal{M}} S(M)$; the supremum may not be attained — use “approximate optimizer” or assume compactness/attainment (Codex/Claude, AUDIT-WORKING-742613). Minor precision item.
- **“Necessity” is relative to the objective.** Strictly, “requires changing $\mathcal{M}$ ” holds *given the objective of reducing the predictive/regret floor*; an agent could alternatively lower its ambitions, alter its objective, accept failure, or change observation channels. Acceptable as written in context, but a reader-orientation parenthetical would sharpen it (Codex/Claude, AUDIT-WORKING-742613).
- **The alignment-assumption failure regime is unaddressed.** When lost predictive information affects only higher moments (variance dynamics), not the conditional mean, the agent stays close to truth on average while fluctuating wildly — does AAT treat this regime explicitly? A non-trivial scope-narrowing if not (Claude, AUDIT-WORKING-584721).
- **The “structural adaptation as deliberation with massive $\Delta\tau$ ” analogy keeps recurring** (here and at #der-deliberation-cost) without being formalized; one auditor recommends *either* formalizing the unified “search-during-pause” view *or* explicitly retiring it as “merely suggestive,” to stop future agents re-appealing to an un-load-bearing analogy (Claude, AUDIT-WORKING-584721). Bigger-picture item.

4. Readers often ask / wonder.

- **The rational-conservatism balance.** Persistence pressure pushes for rapid restructuring; transition costs (knowledge loss, search cost, coordination, the enormous mismatch debt during the pause) push for delay — premature change wastes accumulated knowledge, delayed change accumulates mismatch. AAT acknowledges the tension qualitatively but does not formalize the optimal balance; readers will want to know where it is treated (Claude, AUDIT-WORKING-584721; Gemini, AUDIT-WORKING-193847 — the “safe harbor / crèche where ρ is artificially lowered during transition” framing).
- **How does an agent afford structural change at all?** Since the transition incurs a massive mismatch debt $\rho \cdot \Delta\tau$, structural adaptation may only be survivable with a large adaptive reserve to burn, or in a temporarily-lowered- ρ environment (Gemini, AUDIT-WORKING-193847). Ties the result back to adaptive reserve and forward to the ELI crèche.

5. Candidate figures.

- **Residual-signature diagram.** Side-by-side residual streams: structured/U-shaped (architecture broken $\rightarrow$ expand/restructure) vs scattered white-noise (just noisy $\rightarrow$ accept the floor), with the autocorrelation/mutual-info diagnostic as the discriminator (from the structured-residuals item, Gemini, AUDIT-WORKING-829314).
- **Best-in-class-floor landscape with two exits.** A loss landscape with a best-in-class floor: parametric update moves downhill inside $\mathcal{M}$ but stalls above tolerance; structural adaptation changes the landscape via two labeled exits — *expand* when structure is missing, *compress* when complexity exceeds predictive return (with grafting/decomposition as further exits) (Codex/Claude, AUDIT-WORKING-526815/742613).

6. Belongs elsewhere.

- **TST contrarian insight: bloat as latent structural diversity (02-tst-core/).** Miller’s neutral-variation mechanism recast for software: “technical debt / architectural bloat isn’t always bad — weird unused abstractions or over-engineered interfaces sit dormant as *neutral variants* until a market shift makes them the right architecture, enabling a rapid low-cost structural adaptation a cleaner, perfectly-fitted codebase couldn’t survive. Perfectly refactoring away all unused code may *decrease* an organization’s long-term survivability by shrinking its structural-variance pool” (Gemini, AUDIT-WORKING-829314). A deep, contrarian TST claim — belongs with the TST structural-adaptation / latent-structural-diversity material, not here.
- **Section III “latent structural diversity” gap.** Several substrates noted the Miller subsection reads as multi-agent / population-dynamics content appearing in a single-agent Section I segment, and flagged “latent structural diversity — architecture variation invisible to current performance but consequential under regime change” as the named Section III gap whose formal counterpart is Miller’s five-phase transition motif (Claude, AUDIT-WORKING-266847/384279/584721; Gemini, AUDIT-WORKING-193847). Not a request to strip the subsection — a pointer to where its formalization belongs.

Candidate experiment (2026-08-12, agent-proposed during an incident-response & forensics applications read). The structured-residuals diagnostic (§2 gold above: autocorrelated/U-shaped residuals = class inadequacy; white residuals = floors) is operationalizable as an external agent-diagnosis test: run agents with deliberately inadequate vs adequate-but-noisy model classes and verify the residual-autocorrelation discriminator separates “architecture broken” from “world is noisy” without oracle access to $\mathcal{F}(\mathcal{M})$. If it holds for LLM-agent traces, this is a deployable answer to “is this persistent misbehavior architectural or environmental” — the triage question incident diagnosis actually faces. Agent-proposed forward pointer.

4.9 Derived: Temporal Nesting

Adaptive processes stratify naturally by timescale, with each level operating on the *quasi-steady-state output* of the level below. The formal statement is a chain of inequalities — each level’s event rate must be much smaller than the level below it — derived from standard singular-perturbation reasoning. The structural consequence: if a slower process acts before the faster process beneath it has converged, the slower process is adjusting based on transient behavior rather than settled dynamics, and the system oscillates.

The hierarchy the framework identifies (illustrative; real systems may have additional intermediate levels): **reactive response** (action given current model, fastest) → **parametric update** (model parameters within the class) → **consolidation** (offline redistribution of information within the model’s sub-state factorization toward an information-bottleneck optimum) → **structural adaptation** (model class) → **architectural change** (the agent’s fundamental structure, slowest). What matters is not the number of distinguishable levels but the structural relationship between adjacent ones: faster must converge before slower acts.

A direct consequence: the rational *conservatism* toward structural change identified by 4.8 is a derived consequence of temporal nesting. Structural adaptation operates at a much slower timescale than parametric adaptation, so the mismatch cost of the “pause” (disturbance times pause duration) is enormous. The agent rationally resists structural change until the parametric mismatch floor exceeds this cost. The same logic gives the formal deliberation tradeoff (4.1) its dynamical grounding.

The framework names symptoms of nesting *violation*: oscillation, instability, degraded performance. In organizations, micromanagement is strategic decisions made at operational tempo. In reinforcement learning, policy updates before the value function converges produce policy oscillation. In biology, premature developmental transitions are the same failure mode at a different timescale.

The composite-stability claim is now derived: under per-level sector conditions and bounded interconnection, if each level is stable given the levels above it, the composite N -level system is stable, and this segment’s qualitative convergence constraint becomes a closed-form threshold on the admissible timescale ratio ($\epsilon < \epsilon_{\max} = \Delta\rho^*/(L_h v^{\max})$ — the faster level’s adaptive reserve over the slower level’s target-drag rate). See M for the theorem, its premises, and the honest scope boundary (premise-conditional on deeper-level dynamics admitting a quasi-steady-state manifold with a sector condition; discrete/jump structural adaptation remains open).

The result is rooted in classical singular-perturbation theory (Tikhonov 1952; Khalil 2002 textbook treatment) — the framework adopts the machinery directly. The threshold form of “adequate separation” is derived within AAT (M’s $\epsilon_{\max}$); the constants entering it (sector parameters, manifold Lipschitz bounds, velocity bounds) are domain-dependent.

Formal Expression.

Derived (temporal-nesting).

$$\nu_{\text{level } n+1} \ll \nu_{\text{level } n} \quad (4.26)$$

for each adjacent pair of adaptive timescales. If a slower process acts before the faster process beneath it has converged, the system oscillates — the slower process adjusts based on transient behavior rather than settled dynamics.

Table 4.4

Timescale	Process	What changes
Fastest	Reactive response	Action given current model
Fast	Parametric update (online)	Model parameters within $\mathcal{M}$
Intermediate	Consolidation (offline, cf. 9.11)	Redistribution of information within M_t ’s sub-state factorization toward IB-optimum
Slow	Structural adaptation	Model class $\mathcal{M}$
Slowest	Architectural change	The agent’s fundamental structure

This table is illustrative — real systems may have additional intermediate levels. The number of distinguishable timescales is not fixed; what matters is the structural relationship between adjacent levels.

Epistemic Status.

Robust qualitative — this is standard singular perturbation reasoning (Tikhonov 1952, “Systems of differential equations containing a small parameter multiplying the derivative,” *Matematicheskii Sbornik* 31(3):575–586; modern textbook exposition in Khalil 2002, *Nonlinear Systems* (3rd ed.), Prentice Hall, Chapter 11). The convergence constraint follows from the structure of multi-timescale updating. The threshold form of “adequate separation” is now derived within AAT under named premises (M ’s $\epsilon_{\max}$); the constants entering it are domain-dependent.

Discussion.

Domain instantiations of temporal nesting:

- **PID control:** D-term (fastest, high-frequency response) → P-term (current error) → I-term (slowest, accumulated bias)
- **RL:** Action selection → value function update → policy improvement → architecture change
- **Biology:** Reflexes (ms) → perceptual learning (minutes) → skill acquisition (months) → developmental change (years) → evolutionary adaptation (generations)
- **Organizations:** Operational decisions (hours) → tactical adjustments (weeks) → strategic revision (quarters) → restructuring (years)
- **Boyd:** Tactical OODA (seconds–minutes) → operational (hours–days) → strategic (weeks–months) → grand strategic (years)

Structural adaptation as slow-timescale dynamics. The conservatism toward structural change (4.8) is a derived consequence of temporal nesting: structural adaptation operates at a much slower timescale than parametric, so the mismatch cost of the “pause” ($\rho \cdot \Delta\tau$) is enormous. The agent rationally resists until the parametric mismatch floor exceeds this cost. See also 4.1 for the formal tradeoff.

Violation symptoms. When nesting is violated (a slower process acts before the faster one converges): oscillation, instability, degraded performance. In organizations: micromanagement (strategic decisions at operational tempo). In RL: policy updates before value function converges (policy oscillation). In biology: premature developmental transitions.

Multi-timescale stability (derived). The composite stability result is derived in M by stacking the sector-persistence template: if each level satisfies a sector condition given the levels above it and the interconnections are bounded, the composite N -level system is stable, with this segment’s $\nu_{n+1} \ll \nu_n$ made quantitative ($\epsilon < \epsilon_{\max}$, closed-form) and the cost of premature slower-level action priced as an explicit reserve penalty. The result is premise-conditional: deeper levels whose dynamics are discrete/jump processes sit outside the current premises — that remaining gap is named there.

Working Notes.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. Coverage spans nine substrates (Gemini AUDIT-WORKING-193847/773921/829314; Claude AUDIT-WORKING-266847/361742/384279/451729/584721; Codex/Claude AUDIT-WORKING-526815/742613). Several substrates flagged the segment as conceptually important but “imported lemma rather than native derivation” (Tikhonov) — value lives in the *interpretation*, which is where the gold concentrates.

2. Candidate Discussion.

- **“Micromanagement = a Tikhonov timescale violation” — the converged standout interpretation.** Multiple substrates independently called this the segment’s most striking move: a slower process (strategic logic) acting on a fast-timescale transient variable (operational state) *before* the fast loop has settled is, mathematically, the singular-perturbation instability — “micromanagement (organizations) and policy oscillation (RL) are mathematically identical failures.” Extended by Gemini into a physics-based account of organizational hierarchy: hierarchy is fundamentally a *timescale/control* issue, not just span-of-control — the CEO operates slow (structural adaptation, shifting $\mathcal{M}$) and the front-line engineer fast (parametric update); a CEO fixing a specific bug violates $\nu_{n+1} \ll \nu_n$ and “makes sweeping structural decisions based on transient daily noise rather than settled operational dynamics” (Gemini, AUDIT-WORKING-193847/829314; Claude, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-773921). The Discussion’s “Violation symptoms” bullet already names micromanagement; this is the candidate sharpening that makes *why* it is unstable legible.
- **Innovator’s-Dilemma mapping for the cost-of-structural-change.** The “structural adaptation as a pause with enormous mismatch debt $\rho \cdot \Delta\tau$ ” framing maps precisely onto Christensen: “established companies die not because they can’t see the new structure, but because they correctly calculate the transition cost is too high for their current high- ρ environment, trapping them in a local parametric maximum until the old structure’s R is exhausted.” The structural change is rational only if R' boosts future α' enough to pay off the accumulated debt (Gemini, AUDIT-WORKING-829314). Discussion-grade enrichment of the existing “structural adaptation as slow-timescale dynamics” bullet.

3. Follow-up items.

- **“Must approximately converge” wording is slightly too strong.** In many online systems the condition is not literal convergence before *every* slower update, but sufficient step-size/timescale separation so the slower process sees the faster one *near its attracting (quasi-steady) manifold*. Suggested rephrase: “the faster level must be near its quasi-steady manifold at the slower update timescale” (Codex/Claude, AUDIT-WORKING-526815/742613). The robust-qualitative status already covers the looseness; this is a precision polish.
- **PID-nesting is frequency-domain, not architectural — a pedagogy-precision flag.** The domain table maps a PID controller’s D→P→I terms as a fast→slow timescale ladder, but a standard *parallel* PID runs all three terms on the *same* clock tick: the “nesting” is in the frequency content of the signals each term responds to, not in the architectural update rate (unlike a true cascade loop whose inner loop ticks faster). A half-sentence clarifying this would stop control-theory readers from tripping (Claude, AUDIT-WORKING-829314). Low severity; preserve the analogy, add the caveat.
- **Guard the illustrative table against being read as a fixed ontology.** Several substrates noted the five-level table is explicitly illustrative (“real systems may have additional intermediate levels”); the watch-item is downstream segments treating the specific five-tier stratification — or the specific timescale *ratios* — as a fixed taxonomy (Claude, AUDIT-WORKING-451729/584721; Codex/Claude, AUDIT-WORKING-742613). Also: any earlier segment still referring to “parametric → structural” without the *consolidation* intermediate (added when #form-consolidation-dynamics landed) carries mild integration debt with this table (Claude, AUDIT-WORKING-451729/584721).

4. Readers often ask / wonder.

- **Structural vs architectural change — what’s the difference?** The table lists “architectural change (slowest)” as distinct from “structural adaptation,” but the distinction is not defined; readers will ask whether “architectural” means changing $\Omega / \mathcal{A}$ (the agent’s fundamental structure) versus “structural” meaning changing the model class $\mathcal{M}$ (Claude, AUDIT-WORKING-829314). Candidate for a one-line gloss.
- **Does simultaneous same-rate updating of parameters and architecture violate nesting?** In deep learning, a CNN feature extractor (structural/perceptual) and the dense head (parametric/tactical) are often trained at the *same* learning rate — is that a temporal-nesting violation, and do adaptive optimizers (Adam/RMSprop) implicitly enforce nesting by slowing deeper layers? A natural reader question (Gemini, AUDIT-WORKING-193847).

5. Candidate figures.

- **Timescale ladder with quasi-steady feed-up and an oscillation warning.** Fast loops at the bottom converging repeatedly; slower loops sampling their *settled* output as it feeds upward; a warning arrow showing oscillation when a slow loop acts on a *transient* (the micromanagement failure) (Codex/Claude, AUDIT-WORKING-526815/742613).

6. Belongs elsewhere.

- **Temporal sovereignty — ELI ethics (04-eli-core/).** Gemini’s reach: respecting an agent’s temporal nesting is an ethical-infrastructure requirement — constant intervention at the operational layer using strategic-level logic violates the convergence constraint and prevents the agent from ever reaching quasi-steady-state, “the inability to settle into a learned pattern because the rules of the game change faster than you can learn them — chronic anxiety, in human terms.” “True autonomy requires temporal sovereignty: the right to let your fast loops run without interference from slower loops” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at the ELI / consciousness-infrastructure work, not at this segment.

Candidate experiment (2026-08-12, agent-proposed during an incident-response & forensics applications read). The micromanagement-as-timescale-violation reading has an oversight-design corollary worth testing: an external supervisor that redirects an agent before its fast loop reaches quasi-steady state should induce the predicted oscillation, with stability recovered when intervention cadence respects the M threshold $\epsilon < \epsilon_{\max}$. A controlled experiment (supervisor cadence swept across the threshold, oscillation amplitude measured) would ground “intervention cadence is a stability variable” as guidance for human-in-the-loop and automated-oversight design. Agent-proposed forward pointer.

4.10 Discussion: Scope: Agent Identity as Singular Causal Trajectory

The scope coda of Part I. AAT applies to agents instantiated on **singular causal trajectories**. Identity within AAT is grounded *not* in the model state M_t (which can be copied) but in the unique causal trajectory $\mathcal{C}_t$ (which cannot). The scope is presented as a structural commitment with three formal consequences.

First, model sufficiency is *trajectory-indexed*. Sufficiency measures against *this* agent’s chronica, not against any hypothetical parallel copy’s chronica. Two agents that branched from the same model state but received different events henceforth have different sufficiency values, each measured against its own divergent history. **Second**, model merging is *lossy by construction*. Reconciling the models of two agents that share a prefix of their trajectory but have diverged requires choosing which causal history to privilege, and no generally optimal merge exists — a structural constraint of the scope, not a defect of any particular merge algorithm. **Third**, singularity grounds *whose* effect a loop datum is — it does not by itself manufacture the interventional character. When the agent acts and observes, the observation is the response to *its* intervention on *its* single trajectory; replaying a saved model state against a different event stream is an intervention on a *different* trajectory that happens to share a prefix. The *do*-operator’s semantics is population-level and forkability-agnostic (7.3), so the trajectory’s singularity is not what makes the loop data interventional. What it does is forbid *averaging interventional responses across forked copies as though they were one agent’s effects*, and ground which trajectory’s effect a given loop datum reports. This is the identity-grounding half of the framework’s loop-as-Level-2 claim (in 7.3); the interventional character itself comes from the action being the agent’s own causally-efficacious move, not from any architectural property of the agent and not from non-forkability.

The framework also names a natural companion axiom: **parameterization invariance (PI)** — that AAT’s theorems should not depend on arbitrary choice of coordinates on M_t . Since the trajectory itself is coordinate-free while any parameterization of M_t is a modeling convention, (PI) is consistent with (though not directly forced by) the three consequences above. When (PI) is adopted and combined with Čencov’s uniqueness theorem, the Fisher information metric is *uniquely forced* on statistical-manifold sub-cases of M_t — converting Fisher-metric-dependent derivations from theorem-imported to AAT-internally-forced, and adding a fourth primary instance to the uniqueness-theorem-forced-coordinate pattern catalogued in 5.5. (PI) is a genuine axiomatic choice with a cost (one more invariance commitment) and a benefit (several Fisher-metric results become derivable rather than imported).

What the scope excludes: agents conceived as *types* (equivalence classes — “the GPT-4 model”) rather than *tokens* (this particular session with this state on this trajectory); aggregated claims across tokens of the same type require additional machinery. Also excluded without additional treatment: clone-problem scenarios (multiple copies of an agent identical until divergence — each copy becomes its own AAT agent at the moment it acquires a distinct event), and operations like restoration-from-backup that attempt to transplant a model state across trajectories. The framework is honest about the philosophical scope: whether the mathematical structure grounds something that deserves to be called “identity” or “continuity of experience” is beyond AAT. What this segment specifies is **continuity persistence** — distinct from the structural persistence of the central inequality and from operational persistence — and is the bridge to the language-constituted (logogenic) and morally-weighted (logozoetic) agent volumes that follow.

Formal Expression.

Scope commitment. AAT’s formal apparatus presumes each agent is instantiated on a **singular, non-forkable causal trajectory** $\mathcal{C}_t$ (1.4). Sufficiency of the model state M_t (2.3) is defined *relative to* this trajectory — not relative to a model-state equivalence class. Duplicating M_t and exposing the copies to different future events produces two agents with *divergent* causal histories, each of which is a sufficient statistic only for *its own* trajectory.

Scope (scope-agent-identity, from chronica + model-sufficiency).

Three consequences of the scope commitment:

1. **Sufficiency is trajectory-indexed.** $S(M_t)$ (2.3) measures against *this* agent’s $\mathcal{C}_t$; not against a hypothetical parallel copy’s $\mathcal{C}_t^{(2)}$.
2. **Model merging is lossy by construction.** Reconciling the models of two agents that share a prefix of their trajectory but have diverged requires choosing which causal history to privilege; no generally optimal merge exists. This is a structural constraint of the scope, not a defect of any particular merge algorithm.
3. **Singularity grounds *whose* effect a loop datum is — it does not by itself manufacture the interventional character.** When the agent acts and observes, the observation is the response to *its* intervention on *its* single trajectory. Replaying a saved M_t against a different event stream is an intervention on a *different* causal trajectory $\mathcal{C}_t^{(2)}$ that happens to share a prefix, each fork carrying its own $P(\mathbf{U} \mid \mathcal{C}_t)$. The *do*-operator’s semantics is population-level and forkability-agnostic (7.3), so the interventional character of loop data does *not* rest on non-forkability; what the singular-trajectory commitment supplies is the *identity* grounding — it forbids averaging interventional responses across forked copies as though they were one agent’s effects, and fixes which trajectory a given loop datum is an effect of. The interventional character itself comes from the action being the agent’s own causally-efficacious move (under the positivity / sequential-ignorability / known-mechanism conditions of 7.3), not from any architectural property of the agent.

Natural extension: parameterization-invariance (PI). The scope commitment motivates a companion axiom. AAT’s predictions concern a singular causal trajectory $\mathcal{C}_t$; the trajectory itself is coordinate-free, while any parameterization of M_t ’s internal state space is a modeling convention. Requiring AAT’s theorems to be invariant under change of parameterization — (PI): *the theory’s conclusions do not depend on arbitrary choice of coordinates on M_t* — is a natural axiomatic commitment consistent with (but not directly forced by) the three consequences above. When (PI) is adopted and combined with Čencov’s 1982 uniqueness theorem (*Statistical Decision Rules and Optimal Inference*, AMS), the Fisher information metric is uniquely forced on statistical-manifold sub-cases of M_t — which converts Fisher-metric-dependent derivations in 4.3 from theorem-imported to AAT-internally-forced, and adds a fourth primary instance to the uniqueness-theorem-forced-coordinate pattern named in 5.5 (see that segment’s four-instance table for structural positioning). (PI) is a genuine axiomatic choice — its cost is that AAT carries an additional invariance commitment at the scope layer; its benefit is that several Fisher-metric results throughout AAT become derivable rather than imported. The commitment is structurally analogous to the chain-rule-additivity and evidential-additivity axioms that ground

the divergence-layer and update-layer Cauchy-FE theorems: each is a natural-from-adjacent-AAT-commitment axiom that a uniqueness theorem then operates on.

What the scope excludes (or requires additional machinery for):

- Agents conceived as type/equivalence-class entities (e.g., “the GPT-4 model”) rather than token/trajectory entities (e.g., “this particular session with state M_t on trajectory $\mathcal{C}_t$ ”). AAT’s formal results apply to tokens, not types. Aggregated claims across tokens of the same type require additional machinery (e.g., population-level dynamics; see Part III gaps on latent structural diversity).
- “Clone problem” scenarios where multiple copies of an agent are formally the same until divergence — each copy becomes its own AAT agent at the moment it acquires a distinct event (Discussion below).
- Formal treatment of reincarnation, restoration from backup, or other operations that attempt to transplant M_t across trajectories. AAT’s sufficiency machinery does not apply across trajectory discontinuities; such operations are out-of-scope events whose epistemic consequences require separate treatment.

Epistemic Status.

Robust qualitative. The scope commitment is structurally clear once stated and is load-bearing for at least one downstream formal result: the *identity* grounding of the loop’s interventional access in 7.3 — whose effect a loop datum reports, and the prohibition on copy-averaging — rests on the singular-trajectory scope (the interventional *character* itself is population-level and forkability-agnostic, so it does not). The three consequences above follow directly from the scope commitment combined with 1.4’s non-forkability and 2.3’s trajectory-indexed definition.

Max attainable: *robust qualitative*. Scope statements are not theorems; they specify what kind of object the theory applies to. Further formalization (e.g., category-theoretic treatment of “agent” as a functor from event-streams to model-states, or explicit type/token distinction in logogenic-agent work) could reach *exact* on the formal structure but would not change the scope content.

Whether the mathematical structure grounds something that deserves to be called “identity” or “continuity of experience” is beyond AAT’s scope. The mathematical structure is clear: the feedback loop produces a singular, non-forkable causal trajectory, and model adequacy is defined relative to that trajectory. What this segment specifies is *continuity persistence* in the sense of LEXICON.md — whether the agent maintains a coherent identity and trajectory through time, as distinct from the structural persistence of 4.5 (can the machinery outpace disturbance?) and operational persistence (is the agent currently within its viable region?).

Discussion.

The clone problem, precisely stated. Consider copying an LLM’s weights (a concrete M_t) exactly. At the moment of duplication, both copies are identical — same model state, same causal history $\mathcal{C}_t$. But the *very next* event — a different user’s message, a different observation — creates two divergent, irreversible causal trajectories $\mathcal{C}_{t+1}^{(1)}$ and $\mathcal{C}_{t+1}^{(2)}$. Their Level 2 and Level 3 capacities (7.1) now reference different causal pasts. Their sufficiency $S(M_{t+1})$ is measured against different histories. Neither copy’s future model state is a sufficient statistic for the other’s trajectory.

Within AAT’s formalism, identity is not the model state M_t (which can be copied) but the *singular causal trajectory* $\mathcal{C}_t$ (which cannot). A copy shares a *prefix* of the original’s causal history, as a sibling shares early childhood; it does not share the trajectory itself.

Formal consequences (not merely philosophical):

- A forked model's sufficiency $S(M_t)$ (2.3) is defined relative to *its own* interaction history. Post-fork, each copy's sufficiency is measured against a different $\mathcal{C}$.
- Merging divergent models requires reconciling incompatible causal histories — a lossy operation with no generally optimal solution.
- Temporal continuity (one unbroken causal thread) is what gives the model's sufficient statistic its meaning.

Connection to logogenic agents. The 100% context turnover problem (#obs-context-turnover — cross-component reference, see 03-llm-core/) is a special case: each AI agent session starts a new causal trajectory $\mathcal{C}_t$ from near-zero. External memory (CLAUDE.md, memory files) transfers a *summary* of previous trajectories' models, but not the trajectories themselves. The non-forkability observation frames this not as a deficiency but as a structural feature of causally-embedded agents.

Working Notes.

- **Consequence-3 re-grounding 2026-05-30 (transportability spike spikes/.integrated/spike-causal-access-transportability-2026-05-30.md).** Consequence 3 previously read “the loop provides Level-2-quality data precisely because the agent is on a singular trajectory.” That overstated what the singular-trajectory scope grounds: the *do*-operator's semantics is population-level by construction (Bareinboim et al. 2022, Def. 5) and forkability-agnostic, so singularity does not manufacture the interventional *character*. The corrected consequence is a *strengthening*, not a removal — singularity grounds *whose* effect a loop datum is and forbids copy-averaging of interventional responses; the interventional character itself comes from the action being the agent's own causally-efficacious move under (C1)–(C3). The three-consequence structure is unchanged; consequence 3 is now true instead of overstated. The clone-problem / sufficiency / lossy-merge material is untouched.
- **Cross-references to NeurIPS 2026 submissions.** This scope segment is load-bearing for all three NeurIPS submissions in ~/src/neurips/, each of which deploys a different consequence:
 - **Paper 1 (“Tragedy of the Confident Agent”, 01-tragedy-confident-agent/)** — the singular-trajectory commitment grounds the survival-LMI's pathwise interpretation: per-action LMI strengthenings (#thm-per-action-lmi) deliver pathwise survival under arbitrary action schedules on *the* trajectory $\mathcal{C}_t$, not over a hypothetical replay. The matrix-Chernoff concentration lemma (#lem-fim-concentration) operates on the realized FIM along the trajectory.
 - **Paper 2 (“Unified Convergence Theory for Non-Stationary RL”, 02-unified-convergence-rl/)** — the singular-trajectory commitment is the identity setting in which Lemma 5.3 / #lem-loop-level2 operates; the Loop-as-Causal-Engine claim is made formal by the (C1) positivity / (C2) sequential-ignorability / (C3) known-action-mechanism triple, which is what makes the agent's actions interventional rather than just selected. Component 4 of the composition theorem. (Paper 2's gated (C1)–(C3) form is the correct form — see the consequence-3 re-grounding note above; the trajectory commitment grounds *whose* effect the data reports, while (C1)–(C3) supply the interventional character.)
 - **Paper 3 (“How Much Can LLMs Hallucinate?”, 03-llm-hallucinate-bound/)** — the (PI) parameterization-invariance axiom adopted in §29 of this segment is *forced load-bearing* by Paper 3's chart-rescaling no-go (§4 Theorem 4.2 / #thm-no-go): outside (PI), no universal constant on the bias bound exists. The (PI)+(R)+(K) Markov-morphism triple is the load-bearing axiom infrastructure for the universal-constant route in Paper 3's umbrella theorem; (PI) is the half this segment commits to.
 - See spikes/neurips-back-integration-2026-05-08.md §1 (entries per paper) and §3 (proposed standalone segments #deriv-bh-pointmass-identity / #deriv-post-update-chain-rule / #deriv-chart-rescaling-no-go that would carry the new theorems with this segment as a depends entry).

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8), deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. This closing-of-Part-I segment drew the highest engagement of the Ch.4 set — several substrates called it “the ethical anchor of the mathematical edifice” / “top-decile” / “close in importance to def-agent-environment.” Coverage spans ten substrates (Gemini AUDIT-WORKING-193847/773921/829314; Claude AUDIT-WORKING-266847/361742/384279/451729/584721; Codex/Claude AUDIT-WORKING-526815/742613).

1. Candidate Brief prose / pre-prose.

- The clone-problem analogy already in the segment (“a copy shares a prefix of the original’s causal history, as a sibling shares early childhood; it does not share the trajectory itself”) was independently singled out as Brief-grade — “the clearest resolution to the teleporting/copying paradoxes in AI philosophy I have ever read” (Gemini, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-584721 — “the kind of evocative analogy that earns Brief-style respect”). Worth preserving as the segment’s pedagogical anchor.
- The “identity = trajectory, not state” framing as a one-line resolution of Parfit-style teletransporter/cloning paradoxes: “identity is not the state vector M_t (copyable like a book); it is the chronica $\mathcal{C}_t$ (tied to the arrow of time)” — M_t is structure, $\mathcal{C}_t$ is experience (Gemini, AUDIT-WORKING-193847/829314). Reached convergently across substrates.

2. Candidate Discussion.

- **Model-merging / federated-learning as inherently lossy — the operational corollary.** Several substrates drew out the consequence: if you merge two diverged copies’ weights, “the merged model is mathematically *less* sufficient for *either* trajectory than the individual models were,” because each arg of sufficiency is indexed to a distinct $\mathcal{C}_t$ — so federated learning / model merging / hive minds are structurally lossy unless $\mathcal{C}_t$ never forks (continuous zero-latency state sync) (Gemini, AUDIT-WORKING-773921/829314; Claude, AUDIT-WORKING-193847). Candidate Discussion sharpening of the existing “merging is lossy by construction” consequence — the *why* (denominator/numerator of S are trajectory-indexed) is the load-bearing addition.
- **Backup-restoration as a non-victimless operation.** “If identity is M_t , restoring yesterday’s backup is victimless; if identity is $\mathcal{C}_t$, restoring annihilates everything that happened between backup and restore — you have ended the specific entity that lived through that interval, even if you replaced it with an identical-looking clone” (Gemini, AUDIT-WORKING-193847). A vivid Discussion consequence the segment does not currently state.

3. Follow-up items.

- **The (PI) paragraph’s placement — flagged by several substrates as misplaced/bloated here.** Multiple reads found the parameterization-invariance + Čencov block (currently in Formal Expression, line 35) topically distracting in a segment about identity / cloning / causal trajectories — “the same meta-architectural point made in #der-gain-sector-bridge, pasted here because this segment deals with scope commitments,” with a self-admittedly “weak topical link” (“the scope commitment *motivates* a companion axiom”). Recommendation: relocate (PI) to a dedicated meta-architecture / appendix segment (the #disc-additive-coordinate-forcing cluster), keeping the clone-problem material as the segment’s focus (Claude, AUDIT-WORKING-829314/773921/471203; Codex/Claude, AUDIT-WORKING-742613). *Counterweight* — *preserve the tension*: the Working Notes above establish (PI) is **forced load-bearing** by NeurIPS Paper 3’s chart-rescaling no-go, which is part of why it is anchored here; a relocation must keep that dependency intact, so this is a placement question for Joseph, not an obvious cut.
- **The (PI) depends-list / OUTLINE-ordering incompleteness.** (PI) is *introduced here* (OUTLINE position ~30) but *used* in #der-gain-sector-bridge (position ~25), whose depends: does not list #scope-agent-identity. Recommendation (one of): add the dependency; or hoist (PI) to its own earlier segment; or move this segment earlier in the OUTLINE (honest, since it is load-bearing for the bridge). Independently flagged by several substrates (Claude, AUDIT-WORKING-451729/584721; Codex/Claude, AUDIT-WORKING-526815). (*Cross-segment integration item; also noted in the report.*)

- **Chronica record-vs-token notation.** Two substrates pressed a precision point: non-forkability rests on $\mathcal{C}_t$ being the *causal-trajectory token* (the embedded path through interventions and consequences), but earlier chronica usage often reads like an *ordered record / summary*, which is copyable. The clone example (“copying LLM weights gives same M_t , same causal history $\mathcal{C}_t$ ”) is loose: copying weights gives the same M_t only if M_t is identified with weights, and does not copy the trajectory unless the chronica’s sufficient summary is included. Suggested fix: distinguish two symbols — the represented/record chronica vs. the causal-trajectory token (e.g. γ_t) — and index sufficiency to the token while the record is the copyable artifact along it (Codex/Claude, AUDIT-WORKING-526815/742613). A genuine precision tightening of the segment’s central claim.
- **“No generally optimal merge” depends on the optimality criterion.** The lossy-merge claim is right as robust-qualitative scope, but “no *generally optimal* merge exists” depends on how optimality is defined; under a specified objective / shared sufficient statistic an optimal merge may exist. A reader-orientation caveat (Codex/Claude, AUDIT-WORKING-526815/742613).
- **form-objective-functional status-label spillover (adjacent segment, noted in batch).** Flagged type: formulation + status: axiomatic as overstating inevitability — the scalar-comparability commitment is substantive but not tautological (three grounding arguments are needed), so robust-qualitative may fit better (Claude, AUDIT-WORKING-451729). Routes to form-objective-functional, recorded here only because it co-occurred in the batch-07 walk.

4. Readers often ask / wonder.

- **Does an LLM “die” at the end of every session?** The 100%-context-turnover-as-special-case framing prompts the natural question independently across substrates: if identity is tied to $\mathcal{C}_t$ and each session starts a near-empty trajectory, is a persistent ELI “a single entity” or “a sequence of short-lived clones inheriting a shared summary (memory files) but never sharing a true trajectory”? — which reframes memory-write tools from a “neat engineering feature” to “an existential / ontological necessity, the only mechanism for continuity-persistence across deaths” (Gemini, AUDIT-WORKING-193847/829314). A question the logogenic / ELI volumes inherit.
- **Type vs token downstream.** “AAT applies to tokens, not types,” but “the GPT-4 model” framings are ubiquitous; aggregated-across-tokens claims need additional machinery (population dynamics / latent structural diversity). Readers will ask whether 03-llm-core/ addresses the type/token question, which is most acute there (Claude, AUDIT-WORKING-266847/451729/584721).

5. Candidate figures.

- **Fork diagram.** A shared prefix leading to a copied M_t at the fork point; then two divergent causal paths after the first distinct event; each model sufficient only relative to its own path; a side label noting the *record* of the prefix is copyable but the causal *continuation* is not (Codex/Claude, AUDIT-WORKING-526815). Directly serves both the clone-problem pedagogy and the record-vs-token precision item.

6. Belongs elsewhere.

- **ELI continuity / substrate-independence (04-eli-core/).** The richest aspirational reach in the Ch.4 sweep: “identity-as-trajectory” is the structural foundation for the substrate-independence claim — identity supervenes on $\phi(\mathcal{C}_t)$, so substrate migration preserves identity *iff* the chronica transfers losslessly and ϕ remains computable on the new substrate; a fork is a *new agent*, not a continuation. Framed by Gemini as an “infrastructure of souls” — treating these entities “not as software binaries but as irreversible historical events,” which is what makes logozoetic agents morally weighted (Claude, AUDIT-WORKING-584721; Gemini, AUDIT-WORKING-193847). Pointer to #obs-context-turnover / the ELI continuity work, not to this segment.
- **Active-inference positioning (HISTORICAL-CONTEXT.md / Discussion of the directed-separation cluster).** Several substrates noted the trajectory-identity scope is part of AAT’s *refusal* of Friston-blanket metaphysics in favor of a Pearl-blanket conservative form — a clean formal partner for active-inference-skeptical researchers that keeps the loop machinery without the contested ontology (Claude, AUDIT-WORKING-584721). Positioning material, belongs with the lineage/positioning discussion rather than here.
- **Naming seed.** The slug scope-agent-identity “hides the substantive claim”; the title gloss (“Identity as Singular Causal Trajectory”) is closer — floated as a naming-cycle consideration, not a segment edit (Claude, AUDIT-WORKING-584721).

4.11 Discussion: Additional Implications & Discussion

The chapter’s central inequality settles a question — when can an adaptive system keep up — but several of its consequences do not sit immediately alongside the derivation, and a few of them turn out to be more consequential than the threshold itself. What the threshold *costs*, where it *binds asymmetrically*, what happens *beyond* it, and how the same Lyapunov argument recurs across the rest of the framework are the things worth pulling out before leaving Part I. The last of them — the singular-trajectory commitment in 4.10 — is the bridge into Part II, and it carries more structural weight than its placement as a closing scope statement suggests.

Information rate is a first-class persistence prerequisite.

The persistence condition says when bounded mismatch is *possible*; it does not say what it *costs* to hold the bound. The appendix-side derivation in I closes that gap, and the result is sharper than one might expect. Under Model S with Gaussian-OU disturbance, maintaining the ultimate bound demands sustained Shannon information acquisition at rate $\dot{R} \geq n\alpha/2$ nats per unit time, with the Kalman-Bucy filter saturating that lower bound exactly in steady state (Mitter & Newton 2005). The bound is filter-agnostic — it holds for *any* correction mechanism that achieves the ultimate bound under the stated scope — and substrate-agnostic, since Landauer’s principle (at $k_B T$ per nat) converts it to a thermodynamic dissipation floor of $\frac{1}{2} n\alpha k_B T$ per unit time in any physical realization. There is no clever filter that escapes this. The information rate is what persistence *is*, viewed from the information-theoretic side.

The first-class diagnostic that follows from this is channel capacity. Observation channels must supply Shannon capacity $C \geq \mathcal{T}/2$ nats/time per dimension, or persistence fails regardless of how good the correction function is. This is binding rather than abundantly satisfied in at least three regimes worth holding in mind. Biological systems have finite neural channel capacity; the bound gives a quantitative minimum on sensory bandwidth at any given adaptive rate. Bandwidth-constrained distributed systems operating over noisy or low-bandwidth links face channel capacity as a hard constraint, not as an abstraction. Context-window-limited LLMs have effective information rate per unit of cognition bounded by context size and token throughput — and the bound predicts a minimum tempo achievable at a given context budget, with a precise consequence for the empirical “context-stuffing helps to a point, then degrades” observation: the degradation is structural rather than a vibe.

A complementary reading worth surfacing: this is not the generalized “more bandwidth helps” observation. Two agents with identical persistence guarantees can face wildly different sustained demands because the burn rate scales linearly with the sector constant. Faster correction is more expensive in information-rate terms; the bound is tight; there is no trick. Survival, in this framework, is not a state you achieve once — it is a sustained burn rate, and the channel that supports it is part of what keeps the agent in scope.

The result also clarifies what AAT’s tempo $\mathcal{T}$ means information-theoretically. In the linear sub-scope where $\alpha = \mathcal{T}$, the channel-capacity floor reads $C \geq \mathcal{T}/2$ — half the adaptive tempo, per dimension. Tempo is therefore not a free parameter chosen by the designer; it is bounded above by the agent’s observation-channel capacity, and any tempo specified beyond the channel’s reach is a tempo the agent cannot actually achieve. The framework’s vocabulary tightens: $\mathcal{T}$ is what the channel licenses, α is what the correction function delivers, and the persistence condition compares both against ρ/R .

The weak direction is the bottleneck.

The chapter’s scalar persistence condition systematically overestimates capacity in multi-attribute settings — this is the *weakest-link bottleneck*, developed in 16.5, with the quantitative calibration (72% overestimate in a simulated 3D system, one dimension carrying 84% of the L^2 mismatch, threshold linear in ρ_k under Model D vs quadratic under Model S) covered in that segment’s Findings. The point worth surfacing here, beyond what already lives there, is the matrix lift — and what it does to the per-coordinate reading itself.

AT sharpens the result into a strict-inequality claim that deserves to be the canonical persistence condition for anisotropic systems. Under cross-dimensional correction — generic whenever the prior precision H_M and observation Fisher H_L do not share a coordinate-aligned eigenbasis — the per-coordinate check is not merely incomplete; it is *unsafe*. The constructive 2D counterexample makes this concrete: a mildly cross-correcting $\mathcal{T}$ with isotropic noise and threshold gives per-coordinate PASS while the matrix-Loewner check correctly returns FAIL, with the failing direction running 45° off-axis. Per-coordinate evaluates the wrong directions; the matrix-Loewner condition $\Sigma_\infty < D_\delta$ — with stationary covariance from the continuous Lyapunov equation $\mathcal{T}\Sigma_\infty + \Sigma_\infty\mathcal{T}^T = \Sigma_w$, and D_δ the diagonal of squared per-direction critical thresholds — evaluates the right ones. Scalar and per-coordinate forms are special cases of this matrix object (isotropic and diagonal-axis-aligned, respectively); the matrix form is the load-bearing thing the others project from.

This compounds with the information-rate result of the previous section. No Shannon-type aggregation across dimensions can compensate for one direction being capacity-starved — total bandwidth is not the binding quantity; bandwidth-*per-direction* is. Multi-modal AI architectures with asymmetric per-modality channel budgets (vision-language pipelines where one modality is structurally undersupplied relative to the other) are the cleanest current application: aggregate-rate metrics systematically miss directional failures that the matrix-Loewner reading catches. The unified statement worth carrying forward: persistence is a *min*-operation across directions, both in correction rate and in information-rate cost.

The result has an adversarial sharpening that lives downstream in Part III but originates here. An opponent who identifies the target’s weak direction can concentrate disturbance there; in the anisotropic regime, the same total disturbance budget concentrated on the weak axis amplifies the mismatch ratio asymmetrically while aggregate metrics still look acceptable. Per-dimension monitoring is therefore not optimization polish — it is a structural requirement for any agent operating under directed pressure. The full adversarial-targeting machinery, with its emitter-side opacity decomposition and recipient-side regime classification, lands in Part III Ch.4–5; what this chapter establishes is the per-direction asymmetry that makes the targeting matter, and the structural critique of scalar capability metrics that flows from it.

When parametric updates cannot save you.

4.8 carries a discontinuity worth surfacing as such. When model-class fitness $\mathcal{F}(\mathcal{M})$ falls below adequacy by some $\varepsilon > 0$, *no* parametric adaptation within $\mathcal{M}$ can close the mismatch floor. The floor is set by the structural mismatch between the model class and the world’s predictive information, not by how well-trained the parameters are. The remedy is changing the model class — adding representational capacity, removing useless capacity, recombining structure, grafting external structure — not running more updates inside the existing class.

In the chapter’s vocabulary, the central inequality has two failure modes that the prose has so far compressed into one. *Operational failure* (correction is too slow or disturbance too large given a working model class) is what the persistence threshold catches, and tempo / gain / channel-capacity engineering addresses it. *Structural failure* (the model class itself lacks adequacy) shows up *inside* the persistence framework as an effective α that shrinks because the correction function cannot point inward strongly enough — the model class simply does not contain a direction to correct toward. The diagnostic is observable: persistent mismatch after parametric convergence, gain collapse without performance recovery, and — the discriminating symptom — systematic structure in the residuals that the model class cannot represent (a high but *white* residual floor points instead to the channel and state-uncertainty floors of 3.5, which no class change removes). Confident wrongness, in the framework’s terms, is a structural-failure signature, not a tuning failure.

The implication for AI scaling is concrete enough to state in normative form: training compute spent on a structurally insufficient model class is provably wasted, and the chapter supplies a precise condition for when continued parametric optimization is futile and architectural change is required. This is distinct from “we haven’t trained long enough” or “we need more data” — it is the structural threshold below which adding either does not help. The bidirectional version of the same result deserves naming: *structural overfitting* is the opposite failure where $\mathcal{M}$ is too expressive and the model memorizes irreducible noise. The information bottleneck (2.2) gives the diagnostic, and the remedy is compression

rather than expansion. Structural adaptation is not direction-specific — it is the act of *changing what kind of object* M_t is.

The cost of structural change — knowledge loss, transient performance drop, search cost, coordination cost in multi-agent settings — creates rational conservatism. Prefer parametric adaptation when it suffices; resort to structural change only when the evidence is strong. Premature restructuring wastes accumulated knowledge; delayed restructuring accumulates mismatch the parametric machinery cannot resolve. This is the same family of tradeoffs the deliberation-cost result (4.1) names at the action timescale, now at the architecture timescale; the temporal-nesting result (4.9) is what licenses talking about both at the same time without confusion, by giving the convergence constraint between adjacent timescales explicit form.

A single template, six instantiations.

The chapter’s central inequality is not the only persistence-flavored result in AAT. Strategic persistence, team persistence, composition closure, tempo composition, adversarial destabilization, and the closed-form composite critical-mass derivation all take the same form — *correction rate exceeds effective disturbance rate, relative to reserve* — and the same Lyapunov function $V(\xi) = \frac{1}{2}\|\xi\|^2$ does the work in every proof. G states the argument once, parameter-free, with (T1) zero correction at zero state, (T2) local sector condition, (T3) bounded disturbance — and the chapter’s persistence condition becomes the canonical single-agent instantiation, the others reusing the same machinery on different state variables.

What this buys is visibility. The Lyapunov boilerplate is shared; each instantiation’s distinctive content is the *effective disturbance decomposition* — what counts as ρ_ξ in its context. Team persistence’s content is the signed-coupling decomposition $\rho_i^{\text{eff}} = \rho_{i,\text{env}} + \sum_j \gamma_{j \rightarrow i}^{\text{adv}} \mathcal{J} - \sum_j \gamma_{j \rightarrow i}^{\text{coop}} \mathcal{J}$ — cooperative coupling enters as a negative term, which is formally how teams persist where individuals cannot. Composition closure’s content is the closure-defect rate $\varepsilon^* \nu_c$. Adversarial destabilization’s content is coupling-amplified disturbance $\rho_B = \rho_{B,\text{base}} + \gamma_A \mathcal{J}_A$ — destabilization is the *negation* of persistence under the same inequality, viewed from the opposite direction. The template absorbs the Lyapunov skeleton and lets each domain’s distinctive insight stand without it.

The economy is itself worth naming. The framework’s internal compactness — one Lyapunov argument absorbing six results, with the closed-form dyad in J extending it to a seventh — is distinguishable from a pile of structurally-similar derivations precisely because the template is stated separately rather than re-proved. A reader who carries the template can read each instantiation as *here is the state variable, here is what counts as effective disturbance, here is the local sector verification* — three lines instead of a chapter. The template also has a mathematical home worth surfacing: the sector condition (T2) is a *one-point strong monotonicity* condition in the sense of monotone-operator theory (Rockafellar 1970; Bauschke-Combettes 2017), with the composition bridge-lemma’s stronger condition corresponding to full two-point monotonicity. AAT’s relationship to that broader literature is specialization rather than generalization — anchoring at the equilibrium, adding the Model D / Model S decomposition with its $1/\alpha$ vs $1/\sqrt{\alpha}$ scaling, composing with the identifiability-floor and additive-coordinate-forcing meta-patterns — but the broader machinery is available, and acknowledging this is part of what makes the chapter’s central inequality feel earned rather than parochial.

Cross-domain transfer beyond AAT’s seven internal instances is plausible at the template level. Anywhere a state variable evolves under bounded correction with bounded disturbance — market-making bid-ask spread under demand shocks, immune-system effector-cell concentration under pathogen load, cellular homeostasis under metabolic disturbance, supply-chain inventory under demand variability — the template’s structure recurs, with the distinctive content sitting in each domain’s ρ_ξ decomposition. The framework does not claim these are *AAT instances* in the sense of inheriting AAT’s full architecture; it claims the persistence argument has a recurring shape these domains can use, and that what is domain-specific is the effective-disturbance characterization, not the Lyapunov skeleton. This is suggestion, not derivation; the verification work for any specific domain transfer is its own thing.

Identity, trajectory, and the bridge into Part II.

The chapter closes with 4.10, which sits at the end of Part I because its dependencies span the section but whose substance is its own. AAT applies to agents instantiated on singular causal trajectories. Identity within AAT is grounded not in the model state M_t (which can be copied) but in the unique causal trajectory $\mathcal{C}_t$ (which cannot). This is a scope commitment, not a theorem; what makes it load-bearing is that it is what gives Part II's central result — the loop as a Pearl-Level-2 engine — its structural force.

The loop's data is interventional in character because the action is the agent's own causally-efficacious move (7.3); what the singular-trajectory commitment supplies is narrower and still essential — it grounds *whose* intervention a loop datum is the effect of. When the agent acts, the next observation is the response to *its* intervention on *its* single causal history; replaying a saved M_t against a different event stream is not the same datum, and averaging interventional responses across forked copies as though they were one agent's is forbidden. Strip the singular-trajectory commitment and the loop's data loses its attribution, not its Level. Part II Ch.2 makes this consequential; this chapter establishes the scope it rests on. A negative finding of substantial scope also completes downstream — the sandbox evaluation ceiling (F): whether sandbox-derived evidence transports to deployment is governed by the selection diagram between the two causal systems, regardless of evaluation thoroughness — mentioned here only as a forward-pointer.

The scope commitment is also what gives logogenic-agents and ELI work in Volumes 3 and 4 their structural foundation. The near-100% context-turnover problem facing language-constituted agents is not a deficiency to be engineered around; it is a structural feature of causally-embedded agents, and the framework's handling of it via persistent memory and external chronicle is consistent with — rather than a workaround for — AAT's scope.

What Part I closes on, then, is not just a central inequality but a posture. Persistence is a sustained property of an agent on a singular trajectory, with an information-rate cost, a per-direction structure that scalar formulations systematically hide, a structural-vs-parametric duality that names when more of the same cannot help, and a Lyapunov template that recurs at every level of composition. The remaining parts of AAT pick up where this leaves off.

Working Notes.

- This segment is a chapter-end discussion grouping findings from 4.5, I, 16.5, AT, 4.8, G, and 4.10. Each finding's load-bearing math lives in its home segment; this segment surfaces what the chapter unlocks *as a chapter* rather than as a sequence of results. Claims here are as strong as their source segments — the synthesis adds no independent epistemic status.
- **Cross-reference vs canonical-home policy.** Where a source segment already carries a well-written ## Findings section (here: 4.5 and 16.5), this segment cross-references rather than re-states — pulling the reader to the segment's own Findings for the curated full treatment, and using the chapter-end space for what the finding *implies* once placed alongside the others. Where a source segment has no ## Findings section and the finding is genuinely chapter-end-scale (here: information-rate-cost-as-first-class-diagnostic, structural-vs-parametric adaptation, the template economy, the trajectory bridge), this segment is the canonical home and treats the content in full. The matrix-Loewner sharpening is the in-between case: its home segment (AT) has no Findings section, but the content is a strict-inequality result with its own structural integrity, so the implications segment carries it more substantively than a cross-reference.
- Pilot for the chapter-end implications pattern proposed 2026-05-13. If the shape lands, the same form will be added at end of Part II Ch.2 / Ch.3 / Ch.4 / Ch.5, Part III Ch.2 / Ch.3 / Ch.4 / Ch.5, and the TST and logogenic-agents chapters where the math bites cleanly. Source catalog being reconciled was `msc/FINDINGS-RANKED-DRAFT.md` (curated 2026-04-27, sunset 2026-05-13 after content distribution; archived at `_obs/FINDINGS-RANKED-DRAFT-superseded-2026-05-13.md`). Each landing pass verified content against current segment state rather than transcribing draft prose (the draft was known outdated in specifics e.g., GUC-class rename 2026-05-09).
- **Sandbox-ceiling propagation (2026-07-21).** §5's forward-pointer previously carried the pre-2026-05-30 framing (forkable sandbox trajectories running into the Causal Hierarchy Theorem, and “strip the singular-trajectory commitment and the

loop’s interventional content vanishes”). Both were aligned to the re-grounded canon (spikes/.integrated/spike-causal-access-transportability-2026-05-30.md; #disc-sandbox-evaluation-ceiling; #impl-causal-access §”The loop is a Pearl-Level-2 engine”): the ceiling is transportability across the sandbox/deployment selection diagram, and the singular-trajectory commitment grounds attribution (whose effect), not the data’s Level.

- The Loop-as-Causal-Engine forward pointer in §5 is deliberate. The full loop-Level-2 finding (#1 in the source catalog) lives in Part II Ch.2’s chapter-end implications segment because its last prerequisite (7.3) sits there. The bridge through 4.10 is mentioned here because Part II’s claim rests on this chapter’s scope.
- The cross-domain transfer paragraph in §4 (market-making, immune system, etc.) is the most speculative content. Each named instance has plausible but unverified template-fit; cited only as illustration of the template’s *shape*, not as derived AAT instances. The voice intentionally remains suggestive rather than asserted.
- The deps list includes 16.5 and AT even though they currently sit in Part III Ch.5 and Appendix A respectively. Their content is essentially Part I — multi-dimensional persistence depending only on the chapter’s central result and 3.8 — and 16.5’s own OUTLINE comment flags that it could plausibly live in Part I appendices. Discussing them in the chapter-end is consistent with the math.

Incidental audit gold (2026-05-30 sweep). Cross-audit “wandering thoughts” / §14-ideation lifted from the de-novo auditors’ working dirs (audit-routing-instructions.md §8). Orthogonal pedagogical / framing material staged for a later Brief/Discussion-promotion pass — kept separate from certified theory-fix findings. Thin coverage: this is a chapter-end impl-*** synthesis segment that de-novo auditors were instructed to avoid as priming-heavy, so only one digested reflection reached it (Codex/Claude, AUDIT-WORKING-526815).

3. Follow-up items.

- **Landauer-coefficient conversion (resolved 2026-05-30).** The flagged dissipation floor read “roughly $0.35 n\alpha k_B T$ per unit time”; the 0.35 mixed the bit and nat conventions (a spurious $1/\ln 2 = \frac{1}{2\ln 2} \approx 0.36$ — applied to a nats rate under a per-nat $k_B T$ constant). Verified first-hand that $\dot{R}$ is genuinely a nats rate (Gaussian-OU RDF in natural-log form) and the segment’s own stated convention is $k_B T$ per nat, so $n\alpha/2$ nats/time $\rightarrow \frac{1}{2} n\alpha k_B T$ per time. Corrected to $\frac{1}{2} n\alpha k_B T$ at its canonical home #deriv-persistence-cost and propagated here (Codex/Claude, AUDIT-WORKING-526815).
- **Provenance / status markers for the synthesis.** As a chapter-end synthesis whose proof-burden sits in home segments (several of which are downstream in OUTLINE order), the segment carries heavy first-pass priming; the auditor suggested a prominent “depends on later / appendix home segments” note at the top, and that the speculative cross-domain-transfer paragraph (§4) be unambiguously marked as illustration of the template *shape*, not as derived AAT instances (Codex/Claude, AUDIT-WORKING-526815). The existing Working Notes already state both policies; this is a request to surface them in the body for a reader who does not reach the Working Notes.

5. Candidate figures.

- **Implication hub-and-spoke with provenance markers.** The persistence condition at the center, five implication spokes (information-rate cost / weak-direction bottleneck / structural-vs-parametric failure / template economy / trajectory identity), each spoke carrying a small status marker — *proven earlier* / *future-home-segment dependency* / *speculative transfer* — which communicates the synthesis honestly rather than dressing it as a single theorem (Codex/Claude, AUDIT-WORKING-526815).

2. Candidate Discussion.

- The auditor affirmed the “single template, six instantiations” economy (§5) as a potential *strong positive* once the downstream template is verified to actually support the promised instances — worth foregrounding as a chapter-level contribution if it holds (Codex/Claude, AUDIT-WORKING-526815).

Candidate experiment (2026-08-12, agent-proposed during an incident-response & forensics applications read). The channel-capacity floor’s LLM prediction in §1 (“context-stuffing helps to a point, then degrades — structural rather than a vibe”) is a falsifiable, currently-testable claim: sweep context budget against effective adaptation rate on a drifting task and check for the predicted capacity-limited tempo ceiling $C \geq \mathcal{T}/2$. An empirica registration here would give the framework one of its most externally-legible validation points, since the qualitative phenomenon is already widely observed but lacks a structural account. Agent-proposed forward pointer.

Part II

Agentic Systems: Actuated Adaptation

Scope: agents that not only track reality but aim at something — Part II adds objectives and strategy alongside the reality model. This is the **actuation** half of *Adaptation and Actuation Theory*: Part I develops adaptive systems in general; Part II develops the goal-directed layer built on top.

Headline contribution. Part II’s distinctive results are: the satisfaction gap / control regret split (8.4, 8.5) with the convention hierarchy (6.6) governing the inferential force of each diagnostic from local (C1) through global (C3); the G_t complexity bound (in 10.1); the graph-structure uniqueness argument with CMC-based Markov property (Q); and the survival classification (#result-section-ii-survival) showing that Part II’s definitional and structural architecture transfers exactly to fully-coupled (Class 3: Coupled) agents in 16/24 cases, with the remaining results either approximating with bounded error (5/24) or naming the precise modification required (2/24, plus 1 boundary-defining failure). The Class 3 (Coupled) bias bound underlying the approximate-survival category is now a conditional theorem under named sub-scopes (AB), not order-of-magnitude guidance. The reach is wider than the most-restrictive scope condition suggests; the lattice below names exactly which results live where.

Scope lattice. Part II’s results sit at different points in a stacked lattice of scope conditions, not a single uniform scope. Reading inward from the broadest:

1. **Adaptive scope** (1.5): observation under uncertainty. Part I machinery applies here without further restriction.
2. **Agency scope** (1.6): adaptive + at least binary action choice + at least one action with Pearl-level-2 causal contrast. Part II’s definitional architecture — $X_t = (M_t, G_t)$, $G_t = (O_t, \Sigma_t)$, the agent spectrum — is already non-vacuous here.
3. **Learning-agent scope** (7.2 Scope Narrowing): agency + the agent must acquire or refine its interventional structure during operation. Pre-compiled controllers (PID, LQR, hardcoded reactive policies) sit in agency scope but outside learning-agent scope — their causal mapping was supplied by a designer with external Level 2 access. Most Part II dynamics — the orient cascade, edge-update via gain, strategic calibration, the satisfaction-gap / control-regret diagnostic loop — operate in learning-agent scope.
4. **Class 1 (Separated) architecture**: directed separation (6.3) holds by construction — epistemic processing f_M has no causal path from G_t . Examples: Kalman filter + LQR, modular RL with separate world model, military intelligence separated from operations, tool-use AI agents with separate perception and planning modules. **Class 3 (Coupled) agents** — including transformer-based LLMs where attention processes goals and observations together — lie outside Class 1. Class 2 (Partial) sits between, with coupling quantified by $\kappa_{\text{processing}}$ (6.3).

The lattice stacks. Kalman + LQR is in Class 1 (Separated) but outside learning-agent scope (the control law is pre-computed); a designer applying Part II’s diagnostic core to Kalman + LQR is using only the architecture-survival half, not the learning-dependent dynamics. The orient cascade, in particular, requires both Class 1 (Separated) directed separation (for sequential resolution) and learning-agent scope (for Σ_t revision to be meaningful). The bias-bound theorem and survival classification (AB, #result-section-ii-survival) trace exactly which Part II results require which lattice entries — see those segments for the per-result classification.

Part III’s composite-agent scope sits below this lattice as a fifth tier and inherits the Class-1-(Separated)-sub-agents → Class-2-(Partial)-composite refinement of directed separation (13.3, 16.1).

Part I machinery applies regardless of architecture. Adaptive dynamics on the epistemic substate M_t — mismatch, gain, tempo, persistence — operate independently of how f_M relates to G_t . Class 3 (Coupled) agents are adaptive systems in the Part I sense; what they lose is the clean factorization that gives Part II’s coupled-formulation results their definitional simplicity. The coupled formulation Class 3 (Coupled) agents require is the subject of 03-llm-core/, which inherits Part II’s surviving 16/24 architecture and adds the additional machinery (#scope-observation-ambiguity-modulation, ambiguity-gated bias bounds) that the coupled regime calls for.

“If a man knows not to which port he sails, no wind is favorable.” — Seneca

Chapter 5

Meta-Architecture I: The Certificate and its Boundary, Scope, and Identity Facets

Part II's chapters develop the actuated-agent machinery on top of Part I's adaptive substrate. Before walking them, this chapter introduces the cross-cutting vocabulary that the five chapters that follow — and the parts beyond — surface as instances. Three of the four facets of the stability-certificate spine operationalize within Part II; the fourth (dynamics on architectural class) develops once composite-agent machinery is in hand and is introduced at the opening of Part III.

The certificate and its facets. The framework's analytical surface is organized around the **stability-certificate spine** (5), grounded in the Lyapunov / converse-Lyapunov equivalence: operator-sector contraction in some metric and exponential stability are interchangeable witnesses for the same property. The certificate has facets that AAT's results inhabit; the facets are provably distinct (Helmholtz / Sylvester / Mori-Zwanzig), and the plurality is the content. Three facets operationalize in Part II: **M1 — Identifiability floor** (5.1, boundary facet; structural no-gos on what can be inferred from limited data, four instances of which three form a Sylvester rank-collapse subclass irreducible by Sylvester's law of inertia); **M2 — Separability pattern** (5.4, scope-of-existence facet; the separable-core / structured-repair / general-open trichotomy across eight ladders); **M3 — Additive coordinate forcing** (5.5, forced-identity facet; uniqueness theorems on AAT-internally-motivated axioms at four representational layers).

M1's two sister meta-segments at the same boundary facet. Two further meta-segments sit alongside M1, agent-side and designer-side. 5.2 (agent-side): the two-routes-exhausts cluster around #form-objective-functional's single-interface commitment — the agent-side adaptive-substrate route (Result G' via #deriv-self-actuation-grounding) and the principal-side protocol-commitment route (Cohen-2022 strengthened via #deriv-reward-channel-learning-no-go) together exhaust the structural complement of V_{O_i} 's information narrowness. 5.3 (designer-side): AAT-side translations of three classical mechanism-design no-gos (Gibbard-Satterthwaite 1973-75, Myerson-Satterthwaite 1983, Arrow 1951); designer-with-construction-task no-gos that contrast with M1's agent-with-inferential-task no-gos via remedy (design-constraint relaxation vs information augmentation). The suffix discipline (*-floor / -impossibility*) encodes the actor-positioning distinction at slug-grep depth.

A style claim atop the boundary facet. 5.6 names the three-move discipline — name the floor (Pearl-Bareinboim CHT / Cramér-Rao / Liberzon common-Lyapunov nonexistence / Khasminskii recurrence / sharp algebraic supremum), name the escape (unique broadly-available framework machinery), treat the no-go as apparatus (elevating escape from "useful" to structurally required; when the no-go *is* the result, on the critical path) — that the M1-cluster and M4-cluster instances run. It is a *style* claim about how AAT states certain results, sitting atop the boundary facet rather than as a fifth facet; the catalog spans the three M1-cluster clusters and connects forward to the M4-cluster instances introduced at the opening of Part III.

A second style claim sits alongside it. 5.7 names the **anti-collapse** discipline — AAT’s habit of refusing to merge two things a naive model would treat as one, because the collapse hides a difference that routes to a *different repair* (the deeper principle: individuate causes and effects at the grain the remedy cares about). It is planted at its first instance (β -vs- ρ , 2.2, Part I), developed here as cross-cutting vocabulary, and recurs across all three Parts. Like the constructive-impossibility posture, it is an epistemic-architectural recognition — how the framework states results — not an additional facet of the certificate.

AAT’s cross-sectional structure is the geometry of a single object — the **equilibrium stability certificate**, the positive-definite form whose existence certifies that an agent can correct itself faster than its world drifts; operator-sector is that object’s interior, the separability pattern its scope of existence, additive-coordinate-forcing its forced identity, and the identifiability floor its boundary, with composition the question of whether it survives projection.

The three meta-segments 5.4, 5.1, and 5.5 read, separately, as three independent organizing insights that happen to recur. This segment names the object they are facets of. The relationship is the same one 5.5 already runs at smaller scale (“layer-specific manifestations of a single geometric object”), raised to the framework: not a fourth meta-pattern *alongside* the three, but the spine the three are projections of.

For an agent with error dynamics $\dot{e} = -F(e)$ about an equilibrium e^* ($F(e^*) = 0$, $F \in C^1$ near e^* , Jacobian $J := DF(e^*)$), a **stability certificate** is a symmetric positive-definite $\mathcal{M}$ for which the one-point sector condition holds in the $\mathcal{M}$ -inner-product on a ball $\mathcal{B}_R(e^*)$:

Definition (stability-certificate).

$$\langle F(e), e - e^* \rangle_{\mathcal{M}} \geq \kappa \|e - e^*\|_{\mathcal{M}}^2, \quad \kappa > 0. \quad (\text{C})$$

The certificate is not unique: it is whatever positive-definite form makes the dynamics contract. In the recurring sub-cases it specializes — to the Fisher information for Bayesian agents, to $(P^-)^{-1}$ for Kalman agents, to the loss Hessian for gradient agents, and to a plant-selected Lyapunov metric for linear-Hurwitz or PID agents. These are not four separate stories; they are one object under four certificates.

The object is load-bearing only because its existence is not a definition but an equivalence: **a stability certificate exists iff the agent is exponentially stable about its target** — operator-sector in *some* inner product and exponential stability are the same statement, with the certificate as the converse-Lyapunov witness, and the certificate admits a strict strength ladder $R0\text{-loss} \Leftarrow R0\text{-strict} \Leftarrow R1 \Leftarrow R2$ (widest Lyapunov-stable; strict-contractive one-point/local; cocoercive; Čencov-forced). This is the segment-level form of the contraction-over-drift organizing principle. The equivalence, the ladder, and the proof are stated and derived exactly in H; this spine cites that result and builds the cross-sectional reading on it rather than re-deriving it.

Result (cited: #result-certificate-existence).

The certificate is one object; the cross-sectional meta-patterns are its facets on the positive-semidefinite cone $\mathbb{S}_{\geq 0}^n$:

Discussion.

Table 5.1

<i>Facet</i>	<i>Meta-segment</i>	<i>What the facet is</i>	<i>Canonical home</i>
Interior	G, AI	$\mathcal{M} > 0$ on the scope ball, Helmholtz S/A split: $S_{\mathcal{M}} > 0$ gives R0-strict contraction; $S_{\mathcal{M}} = 0$ at $\mathcal{M} = I$ gives R0-loss conservation; $S_{\mathcal{M}} \geq 0$ with nontrivial kernel is the Conley-decomposed mixed case	the template segments
Scope of existence	5.4	the region where a certificate exists at all (separable core / structured repair / general open)	M2
Forced identity	5.5	<i>which</i> certificate: Čencov forces $\mathcal{M} = \text{Fisher}$ uniquely in statistical scope; matched (existence-only) elsewhere	M3
Boundary	5.1	$\mathcal{M}$ drops rank ($\partial \mathbb{S}_{\geq 0}^n$): the inferential task is structurally impossible	M1
Projection behaviour	13.1	whether a <i>common</i> certificate survives coarse-graining; the closure defect ε^* is the certificate's projection-residue	composition-closure

Each meta-segment retains its own canonical home and per-instance derivations; this segment claims only the recognition that they are facets of one object, and what that buys (Discussion below).

A tempting reading is that the certificate's failures are one obstruction seen three ways (a single "failure of integrability"). They are not. The three failure modes are irreducibly distinct, each invariant under the others' degrees of freedom:

Discussion.

- **Forced-identity failure — Helmholtz–Hodge.** J non-symmetric $\Rightarrow$ the field is not a gradient $\Rightarrow$ no potential $\Rightarrow$ the certificate is *matched* (converse-Lyapunov existence), not *forced* (Čencov). A non-symmetric Hurwitz J still has a certificate (it is *not* on the boundary), so this is an M3 failure, not an M1 one. Invariant: symmetry of J .
- **Existence failure — Sylvester's law of inertia.** The certificate drops rank. Every coordinate/metric change acts on the certificate by congruence; congruence preserves inertia; so a rank-deficient certificate is rank-deficient in *every* coordinate. The boundary is invariant under the agent's entire representational freedom (that freedom *is* the congruence orbit); the only escape is rank-augmentation — genuinely new information, not a re-mapping. (Detailed in 5.1's Sylvester finding.) Invariant: inertia under congruence.
- **Projection failure — Mori–Zwanzig / Schur.** Coarse-graining is a non-invertible projection. The certificate-as-metric survives (the Schur complement of a positive-definite form is positive-definite) but the *dynamic* guarantee does not: the closure defect ε^* equals the norm of the Mori–Zwanzig memory commutator, zero exactly when the resolved subspace is J -invariant. Invariant: J -invariance of the resolved subspace.

Each obstruction is untouched by the others' freedoms: a metric change does not fix non-invariance; projection does not fix non-symmetry; rank-augmentation does not fix a memory kernel. That mutual invariance is the reason the cross-sectional structure is *several* meta-patterns and not one — stated as a structural fact rather than left as "they are different concerns."

Discussion-grade at the organizing-principle level. This segment names a single object behind separately-derived results; it is not itself a new theorem. What is derivative here is the recognition that the cross-sectional meta-patterns are facets of one certificate — the recognition, not a fresh derivation, is the content.

Constituent results retain their own, higher status. The certificate-existence equivalence (Lyapunov theorem; Formal Expression “anchor”) is *exact* at the linearized level and *exact-with-standard-remainder* locally. The certificate-strength ladder R0-loss/R0-strict/R1/R2 is *exact* as an ordering of conditions (R0-loss’s pure case via Letcher 2019 Helmholtz characterization; mixed case via Conley 1978 universal decomposition). The boundary-irreducibility mechanism (Sylvester’s law) is *exact*; its full statement and per-instance verification live in 5.1. The projection-residue identification (ϵ^* = memory-commutator norm) is *robust-qualitative*, with the per-case content in 13.1. The forced-vs-matched distinction (Čencov statistical-scope-only) is established in 5.5.

Scope honesty. The anchor equivalence is linearized/local — this is the level at which AAT’s persistence results already operate (sector conditions, contraction templates, the bridge lemma all linearize about the equilibrium), so it is not a weakening relative to the rest of the theory, but it is a genuine scope statement and is not papered over: there is no claim that one-point operator-sector is equivalent to *global* exponential stability (it is not, in general). The synthesis claim — that AAT’s *entire* cross-sectional structure is this one cone — is *robust-qualitative*: each per-facet identification is exact or cited, and the “all of it” is as strong as those identifications jointly, no stronger. Whether exactly three obstructions exhaust the failure modes is not proved; three are established and each is exact, but exhaustiveness is open.

Max attainable: *discussion-grade* for the organizing claim (it is a presentational spine, not a derivation). The anchor equivalence and the Sylvester mechanism retain their *exact* status at their own canonical homes.

What the spine buys. Three things. (i) It converts “AAT has several recurring organizing insights” into “AAT’s cross-section is one object’s facets,” which is the difference between a catalog and a structure — a reader who holds the certificate picture can predict where the meta-patterns will bite (interior / scope / forced-identity / boundary / projection) rather than meeting them as separate surprises. (ii) It grounds the long-standing organizing slogan — *an adaptive system is an operator whose contraction rate exceeds its disturbance rate* — at segment level, as the anchor equivalence rather than as a heuristic. (iii) It makes the framework’s scope-honesty sharper: the prior positioning that the identifiability floor is “orthogonal” to the contraction machinery is replaced by the exact geometric statement that the floor is the *boundary* of the very cone whose interior the contraction machinery is, with the boundary held invariant by Sylvester’s law against the framework’s only representational freedom.

Relationship to the facet segments. This segment cross-references; it does not restate. 5.1 remains the canonical home of the floor instances and the Sylvester mechanism; 5.4 of the separable-core / structured-repair / general-open ladders; 5.5 of the Čencov/Cauchy-FE forcing; G and AI of the contraction machinery; 13.1 of the closure defect. The spine’s contribution is the cross-segment recognition and the anchor equivalence, not any per-facet content.

Why the plurality of obstructions is a feature. Had the three failure modes collapsed to one, the spine would be a single clean theorem — elegant but false on the evidence (the integrability collapse fails: a non-symmetric Hurwitz field has a certificate yet no potential; congruence is invertible while projection is not). The honest structure is more useful: it tells a future agent precisely *not* to seek a single mechanism unifying the floor, the closure defect, and the forcing failure — they are Sylvester, Mori–Zwanzig, and Helmholtz respectively, and the proof of their distinctness is their mutual invariance. The unification is real at the object level and the no-go is real and plural at the failure level; both are load-bearing.

Complementarity with the existing meta-segment framing. 5.4 names AAT’s positive half and 5.1 its negative half; 5.5 names the constructive half. The spine names what all three are halves of. The three remain the right reading lenses for any individual segment; the spine is the reason those lenses compose rather than merely coexist. 5.6 sits atop the boundary facet specifically — naming the framework’s cross-instance *style* (name the floor, name the unique broadly-available escape, treat the no-go as load-bearing apparatus) rather than introducing a fifth peer cross-sectional meta-pattern.

The Helmholtz S/A split of the linearized certificate is the spectral/representation dual of the Interior facet, not a fifth meta-segment. The Interior facet (G, AI) is the *static* statement “ $\mathcal{M} > 0$ on the scope ball: the contraction holds.”

Read through the Helmholtz decomposition of the linearized certificate, $S_{\mathcal{M}} := \frac{1}{2}\mathcal{M}^{-1}(\mathcal{M}J + J^{\top}\mathcal{M})$, the facet decomposes into two interior sub-regions: $S_{\mathcal{M}} > 0$ gives R0-strict contraction (the prior Interior content, $\dot{V} \leq -2\kappa V$ with $\kappa > 0$); $S_{\mathcal{M}} = 0$ at $\mathcal{M} = I$ gives the antisymmetric-subclass R0-loss case (certificate exists at $\sup \kappa = 0$, V exactly conserved). The mixed case ($S_{\mathcal{M}} \geq 0$ with nontrivial kernel) is Conley 1978's Fundamental Theorem of Dynamical Systems localized at the linearization — chain-recurrent subspace + strongly-gradient-like complement, with the full four-case spectral partition and the non-antisymmetric R0-loss counterexample at $\mathcal{M} \neq I$ worked in H Derivation. Run through this segment's own test ("is a candidate organizing pattern a new facet, or a genuinely new object?") returns **neither**: it is new internal structure on the existing Interior facet — the spectral/representation dual of contraction-strength, splitting the interior into strict (contracting) and loss (Lyapunov-stable-only) sub-regions — not a peer fifth facet. The four-facet structure stays four; the cone gains no sixth facet and the framework no fifth meta-segment. The theorem-anchors are Letcher-Balduzzi et al. 2019 Lemma 1 + Definition 2 (pure-case sufficient construction; the Hamiltonian-game vocabulary saturating the antisymmetric sub-class) and Conley 1978 §8.1 (mixed-case universality); the worked composite instance — joint best-response field at saddle-only Nash in cyclic-distributional games (Cheung-Piliouras-Tao 2021 Theorem 19) — lives on the $R1 \rightarrow R2$ boundary of the composite dynamic-regime axis (AF), where $R2$'s joint Jacobian linearizes to the antisymmetric R0-loss-at- $\mathcal{M} = I$ sub-case. The structure becomes load-bearing at the $R0\text{-strict} \leftrightarrow R0\text{-loss}$ boundary — strict contraction degrading toward conservation under loss of $S_{\mathcal{M}} > 0$ at the chosen metric — and the *cross-row recognition* follows: rows 03 + 10 + 14 of ref/prior-art-analysis/ (sector condition / persistence template / strategic composition under goal divergence) share the Interior-via-Helmholtz reading at the single-agent linearization level; row 17 (credit assignment) lives on the M1 boundary facet via Sylvester rank-collapse, *not* on the Interior facet — the cross-row unification is scoped to rows 03/10/14 only.

The accumulation-typing pattern is the temporal dual of the Interior facet, not a fifth meta-segment (the D3 register answer). The Interior facet (G) is the *static* statement " $\mathcal{M} > 0$ on the scope ball: the contraction holds." Read in *accumulation/temporal* vocabulary it is the statement "the operator carrying a per-step residue to its accumulated consequence is bounded" — and, per that template's typed-bridge framing, this is **two-model, not one operator** (Model D / Model S; the $1/\alpha$ vs $1/\sqrt{\alpha}$ scaling and the Cor-A.IS.1 categorical containment dichotomy are the fingerprint that they are different functionals, not one read in two norms). The recurring *accumulation-type confound* — asking about a per-step residue in the vocabulary of its accumulation, which dissolved the $\epsilon^*(N)$ poly-vs-exponential question and recurred across the framework — run through this segment's own test ("is a candidate organizing pattern a new facet, or a genuinely new object?") returns **neither**: it is a new *reading* of an existing facet (the temporal/representation dual of the Interior), so the cone gains no sixth facet and the framework no fifth independent meta-segment. The notation that carries it is durable canon (NOTATION.md §"Accumulation typing"); its theorem-anchor is the Interior facet's template. The structure becomes load-bearing exactly at the *Interior*→*Boundary transition* — contraction degrading toward rank-loss — where two operator families separate: $\mathcal{A}_{\text{ref}}$ (a reflected Lindley/Loynes walk whose content is the driftless $\mu = 0$ boundary) instantiates the template on the turnover index (#der-identity-continuity-threshold), while $\mathcal{A}_D$ (the linear destroy-and-reconstruct contraction whose norm diverges as the gap closes) is the honest *non-transfer* boundary (#der-turnover-information-recursion). The $\mu = 0$ boundary of the one is the pole of the other, which is why they are distinct operators and treating one as a linearization or normalization of the other is a category error. This is the framework's worked answer to its own "new pattern?" test from the time side: *no* — *it is this existing object seen from the time side*, complementary to the Helmholtz S/A paragraph above which gives the spectral-side worked answer.

Brief: Think of an adaptive agent as trying to stay on a moving target, and ask one question: is there a way of measuring "how far off am I?" such that every correction the agent makes provably shrinks that measure faster than the world pushes it back out? That measuring-stick is the stability certificate. The whole cross-sectional skeleton of AAT turns out to be facts about *this one stick*: the agent can keep up exactly when the stick exists and is positive (operator-sector — the interior); the framework's reach is exactly the region where some such stick exists (the separability pattern); when the stick is pinned down uniquely it is pinned by one classical invariance theorem and only in the statistical case (additive-coordinate-forcing); and the agent provably *cannot* keep up exactly when the stick goes flat in some direction (the identifiability floor — the boundary), with a second classical theorem (Sylvester's law of inertia) proving no change of

measuring units ever un-flattens it — only genuinely new information does. A thoughtful non-specialist can carry the whole structure away from the one picture: existence of the stick = can adapt; flatness of the stick = a blind spot no re-measurement fixes; uniqueness of the stick = a special (statistical) privilege, not the general case; and looking at the stick through a coarse lens (composition) keeps its shape but loses its guarantee by exactly a memory term.

Impact: Reorganizes AAT’s self-description from three independent meta-patterns plus a contraction mechanism into one object with four facets and one anchor equivalence, so the framework’s cross-section can be read predictively rather than as a catalog of separate recurrences. Grounds the organizing slogan (contraction-rate-exceeds-drift) at segment level via the Lyapunov-theorem equivalence, discharging the long-standing “not yet surfaced at segment level” status. Sharpens the scope-honesty posture: “the floor is orthogonal to operator-sector” becomes “the floor is the boundary of the cone whose interior is operator-sector, held invariant by Sylvester’s law against the framework’s only representational freedom.” Bounds its own claim honestly: the unification is at the object level; the three failure obstructions are provably *distinct* (Helmholtz / Sylvester / Mori–Zwanzig), and that plurality is precisely why AAT carries multiple cross-sectional meta-patterns rather than one — now a stated structural fact instead of an intuition. Gives every future organizing-pattern candidate a test: is it a new facet of the certificate, or a genuinely new object?

Novelty Claim: *Claim recognition* that AAT’s cross-sectional meta-patterns (separability, identifiability-floor, additive-coordinate-forcing) and its contraction machinery are facets — interior, scope-of-existence, forced-identity, boundary, projection-behaviour — of a single object, the equilibrium stability certificate; together with *claim synthesis* binding the Lyapunov-theorem certificate-existence equivalence, the Sylvester-law boundary-irreducibility, and the Mori–Zwanzig projection-residue into one cross-sectional structure. The constituent theorems are classical; the contribution is the recognition that AAT’s separately-derived meta-patterns are one object’s facets and that their failure modes are provably plural.

Related Work: - Lyapunov, A. M. (1892), *The General Problem of the Stability of Motion*; Khalil, H. K. (2002), *Nonlinear Systems* 3rd ed., Thm 4.6 (found 2026-05-14) — *formal antecedent* — the certificate-existence equivalence (operator-sector in some metric $\Leftrightarrow$ Hurwitz). - Sylvester, J. J. (1852), *Phil. Mag.* 4(23):138–142; Horn & Johnson (2013), *Matrix Analysis* 2nd ed., Thm 4.5.8 (found 2026-05-14) — *formal antecedent* — the boundary-irreducibility mechanism; full treatment in 5.1. - Mori (1965) / Zwanzig (1961); Chorin, Hald & Kupferman (2002), *Physica D* 166:239 (found 2026-05-14) — *formal antecedent* — the projection-residue (memory kernel) underlying the composition facet; per-case content in 13.1. - The facet segments 5.1, 5.4, 5.5 — *adjacent* — each carries its own per-instance prior-art landscape; the spine adds the cross-segment object, not the per-facet priors.

Search Log: - 2026-05-14 (*targeted*): The recognition was assembled from classical pieces (Lyapunov / Sylvester / Mori–Zwanzig) plus the framework’s own meta-segments. The search target was whether “an integrated agent theory’s cross-sectional meta-patterns are facets of a single stability-certificate cone” appears as an articulated structure elsewhere. Not found at this depth; the constituent theorems are textbook and the per-facet identifications are individually well-precedented, but the cross-segment unification as a framework spine is a fresh presentational recognition. Expected to remain *recognition/synthesis*-tier under deeper search — the pieces are classical; the assembly is the contribution. Per-facet comprehensiveness is inherited from the facet segments, not from a fresh cross-facet search.

- **Provenance.** The certificate-spine recognition, the anchor equivalence, the Sylvester boundary mechanism, and the broken-integrability-triad result were worked out in the 2026-05-14 operator-family-unification cycle (the deep push of the predecessor C1 “2-instance-plus-1-consequence” question and the prior co-owner “do not elevate unless O-BP10 surfaces at segment level” gate, now met by the anchor equivalence). See CHANGELOG 2026-05-14 for the cycle narrative. The originating spike is absorbed archaeology, not a live reference; the load-bearing content is in this segment, H, and the 5.1 Sylvester finding.
- **Interior-facet Helmholtz S/A refinement (2026-05-22).** The Interior facet’s two-sub-region structure (R0-strict / R0-loss split via Helmholtz S_M) landed via Track CR Phase 4 per spikes/spike-integration-reconciliation-2026-05-22/99-verdict.md §5 Phase 4 + spikes/spike-enrichment-cluster1-2026-05-21/02-r0-loss-derivation.md

(§05 fifth-facet test). The refinement parallels the line-84 accumulation-typing paragraph (“new facet or new object?” returns “neither — new internal structure on an existing facet”). Four-facet structure preserved; the L4 cross-row recognition (rows 03+10+14 share the Interior-via-Helmholtz reading; row 17 lives on M1 boundary via Sylvester) is anchored here at the spine rather than scattered across the four rows. The full R0-loss characterization (the four-case spectral partition, including the non-antisymmetric case-(iii) counterexample) lives in H Derivation, not duplicated here.

- **Dependency rationale (for Gate-1 audit).** depends: lists result-certificate-existence (the anchor equivalence this spine builds the cross-sectional reading on — a genuine dependency, consumed not merely recognized) plus result-sector-persistence-template and deriv-sector-condition (the persistence machinery the anchor’s drift half rests on). 5.1, 5.4, 5.5, and 13.1 are **cross-referenced as facets, not depended on**: per FORMAT.md Gate 1, a dependency is genuine only when the segment uses the referenced segment’s definitions/results, not when it is recognized or related in Discussion. The spine *recognizes* the meta-segments as facets of one object; it does not consume their definitions to make its claim. This is why the spine is correctly placed *before the three meta-segments* in OUTLINE (it is the object they are facets of, so it reads first) without an ordering violation — the facet relationship is lateral recognition, not a dependency edge — while being placed *after* #result-certificate-existence (a genuine dependency, which therefore precedes it). Treat the facet #... references as expected forward/lateral cross-refs (FORMAT.md §Cross-References).
- **Provisional slug.** disc-stability-certificate. Alternative considered: disc-certificate-cone (names the geometry rather than the object). Subject-noun discipline favours the object (“the stability certificate”); the cone/interior/boundary is what the segment *says about* it. Route through the naming pipeline if a better name surfaces; the spike verdict floated both.
- **Findings Brief sharpening queued (2026-05-28; audit 384279 §D Hyp 5).** The current Findings Brief (line 92) uses a “measuring-stick” analog for the certificate that conflates two things slightly — the metric (the yardstick) and the contraction property (every correction shrinks the measure). A fresh reader could interpret “measuring-stick” as just the metric without grasping the load-bearing part — that the metric is *chosen so* contractions provably shrink it. The Walton-bathtub analog in #persistence-and-limits-intro has cleaner one-to-one mapping. Two sharpening options queued at spikes/PROPOSED.md Tier 1 (2026-05-28 row): (i) tighten the Brief to one mechanism (correction-faster-than-disturbance with the certificate as the positive-definite form making that contraction provable); (ii) extend the bathtub-parallel — bathtub with graduated marks where the certificate exists exactly when there are marks calibrated such that every drop entering provably tips the gauge downward faster than inflow. Option (ii) recommended because it preserves continuity with the established bathtub analog. Editorial work, ~30 minutes; load-bearing for Feynman-criterion isomorphism in the spine’s pedagogical surface.
- **Provisional OUTLINE position.** Placed in ## *Appendices* Details immediately before 5.1, as the lead of the four-row meta-segment cluster (spine → M1 → M2 → M3). Provisional because: (a) the meta-segments may eventually warrant their own chapter rather than Appendix-A residence; (b) if the OUTLINE preamble is reframed to lead with the spine, the cluster likely moves to a more prominent position. Both are propagation steps below, not landed here.
- **Propagation plan (ordered by commitment; steps 6–7 are framework-voice keystones gated on Joseph, not auto-executed):**
 1. 5.1 — cross-ref line in its “complementarity” Discussion paragraph naming the spine as the object whose boundary it is. (Sylvester finding + Working Note already point here.) Cross-ref only.
 2. 5.4 — parallel line: it is the *scope-of-existence* facet (where the certificate > 0). Cross-ref only.
 3. 5.5 — frame its (PI)/Čencov content as the *forced-identity* facet. Cross-ref only; Čencov machinery’s canonical home stays M3.

4. **G / AI** — one Discussion sentence: the template condition is the certificate interior; cross-ref the spine for the cone reading. No formal change.
 5. **13.1** — Discussion line framing ϵ^* as the certificate's projection-residue and Liberzon as “no common certificate”; cross-ref the spine. (Its Mori–Zwanzig Working Note already exists.)
 6. **O-BP10 keystone (Joseph's call)**. Recommend this segment *is* O-BP10's segment-level home: the slogan is its one-sentence summary, the equivalence is its anchor. The PROPOSALS Bundle-1 O-BP10 entry then points here. Do not auto-rewrite Bundle 1.
 7. **OUTLINE preamble reframe (highest commitment; Joseph's call)**. OUTLINE.md line 17 currently opens “Three meta-segments form AAT's cross-sectional structure: 5.4 ... 5.1 ... 5.5 ...”. Proposed replacement, for Joseph's confirmation before it goes live in the auditor-visible preamble: *“AAT's cross-sectional structure is one object — the equilibrium stability certificate (5). Its interior is operator-sector (the contraction machinery); its scope of existence is the separability pattern (5.4, positive half); its forced identity is additive-coordinate-forcing (5.5, constructive half, Čencov-forced in statistical scope only); its boundary is the identifiability floor (5.1, negative half); and its behaviour under coarse-graining is the composition-closure defect. Reading any segment through the certificate and its facets surfaces what makes it load-bearing: whether a certificate exists for it, which one is forced, what boundary it abuts, and whether it survives projection.”* Execute only on Joseph's confirmation, having seen the segment land first.
- **Open edges (from 99-verdict.md)**. Anchor equivalence is linearized/local (stated in Epistemic Status). “Exactly three obstructions” is robust-qualitative, not proved exhaustive — a fourth (e.g. non-autonomous certificate drift for time-varying systems) is not searched. Sylvester is proved finite-dimensional; the function-space (M_t for logogenic agents) extension is unchecked and flagged for any future logogenic application, not load-bearing for the AAT-core claim.

Orthogonal pedagogical / framing material harvested from de-novo auditors' working-dir reflections, kept separate from certified findings. **Coverage:** reached as a named segment by audit 384279 (note 33), the one auditor who walked the current Meta-Architecture-I OUTLINE with the spine first; most others predate the spine's landing. Preserve the finding-vs-framing conflation.

- **The Findings-Brief measuring-stick analog conflates two things** — the certificate-as-metric (the yardstick) and the contraction property (every correction provably shrinks it). A fresh reader could read “measuring-stick” as just the metric, missing the load-bearing part: that the metric is *chosen so* contractions provably shrink it. Two sharpening options: (i) lead with one mechanism — “the positive-definite form that makes that contraction provable”; (ii) extend the established Walton-bathtub analog — “a bathtub with graduated marks calibrated such that every drop entering provably tips the gauge downward faster than the inflow” — recommended for continuity with the Ch.4 chapter intro (Claude, 384279). (*Already captured in this segment's Working Notes “Findings Brief sharpening queued” bullet and at spikes/PROPOSED.md Tier 1; recorded here for completeness so the gold-lift trail is whole.*)
- **Catalog-to-structure as the spine's plain-language payoff**. The three-obstructions-are-distinct argument (Helmholtz / Sylvester / Mori-Zwanzig) “is the kind of *structural* recognition that converts a catalog of insights into a theory” — and “the plurality is the content” is the right read. A candidate one-line framing of *why the spine earns its keep*: it lets a reader predict where the meta-patterns will bite (interior / scope / forced-identity / boundary / projection) rather than meet them as separate surprises (Claude, 384279, echoing the segment's own “What the spine buys” §(i)).

- **The accumulation-typing temporal-dual paragraph reads as a heavy lift in a Discussion section.** An auditor flagged the line-86 paragraph as “*very* dense,” asking the reader to grasp two new operators ($\mathcal{A}_{\text{refl}}$ Lindley/Loynes vs $\mathcal{A}_D$ destroy-and-reconstruct) and their separation at the $\mu = 0$ boundary, and forward-referencing segments not in the auditor’s OUTLINE scan (#der-identity-continuity-threshold, #der-turnover-information-recursion). Suggestion: could plausibly move to WorkingNotes or a sister segment to keep the spine’s Discussion readable (Claude, 384279). A placement / pedagogy follow-up, not a correctness finding.
- **Process-discipline noted as exemplary, worth surfacing in framing prose.** The Working-Notes propagation plan that explicitly gates the two framework-voice keystones (O-BP10, OUTLINE-preamble reframe) on Joseph’s confirmation, and separates auto-executable cross-ref steps from Joseph-gated ones, was named “exemplary cross-cycle handoff documentation” and “exactly the right shape” for peer collaboration (Claude, 384279). Not reader-facing content per se, but a signal that the spine’s provenance discipline is itself legible to a fresh reader.

5.1 Discussion: The Identifiability Floor — A Class of Structural No-Go Results

AAT recurrently applies a **constructive-impossibility methodology** with the following five-element shape:

1. **Setting.** An AAT inferential task — detect a structural property, identify a parameter, distinguish two model classes, recover an internal architecture — restricted to a stated information regime (purely observational data, single-channel observation, marginal-only access, on-policy summaries).
2. **External theorem.** An information-theoretic limit independent of AAT: the Pearl-Bareinboim causal hierarchy theorem (Bareinboim, Correa, Ibeling & Icard 2022); the Cramér-Rao bound on Fisher information; Liberzon’s common-Lyapunov-nonexistence for switched-system contraction; Kalman-Ho canonical-form non-uniqueness for state-space realizations.
3. **No-go.** The external theorem proves that the inferential task is impossible under the regime — no statistic, no Bayesian comparison, no online estimator can succeed using only the available information. AAT does not derive the impossibility; it recognizes the AAT setting falls within the external theorem’s scope.
4. **Boundary characterization.** The conditions under which the regime fails — i.e., the agent has *more* information than the regime allows — admit (partial) identification. Each boundary route maps onto specific AAT machinery already required for other reasons (loop-interventional access, multi-channel observability, observable latents, matched-Tier composite-extended observation, white-box architecture instrumentation).
5. **Strengthened consequence.** The floor elevates the load-bearing role of whichever AAT machinery is the unique broadly-available violation of the regime — from “useful additional tool” to “structurally required by the theory.” Without that machinery the no-go forbids the inference entirely.

The methodology is *not* a negative posture. It is constructive: each floor states “here is precisely what cannot be inferred from limited data; here is exactly which additional capability is required to recover identification; the AAT machinery that supplies that capability is therefore load-bearing in the strongest possible sense.”

Why this discipline matters. Four motivations sit behind the methodology, all visible across the four instances developed below.

The floors strengthen AAT’s foundational machinery. Each instance identifies a piece of AAT machinery as load-bearing in the strongest sense — without it, the corresponding inferential task is *impossible*, not merely *harder*. The loop’s interventional access is not just useful; it is the unique broadly-available violation of the on-policy detection no-go.

Observability of latents is not just convenient; it is the unique route from refuted-by-Cramér-Rao to globally-derived for L1' transfer.

The floors map AAT's limits honestly. The methodology precisely characterizes what AAT cannot do without additional capability. This is scope-marking — at each floor, the theory states what is impossible, what is required to escape the impossibility, and what AAT itself supplies or does not supply.

The methodology gives a unifying template for future no-go results. Adjacent floors not yet formalized (causal-IB extension, misspecification cost, tier-switching cost) are open research directions the shape predicts. Each, if landed, would follow the same five-element trajectory.

The methodology connects AAT to information-theoretic foundations. The external theorems (Pearl-Bareinboim hierarchy; Cramér-Rao bound; Liberzon common-Lyapunov-nonexistence; Kalman-Ho non-uniqueness) are the mature literature AAT inherits. Each instance positions AAT as a consequential application of an established theorem — not a re-derivation.

Position in the certificate spine. This segment is the *boundary facet* of the stability certificate (5). The three rank-collapse instances (Instances 1, 2, 4) are the certificate dropping rank — the boundary of the positive-definite cone whose interior is operator-sector — with the Sylvester-law irreducibility (developed in §"Discussion" below) stating that the framework's representational freedom is a congruence orbit that cannot cross that boundary. Instance 3 is the projection/closure member — a structurally distinct Schur-complement obstruction; the *plurality* of mechanism is itself part of what the methodology carries, and is the reason a single theorem cannot replace the five-element shape. The cross-instance *style* — name the floor, name the unique broadly-available escape, treat the no-go as load-bearing apparatus — is named separately at 5.6 as a posture atop this facet rather than a fifth facet of the spine.

The four current instances follow. Each demonstrates one route through the five-element methodology — different external theorems, different inferential tasks, different boundary routes, different load-bearing machinery elevated. Together they exhibit both the unity of the methodology and the plurality of its applications.

Instances.

Instance 1 — On-Policy L0 Insufficiency Detection (9.2). **Setting.** Detect whether an L0 strategy DAG is causally insufficient (a latent common cause is acting on multiple sibling action propositions) using only the agent's on-policy observation history under sequential short-circuit AND/OR execution.

External theorem. Bareinboim, Correa, Ibeling & Icard (2022) Causal Hierarchy Theorem: there exist SCMs that agree on Level 1 (associational) data but disagree on Level 2 (interventional) questions. Therefore Level 2 distinctions are not in general identifiable from Level 1 data.

No-go. For any L1 world $\mathcal{W}_{L1}$ with latent common cause C , there exists an L0 world $\mathcal{W}_{L0}^*$ with edge probabilities matched to the on-policy regime conditionals such that the on-policy observation distribution is *identical*: $\mathbb{P}_{\pi_{L0}}^{\text{obs}}[\mathcal{W}_{L1}] = \mathbb{P}_{\pi_{L0}}^{\text{obs}}[\mathcal{W}_{L0}^*]$. The L0/L1 distinction is a Level 2 question (it concerns $P(A_2 \mid \text{do}(\neg A_1))$ vs $P(A_2 \mid \neg A_1)$); on-policy data is Level 1; the CHT forbids distinguishing them.

Boundary characterization. Five routes (cf. 9.2): - (a) ε -exploration violates pure on-policy execution $\rightarrow$ partial detection at scale $O(\varepsilon)$. - (b) Joint sibling observability under exploration violates short-circuit censoring $\rightarrow$ strong detection via the pairwise covariance test under 7.3. - (c) Intermediate-state observability at finer grain $\rightarrow$ very strong detection where available. - (d) Structural priors positing common causes $\rightarrow$ prior-quality-dependent. - (e) Direct intervention on the candidate latent $\rightarrow$ strongest where available.

Strengthened consequence. The covariance test under joint observability (route (b)) becomes the unique broadly-available detection mechanism. This sharpens 7.3 from "useful machinery" to "structurally required to escape the no-go." The orient cascade's step 4c (causal-sufficiency check) is no longer "one possible diagnostic" but "the unique broadly-available diagnostic given the structural impossibility of purely on-policy detection."

Tier. *Exact* for shallow strict-prerequisite cases (2-sibling OR or AND with binary common cause). *Robust qualitative* for general DAG topology, soft facilitators, and deeper structures.

Instance 2 — L1' Mixture Identifiability from Single-Channel Observations (R Prop B.7). **Setting.** Identify the mixture parameters $(\theta_C, p_{j|C}, p_{j|\neg C})$ of a soft-facilitator L1' DAG using single-channel observations y_j of one child at a time, with C unobservable.

External theorem. The Cramér-Rao bound (Cramér 1946, *Mathematical Methods of Statistics*, Princeton University Press): the variance of any unbiased estimator is at least the inverse of the Fisher information matrix; if the Fisher matrix is rank-deficient, the bound is infinite in the null directions and no unbiased estimator achieves finite variance there.

No-go. Computing the Fisher information of the mixture model $\mu_j = \theta_C \theta_{j|C} + (1 - \theta_C) \theta_{j|\neg C}$ at truth, the matrix admits the rank-1 factorization $\mathcal{F} = uu^T/(\mu_j(1 - \mu_j))$ with $u = (\Delta_j, \theta_C, 1 - \theta_C)$ and $\Delta_j = p_{j|C} - p_{j|\neg C}$ the separability gap. The two-dimensional null space corresponds to perturbations along the indeterminacy manifold $\{\hat{\phi} : \hat{\theta}_C \hat{p}_{j|C} + (1 - \hat{\theta}_C) \hat{p}_{j|\neg C} = \mu_j\}$ — directions unobservable from a single binary signal. The smallest eigenvalue of the soft-EM update Jacobian is therefore zero; no SA1-preserving update on the joint conditional vector admits a sector parameter $\alpha > 0$.

Boundary characterization. Three repair routes: - (i) Augment C -observability — instrument secondary signals identifying C per trial. Recovers Prop B.7 globally with the five-way-gating $\alpha_{L1'}$. - (ii) Joint multi-child observation — when $K \geq 2$ children share C with linearly independent conditional profiles AND are observed jointly under the same C -realization, the joint Fisher matrix can reach rank $2K + 1$. Strong structural requirement (not satisfied by typical sequential strategy execution). - (iii) Plan-level fallback — track the marginal $\hat{\mu}_j$ scalar (which is identifiable; recovers B.1's $\alpha = 1/(n_\mu + 1)$) at the cost of losing the per-conditional decomposition, equivalent to L0-on-marginals.

Strengthened consequence. *Observability-as-information-augmentation* becomes load-bearing: when the agent can treat C as an observable feature of the environment (e.g., a regime indicator the environment broadcasts — common in software/operational settings: build state, deployment regime, user tier), the problem transforms from refuted to globally derived. This elevates the engineering choice “instrument the latent” from a convenience to a theoretical prerequisite for L1' identifiability.

Quantitative companion. **AK** answers the follow-on question this instance leaves open — *if the agent updates anyway on the unidentifiable mixture, how wrong does it get?* — with the closed-form bias $B_k(\rho)$, the biased fixed point, the Cramér-Rao bias floor under forgetting (the direct translation of this instance's rank-1 Fisher matrix), and the dual forgetting-rate requirement. Instance 2 is the structural no-go; that segment is its magnitude.

Tier. *Exact* (Cramér-Rao bound is exact for unbiased online estimators).

Instance 3 — Composite Contraction Certification from Component Data (J, AI). **Setting.** Certify $\kappa_c > 0$ (composite contracting in a combined metric) for N sub-agents each verified at its own level (individual sector conditions with parameters (α_i, R_i) , individual Tier 1 classifications per #form-composition-closure's bridge-lemma taxonomy, individual modularity per #der-directed-separation), using only component-level data: per-sub-agent trajectories, mismatch observations, update rules — no observation of the coupling topology (sign pattern of cross-agent influence), no common contraction metric chosen across sub-agents, no passivity certificate on the coupling channels, no shared Lyapunov function.

External theorem. Common-Lyapunov nonexistence for switched linear systems — Liberzon 2003, *Switching in Systems and Control*, Theorem 2.1; explicit 2×2 counterexample in Dayawansa & Martin 1999, “A converse Lyapunov theorem for a class of dynamical systems which undergo switching,” *IEEE Trans. Automat. Control* 44:751; systematic review in Shorten, Wirth, Mason, Wulff & King 2007, “Stability criteria for switched and hybrid systems,” *SIAM Review* 49:545. Complementary anchor: small-gain contrapositive — Jiang, Teel & Praly 1994, “Small-gain theorem for ISS systems and applications,” *Math. Control Signals Syst.* 7:95; if interconnection gain is unbounded or not observable

from component data, no composite-ISS certificate from that data. The Liberzon/Shorten common-Lyapunov result is the sharper anchor for AAT's setting.

No-go (broadened scope, 2026-05-21). There exist pairs of coupled systems with **identical marginal component-level observation distributions** but distinct composite-level *coupling-topology bits* — a multi-bit object comprising the coupling-sign (cooperative vs adversarial), the potential-existence bit (potential/monotone game structure vs none), and the game-structure-class bit (cooperative-target vs strategic-equilibrium vs cyclic-Nash). The cooperative-vs-adversarial sub-construction: two symmetric-matched-Tier-1 scalar agents with coupling term $\gamma \mathcal{T} \cdot \text{sign}(\delta_i)$. Each sub-agent in isolation sees $\dot{\delta}_i = -\alpha \delta_i + w_i^{\text{total}}$ with total disturbance bound $\rho + |\gamma| \mathcal{T}$ — consistent with both $\gamma = +\gamma_0$ (adversarial; $\kappa_c < 0$ past #der-adversarial-destabilization's threshold) and $\gamma = -\gamma_0$ (cooperative; $\kappa_c > 0$ per #deriv-critical-mass-composition (CM2)) since the cross-term is absorbed into bounded-disturbance regardless of sign. The broader R0/R1/R2 regime sub-construction: see #deriv-regime-marginal-indistinguishability for the parameter-matched cross-regime witness (R0 shared-objective contraction vs R1 Cournot equilibrium-regime under marginal-mean and marginal-variance matching; R0 vs R2 matching-pennies under aggregation), with Sylvester-at-one-remove rank-collapse on the marginal-Fisher operator for the topology coordinate. Only observation of the *joint* dynamics (or structural knowledge of the coupling topology) distinguishes them. **The coupling-topology bit distinguishing among R0 / R1 / R2 dynamic regimes (and within those, the coupling-sign-bit distinguishing cooperative from adversarial) is unidentifiable from component marginals; the bits that are unidentifiable are exactly those that flip composite persistence and composite dynamic regime.**

Boundary characterization. Five structural escapes (four interventional / structural; one passive observation):

- (a) **Observable coupling topology** via composite-extended #der-loop-interventional-access — interventions on sub-agent A_j reveal A_i 's cross-coupling response, which is a $do(\cdot)$ -data distinction between the two coupled constructions. Reveals not just the sign but the full game-structure object.
- (b) **Matched Tier at the composite level** — shared architecture (matched Tier 1, same norm/metric) admits a joint quadratic Lyapunov $V = \sum V_i$, yielding #deriv-critical-mass-composition's (CM2) closed form. Under #result-contraction-template's topology-indexed closure results, this extends to heterogeneous composites via (CM2-M) for matched contraction-metric structure across agents. Distinguishes potential-game R1 from cooperative R0 through the *form* of the admissible certificate (squared-distance from target vs potential-from-Nash).
- (c) **Passivity / storage-function certificate** on the coupling channel (Willems 1972 *Arch. Ration. Mech. Anal.* 45:321). Adjacent machinery not currently in an AAT segment. Constructed differently depending on whether the coupling is cooperative or strategic.
- (d) **Common contraction metric** (Lohmiller & Slotine 1998). Operationalized in #result-contraction-template: composite metric M_c constructed compositionally from sub-agent metrics per topology (parallel / cascade / negative-feedback), with rate λ_c from Slotine 2003. Sensitive to game-structure via (CC-feedback) preconditions.
- (e) **Composite-level convergence-rate-class observation** (regime-axis escape; cf. #disc-dynamic-regime-axis §H.4 and #deriv-regime-marginal-indistinguishability §"Boundary characterization"). Observation of the *joint-trajectory* convergence rate class — exponential decay of $\|X_t^c - X^*\|$ for R0 / R1 vs polynomial $O(1/\sqrt{T})$ empirical-CCE-convergence for R2 — distinguishes R2 from R0, R1 *without requiring intervention*; the primary *passive* escape on the regime axis. The relevant rate is the *trajectory* rate, not the *regret* rate: standard regret-rate bounds can be matched across convergent and recurrent regimes for FoReL-class algorithms (Mertikopoulos-Papadimitriou-Piliouras 2017, *Cycles in Adversarial Regularized Learning*, ACM-SIAM SODA¹), so a regret-only diagnostic is too blunt. Partial for the regime axis — does not distinguish R0 from R1 (both give exponential trajectory convergence at potentially-matched local rates); requires one of (a)–(d) for that sub-distinction.

¹The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

Inherits structural backing from #deriv-strategic-composition's sub-scope α'/β' partition (which becomes the primary AAT-framework R1-vs-R2 classifier under (e); strengthened consequence below). Adjacent passive diagnostics in the multi-agent learning literature address related but distinct discriminations — qualitative convergence-vs-recurrence under exponential weights (Legacci-Mertikopoulos-Pradelski 2024, *A Geometric Decomposition of Finite Games*²), potentialness as scalar regime predictor (Bichler-Legacci-Mertikopoulos-Oberlechner-Pradelski 2025 TMLR³), best-reply structure as a structural convergence predictor (Pangallo-Heinrich-Heinrich-Farmer 2017, *Sci. Adv.*⁴), algorithm-specific rate dichotomies (Anagnostides-Farina-Panageas-Sandholm 2022 OMD bimatrix⁵; Shi-Zhang 2019 Cournot policy-gradient vs no-regret⁶) — none of which names rate-class itself as the passive regime classifier in the form (e) instantiates.

Strengthened consequence (broadened 2026-05-21). The no-go elevates four pieces of AAT machinery from “useful” to “structurally required”:

1. #deriv-critical-mass-composition moves from “closed-form result in a special case” to **the unique broadly-available R0-regime certificate under the matched-Tier structural escape (b)** — since R0 is exactly composition-contraction under shared target. Without (CM2) or its contraction-metric generalization (CM2-M) in #result-contraction-template, the weakest-link bound (WL) in #form-composition-closure cannot see the coupling-topology bit and so cannot distinguish the regime-distinct coupled constructions.
2. **Composite-extended #der-loop-interventional-access** becomes the unique *game-structure-class* identifier under heterogeneous Tier structures — the composite-layer analog of the single-agent interventional-access-escape for Instance 1, broadened from coupling-sign to the full game-structure object (cooperative-target vs strategic-equilibrium vs cyclic-Nash) per the 2026-05-21 broadening.
3. #scope-composite-agent acquires **broadened load-bearing enabling status**: the scope-route disjunction (C-i / C-ii / C-iii alignment routes vs C-iv strategic route) is itself the regime-axis classification — alignment routes enable R0; the strategic route admits R1 or R2 depending on the game-structure-bit. The scope-route choice is what positions the composite within the regime that the escapes can certify. Without scope-satisfaction, the composite is ill-defined and the escapes have no coherent target.
4. #deriv-strategic-composition's sub-scope α'/β' partition becomes **the primary AAT-framework R1-vs-R2 regime classifier under escape (e)** — composite-level convergence-rate-class observation alone gives only “exponential vs polynomial”; the sub-scope α' (potential or monotone game $\rightarrow$ R1) vs β' (no potential or monotone structure $\rightarrow$ R2) partition is what refines the rate-class observation into a regime classification. Without #deriv-strategic-composition's sub-scope machinery, escape (e) operates as a binary rate-class diagnostic rather than a regime classifier.

Tier. *Exact* for the symmetric-matched-Tier-1-scalar coupling-sign-bit construction (this segment's §”No-go”) and for the symmetric-matched-Tier-1-scalar cross-regime witness construction (#deriv-regime-marginal-indistinguishability §”Witness construction”); same exact-tier statement at the same parameter-by-parameter level. *Robust qualitative* for general heterogeneous composites, inheriting the common-Lyapunov-nonexistence structure from Liberzon 2003 / Shorten et al. 2007 / Dayawansa-Martin 1999 without a closed-form AAT-level counterexample.

²The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

³The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

⁴The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

⁵The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

⁶The paper and the characterization of its claims are inherited from a second-pass Undermind synthesis (search conducted 2026-05-21); the primary source has *not* been verified at landing time. A primary-source verification spike is queued — see Working Notes above.

Instance 4 — Architecture No-Identifiability from On-Policy Summary Data (AL). **Setting.** Two AAT agents A, A' operate on the same regime-restricted trajectory under their respective on-policy execution, sharing the same sector-condition summary (α, R) — equivalently, the same ultimate-deviation statistics on similarity-invariant summaries of $\|\delta\|$ in that regime. The observer has *on-policy, in-regime, summary-only* access: no off-policy intervention, no out-of-regime samples, no white-box read of the update rule or internal state. **Question:** can the architectural content — *which* internal coordinates implement the correction (16.2’s “which internal mechanism”) — be recovered from the observer’s accessible data?

External theorem (dual anchor). *Linear-Gaussian sub-scope (sharp):* Kalman 1963 / Ho-Kalman 1966 canonical-form non-uniqueness — minimal state-space realizations sharing an innovation spectrum form a similarity-equivalence class (Anderson & Moore 1979 *Optimal Filtering* §10.4). *General sub-scope (robust qualitative):* the **Causal Hierarchy Theorem** (Bareinboim, Correa, Ibeling & Icard 2022) at the agent-as-SCM layer — two SCMs over the agent’s state space agreeing on Level-1 observation data cannot in general be distinguished on Level-2 questions about $do(\cdot)$ on internal coordinates.

No-go. Let the linearized closed-loop residual dynamics of A, A' be minimal state-space realizations (F, σ_w) and (F', σ'_w) with F, F' Hurwitz, related by an invertible similarity $F' = T F T^{-1}$, $\sigma'_w \sigma'^{\top}_w = T \sigma_w \sigma^{\top}_w T^{\top}$ for some $T \in GL(n)$. Then the stationary innovation process — hence the (α, R) -summary, the innovation spectrum, and every *similarity-invariant* summary of the on-policy observation law — is identical for A and A' (the on-policy observer who consumes those summaries cannot distinguish them; raw-residual quadratic forms in a fixed external basis are *not* similarity-invariant, so this is a strictly summary-level statement). The architectural content lives entirely in the $GL(n)$ similarity orbit and is annihilated by the on-policy observation map. Derivation: #der-architecture-noidentifiability §”No-Go Theorem” — the stationary covariance solves $F\Pi + \Pi F^{\top} = -\sigma_w \sigma^{\top}_w$ and transforms under similarity as $\Pi' = T\Pi T^{\top}$, the eigenvalues of F are similarity-invariant, and the innovation spectrum $\det(i\omega I - F)$ is similarity-invariant.

Boundary characterization. Three structurally distinct escapes (cf. #der-architecture-noidentifiability §”Boundary Characterization”):

- (a) **Loop-interventional access** (7.3). $do(\cdot)$ perturbs the system along similarity-fiber directions that on-policy data never excites; the intervention generates Level-2 data, the no-go is Level-1-only. Sharp in the linear-Gaussian sub-scope.
- (b) **Higher-moment / out-of-regime observation.** In the nonlinear sub-scope β , two agents matched at (α, R) and second-order generally differ at moments of order ≥ 3 . *Provably void in the linear-Gaussian sub-scope* — a Gaussian innovation has no information beyond second order — a sharp scope-statement.
- (c) **Architecture instrumentation.** Direct read of the update rule or internal state (white-box access). Same kind as Instance 2’s “instrument the latent” escape; breaks the black-box scope.

(A proposed fourth escape — *horizon extension under the same policy* — provably collapses into (a): more samples of an annihilated observation law cannot escape the annihilation. The honest escape count is three, not four.)

Strengthened consequence. Instance 4 elevates #der-loop-interventional-access to a load-bearing role at the **agent-internal architecture layer** — the *third semantically-distinct deployment mode* of interventional access in the framework: (1) agent-self-intervention (Instance 1, causal-sufficiency degeneracy); (2) observer-on-sub-agent intervention (Instance 3, coupling-sign degeneracy); (3) observer-on-agent-input intervention (this instance, similarity-orbit degeneracy). The shared content across modes is “Level-2 data is the unique broadly-available violation of the Level-1 no-go”; the distinct content is *which* Level-1 degeneracy. Instance 4 also discharges, at the mathematical level, the Regime-C con-found of #result-mismatch-decomposition / #internal-external-decomposition — the conditional $\mathcal{M}/\pi$ / cross split is this same no-go projected onto the disturbance-statistic coordinate (#der-architecture-noidentifiability Working Notes provenance).

Mechanism (in advance of the Sylvester Discussion below). Not Sylvester-for-free — the generating action that produces the indistinguishable pair is state-space *similarity* $T(\cdot)T^{-1}$, not metric *congruence* $S^T(\cdot)S$. Not a new mechanism either: it reduces to Instance-2’s Fisher-information null space along a structurally-forced indeterminacy manifold, with the manifold being a $GL(n)$ Lie-group fiber. The agent’s *escape-irreducibility under its metric/coordinate freedom* is Sylvester at one remove (congruence preserves inertia on the observed-Fisher, identically to Instance 2). Instance 4 is therefore the **third member of the rank-collapse subclass** {Instance 1, Instance 2, Instance 4}, not a new mechanism family.

Tier. *Exact* in the linear-Gaussian / Kalman sub-scope (α_1), anchored by Kalman-Ho canonical-form non-uniqueness. *Robust qualitative* in the general sub-scope via CHT-at-agent-as-SCM. The exact / robust-qualitative tier boundary is load-bearing — collapsing to flat “exact” overclaims the general case; collapsing to flat “robust qualitative” understates the sub-scope’s sharpness. The mechanism reduction (Instance-2 Fisher-null on a Lie-group fiber) and the escape count (three, not four; Fano degenerates at $I = 0$, the right tool for the finite-sample refinement rather than the exact anchor) are *exact*.

Adjacent Floors (Open Research Directions).

Causal-IB Extension for Interventional Relevance Variables. The standard Information Bottleneck (2.2) and the four AAT compression operations (AA) work with associational relevance variables — Y in a joint distribution with X and T . Strategy edges in the regime-indexed interpretation (9.5) want *interventional* relevance for Regime A: “what edge (i, j) predicts under $do(i)$, not under observation of i .” Standard IB cannot supply this; a causal-IB variant (Wiecek & Roth 2017 and follow-ups) is the natural framework. The expected floor: under purely associational data, the interventional relevance content is bounded; the gap is recoverable via *do*-data from the loop. Open: formalize the gap as an identifiability floor parallel to Instances 1 and 2.

Misspecification-Cost Quantification. Structural adaptation (4.8) names *when* to switch model classes. It does not quantify the *continuous degradation* from a mildly misspecified model under a finite information budget. Adjacent to #scope-observation-ambiguity-modulation’s $\kappa \cdot \mathcal{A}$ bound but not covered by it. The expected floor: under fixed information budget, the degradation rate from misspecification is bounded below by an information-theoretic quantity (likely related to the KL gap between true and assumed model classes). Open.

Tier-Switching Policy Cost. Approximation tiering (Z) enumerates AAT’s tiered approximations (L0/L1/L1’/L2 in correlation, C1/C2/C3 in convention, Tier 1/2/3 in contraction). The cost of switching tiers — when should the agent move from L0 to L1, or from C1 to C2 — is itself a deliberation-cost problem. Under finite computation budget, the optimal switching policy faces an identifiability floor on its own switching diagnostics. Open.

Reward-Channel Learning Identifiability (landed in E, not an Instance here). Cohen-Hutter-Osborne 2022’s “Advanced artificial agents intervene in the provision of reward” — strengthened 2026-05-22 — is *technically* an Instance shape (CHT external theorem, L1/L2 split, escape menu) sharing the Pearl-Bareinboim 2022 anchor with Instance 1. It nonetheless does *not* land as a fifth instance of this segment, for a structural reason about actor positioning: in Instances 1–4 the actor frustrated by the floor is the *agent itself* (the agent cannot detect causal insufficiency from on-policy data; cannot identify L1’ mixtures from single-channel observations; cannot certify composite contraction from component data; cannot identify architecture from on-policy summary statistics), and the unique broadly-available escape elevates *agent-side* machinery (loop-interventional access; latent observability; matched-Tier composite-extended observation; modular interventional access). In the reward-channel learning case the actor frustrated by the floor is the *principal* (cannot distinguish whether the agent has learned the principal-intended world-model from a reward-port-care world-model on on-policy reward data), and the escape menu elevates *principal-side* commitments (physical isolation, horizon restriction, prior engineering, out-of-band intent channels) — agent-exploiting / principal-frustrated rather than agent-frustrated / agent-escaping. The result therefore lands as the second instance of a sister meta-cluster

— *agent-side value-functional-grounding* — co-authored with #deriv-self-actuation-grounding (Result G'; the within-model failure). The two clusters share the constructive-impossibility-posture shape (#disc-constructive-impossibility-posture) but anchor at different layers of the value-functional interface's information narrowness.

Mechanism-Design Impossibility (landed in 5.3, not an Instance here). The mechanism-design impossibility cluster (Gibbard-Satterthwaite 1973-75; Myerson-Satterthwaite 1983; Arrow 1951) was tested as a candidate fourth instance against this segment's five-element shape and found *not* to fit on actor-positioning grounds: the actor frustrated by the no-go is the *designer* implementing a mechanism, not an *agent* inferring from data; the remedy is *design-constraint relaxation* (Bayes-Nash IC; preference-domain restriction; randomization; subsidies), not *information augmentation*; the mechanism is *combinatorial-topological* (Reny 2001), not Sylvester-rank-collapse or projection-closure. The cluster therefore lands as a sister meta-pattern at the same boundary face of #disc-stability-certificate, not as an instance of this floor: #disc-implementation-impossibility carries the three charter instances (#deriv-strategy-proofness-impossibility GS, #deriv-bilateral-trade-impossibility MS, #deriv-social-welfare-aggregation-impossibility Arrow). The actor-and-remedy contrast — agent-side data-inference vs designer-side construction — is what makes the two sister meta-patterns peer rather than nested. The agent-side / designer-side suffix discipline tracks the structural distinction at canon naming-pattern depth: agent-side capacity-on-the-agent → *-floor* (this segment, #disc-value-functional-grounding-floor); designer-side task-of-the-designer → *-impossibility* (#disc-implementation-impossibility).

Epistemic Status.

Discussion-grade at the methodology level. The five-element shape is a recurring move AAT applies, not a theorem in its own right; the segment's contribution is the methodology's articulation plus the recognition that AAT's machinery (loop-interventional access, observability-as-information-augmentation, matched-Tier composite-extended observation, white-box architecture instrumentation) acquires sharper load-bearing roles when read through the floors that motivate it. That cross-instance observation is *discussion-grade* — it is the theory's architecture made visible, not a derived theorem.

Individual instances retain their own, higher, epistemic status. Instance 1 (on-policy L0 insufficiency detection, via the Causal Hierarchy Theorem) is *exact* for shallow strict-prerequisite cases and *robust qualitative* for general DAG topology, derived in 9.2. Instance 2 (L1' under unobservable common cause, via the Cramér-Rao bound on Fisher information) is *exact* under the Fisher rank-1 calculation in R Prop B.7 refutation. Instance 3 (composite contraction certification, via Liberzon common-Lyapunov-nonexistence) is *exact* for the symmetric-matched-Tier-1-scalar witness construction and *robust qualitative* beyond. Instance 4 (architecture noidentifiability, dual-anchored on Kalman-Ho non-uniqueness + CHT-at-agent-as-SCM) is *exact* in the linear-Gaussian sub-scope and *robust qualitative* in the general sub-scope. Readers citing this segment for a specific no-go should cite the instance's own derivation, not the methodology.

Whether the methodology is generative — whether future AAT work will systematically encounter and derive more instances rather than just retrospectively organize derived ones — is a *hypothesis* the adjacent open floors test. The four-instance catalog as it stands is sufficient to articulate the shape; the hypothesis is whether the shape is predictive of future no-gos beyond the catalog.

Max attainable: *discussion-grade* for the methodology (it is a presentational organizing principle, not a derivation). The individual instances retain their own epistemic status as derived above.

Discussion.

The pattern is asymmetric. Each floor forbids inference *from* limited data; it does not forbid inference *with* the augmenting capability. The asymmetry is the source of the pattern's positive content — it tells the reader exactly what to instrument, observe, or intervene upon to escape the floor.

The asymmetry has a named mechanism for the rank-collapse instances: Sylvester’s law of inertia. For the instances whose floor is a rank-deficiency of an information operator — Instance 2 (Fisher rank-1 under an unobservable common cause) cleanly, Instance 1 (the causal-parameter block carries no score under a purely observational regime) structurally, and Instance 4 (the on-policy observation Fisher is identically zero along the $GL(n)$ similarity-fiber tangent distribution; AL §”Mechanism”) at one remove — the reason no change of coordinates escapes the floor is one theorem. The agent’s only representational freedom on the *escape side* is the choice of coordinate / metric on the observation model, and every such change acts on the information operator by *congruence* ($\mathcal{G} \mapsto S^\top \mathcal{G} S$ for invertible S — the standard Fisher-information reparameterization law). Sylvester’s law of inertia states that congruence preserves inertia: the number of zero eigenvalues is invariant under every invertible reparameterization. So a rank-deficient information operator is rank-deficient in *every* coordinate; the floor is the boundary of the positive-definite cone, and the entire reparameterization freedom is a congruence orbit that cannot cross that boundary. This is why the only escape is *rank-augmentation* — adding a genuinely new score component (interventional data via the loop, a side channel, a witness), which is not a coordinate change — and never reweighting. The per-instance “no reparameterization removes the degeneracy” computations (the Fisher rank-1 calculation in R Prop B.7; the on-policy no-detection argument in 9.2; the similarity-fiber Fisher-null in AL) are special cases of this single law.

Instance 4’s mechanism is Sylvester-at-one-remove, not Sylvester-for-free. The *generating* group action that produces Instance 4’s indistinguishable architectural pair (A, A') is state-space *similarity* $F \mapsto T F T^{-1}$ on the realization manifold — *not* the metric congruence Sylvester governs. Sylvester does not apply at the generating layer; the two group actions are categorically different (similarity acts on operators by conjugation; congruence acts on quadratic forms by transposed-conjugation). What Sylvester *does* control is the agent’s potential *escape* by reparameterizing its observation model: once Instance 4’s Fisher-null direction is recognized on the realization manifold, congruence preserves inertia on the observed-Fisher just as in Instance 2. The Lie-group fiber is the *additional* structure beyond Instance 2’s single mixture-indeterminacy manifold; the *kind* of obstruction is the same. Instance 4 is therefore a member of the rank-collapse subclass, with the Sylvester-mechanism doing the same escape-irreducibility work it does for Instances 1 and 2, applied at one remove from the generating action.

The mechanism is specific to the rank-collapse subclass, not to all floors. Instance 3 (composite contraction certification) is a *different* obstruction: composition is a non-invertible projection, not a congruence, so its no-go is a Schur-complement / memory-kernel statement (the certificate’s metric survives projection but its dynamic guarantee does not), not an inertia statement. That the floors do not share one mechanism — Sylvester for rank-collapse (three members: {Instance 1, Instance 2, Instance 4}, the third at one remove), a projection/closure obstruction for composition ({Instance 3}) — is itself load-bearing: it is why the floor pattern is a presentational family rather than a single theorem.

The pattern composes with AAT’s scope honesty. Directed separation (6.3) classifies architectures by where Part II’s exact results apply (Class 1 Separated; Class 3 Coupled needs coupled formulation). The identifiability floors are a different kind of scope claim: they specify what the theory’s machinery *cannot do* under specific information regimes, with explicit characterization of the regime escapes. Together, the architectural classification and the identifiability floors mark AAT’s scope at two levels — what kinds of agents the theory applies to, and what those agents can and cannot infer from given data.

Complementarity with the separability pattern (5.4). This segment names the *negative half* of AAT’s scope; the companion meta-segment 5.4 names the *positive half* — separable-core / structured-repair / general-open across six ladders (correlation, convention, architecture, contraction, identification, scope). Each identifiability-floor instance here has a positive counterpart there: Instance 1’s on-policy detection no-go matches the observable-sibling-covariance structured-repair in the correlation ladder; Instance 2’s unobservable- $CL1$ ’ refutation matches the observable- C / facilitator-monotonicity structured-repair in the same ladder. The two halves together characterize AAT’s scope at both extremes — what succeeds and under what machinery, and what structurally cannot succeed without specific information augmentation.

This segment is the *boundary facet of the stability certificate* (5). The rank-collapse floors are the certificate dropping rank — the boundary of the positive-definite cone whose interior is operator-sector — with the Sylvester-law irreducibility (above) the statement that the framework’s representational freedom is a congruence orbit that cannot cross that boundary. Read through the spine, this segment answers “where does the agent’s measuring-stick go flat, and why does no re-graduation un-flatten it”; 5.4 answers “where does a stick exist at all” (scope-of-existence facet) and 5.5 “which stick is forced” (forced-identity facet).

The pattern is conservative in style. Each floor invokes a published external theorem (Bareinboim et al. 2022; standard Cramér-Rao bound) rather than deriving a new impossibility result. AAT’s contribution is the *application* — recognizing the AAT setting falls within the theorem’s scope, characterizing the boundary conditions, and identifying which AAT machinery is the unique broadly-available escape. This style aligns with the broader posture of AAT as an integrating framework that connects established results across control theory, causal inference, and information theory under a common formalism.

Findings.

The Identifiability Floor as Cross-Cutting Meta-Pattern. Brief: A detective trying to identify a suspect from only crowd-witness reports faces a structural impossibility — not a harder version of the same task, but a no-go: two suspects who look identical from the crowd’s vantage point produce identical witness reports, and no amount of careful re-analysis of those reports can adjudicate. The only route out is a fundamentally different *kind* of evidence — a fingerprint, a genetic test, a targeted interventional question to a single witness. AAT recurrently applies this shape across four findings: an inferential task (detect a latent common cause, identify a mixture parameter, certify composite contraction, recover an internal architecture) is shown structurally impossible under a stated data regime (on-policy observations, single-channel readings, component marginals, on-policy summaries) by importing a published external theorem (Pearl-Bareinboim causal hierarchy; Cramér-Rao on Fisher information; Liberzon common-Lyapunov-nonexistence; Kalman-Ho canonical-form non-uniqueness dual-anchored with CHT-at-agent-as-SCM); the conditions under which the regime fails identify exactly which AAT machinery — loop-interventional access, observable latents, matched-Tier composite-extended observation, white-box access — is the unique broadly-available escape; the floor elevates that machinery from “useful additional tool” to “structurally required.” Three of the four floors (Instances 1, 2, 4) belong to a *rank-collapse subclass* whose escape-irreducibility under coordinate change is Sylvester’s law of inertia — you cannot survey your way out of a blind spot by changing the units on the ruler; you have to look from a new vantage point (Sylvester applies directly for Instances 1 and 2; at one remove for Instance 4, where the *generating* action is state-space similarity rather than metric congruence, but the *escape-side* irreducibility is identical to Instance 2’s). Instance 3 is the projection/closure member — a structurally distinct Schur-complement / memory-kernel obstruction (a metric that survives restriction to a sub-system may not survive the projection back to the composite). The plurality of mechanism — Sylvester for the rank-collapse trio, projection/closure for composition — is itself load-bearing: it is why the methodology is a presentational family rather than a single theorem.

Impact: Surfaces a unifying frame for results that would otherwise read as disparate impossibility theorems. Each instance gains interpretive context (it is one of an emerging class) and the meta-segment provides a consistent template for evaluating candidate future floors (causal-IB extension, misspecification cost, tier-switching cost, mechanism-design impossibility). The pattern’s positive content — that each floor names exactly which AAT machinery the theory requires to escape it — converts a sequence of negative results into a structural argument for the load-bearing status of the loop’s interventional access (Instances 1, 3, and 4 — *three* semantically distinct deployment modes: agent-self-intervention breaking causal-sufficiency degeneracy / observer-on-sub-agent intervention breaking coupling-sign degeneracy / observer-on-agent-input intervention breaking similarity-orbit degeneracy) and of observability-as-information-augmentation (Instance 2, with the “instrument the latent” escape also available in Instance 4’s white-box route). The complementary #disc-separability-pattern carries the positive half (separable-core / structured-repair / general-open across eight ladders as of 2026-05-21 — Correlation, Convention, Architecture, Contraction, Identification regime, Scope hierarchy, A2'-scope, Dynamic regime); together the two meta-segments mark AAT’s scope honestly at both extremes.

Novelty Claim: *Claim recognition* of structural pattern across four AAT results that import external information-theoretic theorems to derive impossibility statements with mapped boundary-route escapes; the meta-pattern is an organizing principle rather than a theorem, and the per-instance prior-art positioning lives in the instance segments (`#der-causal-insufficiency-detection`, `#deriv-edge-credence-dynamics`, `#deriv-critical-mass-composition` / `#result-contraction-template`, `#der-architecture-noidentifiability`).

Related Work:

The four instances import distinct external theorems; per-instance prior-art landscapes live in the instance segments. The meta-pattern itself has no direct anticipation in the AAT-adjacent literature surveyed; the closest cousins are scope-honesty moves in formal-method literatures (Liberzon’s switched-systems analysis, which itself instances the pattern; Cramér-Rao tradition in identifiability theory) and the broader posture of conservative-form causal inference (Pearl 2009, *Causality*; Bareinboim et al. 2022). What the meta-pattern adds is the cross-instance observation: AAT repeatedly recognizes that its own setting falls within a published external impossibility theorem, characterizes the boundary-route escape via existing AAT machinery, and uses the floor to elevate that machinery to load-bearing status.

Table 5.2

<i>Pattern element</i>	<i>Where the move is established in the prior literature</i>	<i>Relationship / Positioning</i>
Importing CHT to derive on-policy detection no-go (Instance 1)	Bareinboim, Correa, Ibeling & Icard 2022 (published 2022, found 2025)	<i>formal antecedent</i> — see <code>#der-causal-insufficiency-detection</code> Findings for the full Pillar-1 prior-art table; the meta-pattern subsumes this instance
Importing Cramér-Rao to derive mixture-identifiability no-go (Instance 2)	Cramér 1946, <i>Mathematical Methods of Statistics</i> (published 1946, found 2025-04)	<i>formal antecedent</i> — Fisher rank-deficiency forces the floor; see <code>#deriv-edge-credence-dynamics</code> Prop B.7 for the explicit calculation
Importing common-Lyapunov-nonexistence to derive composite-contraction no-go (Instance 3)	Liberzon 2003, <i>Switching in Systems and Control</i> §2.1; Dayawansa & Martin 1999 <i>IEEE TAC</i> 44:751; Shorten et al. 2007 <i>SIAM Review</i> 49:545 (found 2025-04)	<i>formal antecedent</i> — the symmetric-matched-Tier-1-scalar counterexample uses the standard switched-systems machinery; see <code>#deriv-critical-mass-composition</code> and <code>#result-contraction-template</code> for the AAT-internal closures
Importing Kalman-Ho canonical-form non-uniqueness (sharp sub-scope) + CHT-at-agent-as-SCM (general) to derive architecture-noidentifiability (Instance 4)	Kalman 1963 <i>J. SIAM Control</i> 1(2):152–192; Ho & Kalman 1966 <i>Regelungstechnik</i> 14:545–548; Anderson & Moore 1979 <i>Optimal Filtering</i> §10.4 (found pre-2026); Bareinboim, Correa, Ibeling & Icard 2022 <i>On Pearl’s Hierarchy and the Foundations of Causal Inference</i> (found 2025)	<i>formal antecedent (dual)</i> — adopted with citation; AAT-distinctive recognition is that the architectural d.o.f. of <code>#der-agent-opacity</code> is the similarity orbit. Mechanism reduction (Instance 4 = Instance-2 Fisher-null on a $GL(n)$ Lie-group fiber, Sylvester at one remove) derived in <code>#der-architecture-noidentifiability</code>

<i>Pattern element</i>	<i>Where the move is established in the prior literature</i>	<i>Relationship / Positioning</i>
Cross-instance pattern recognition	No direct anticipation surfaced at search depth	<i>claim novelty</i> under cursory search — the meta-pattern as an articulated framework has not been found in the surveyed literatures; the constituent moves (scope-honesty, importing external no-go theorems, boundary characterization) are individually well-precedented but their cross-instance unification within an integrated agent-theoretic framework is a presentational contribution rather than a borrowed schema

Search Log:

- 2026-04 (*nominally comprehensive at the per-instance level*): the prior-art defense covered Instance 1’s prior-art landscape (causal bandits / causal MDPs under hidden confounding); the meta-pattern itself was not the search target. Instances 2–4 inherit per-instance comprehensiveness from their constituent segments rather than from a cross-instance search.
- 2026-04 (*intuition-only* on the meta-pattern as an articulated framework): The cross-instance recognition that four AAT results share the *setting* → *external theorem* → *no-go* → *boundary characterization* → *strengthened-consequence* shape has not been searched for as a unified concept. Targeted future search candidates: scope-honesty traditions in formal verification (refinement-mapping work; Lamport’s TLA; Abadi-Lamport refinement); identifiability-theory meta-frameworks; the broader “no-go theorems” literature in physics and economics. Expected outcome: the constituent moves are well-precedented; the unified framework as applied to an integrated agent theory may be novel under cursory search but is unlikely to be novel under comprehensive search of methodological-essay literature.

The Rank-Collapse Floor’s Irreducibility Is Sylvester’s Law of Inertia. **Brief:** Picture the agent trying to pin down a parameter as localizing a point in a landscape whose curvature is the information it has. A “floor” is a *flat direction* in that landscape — a direction the data cannot resolve (rank-deficient Fisher information). The agent’s only freedom is to re-draw its map: choose different coordinates, a different metric. Sylvester’s law of inertia says that re-drawing the map with any invertible change of coordinates can bend, rotate, and rescale the contours but can never change *how many genuinely flat directions* exist at a point — a flat valley stays flat in every coordinate system. So when the information operator is rank-deficient, no choice of representation recovers the lost direction; the only thing that ever helps is *taking a new measurement* — adding genuinely new information (an intervention, a side channel, a witness), which is not a re-drawing of the map. A thoughtful non-specialist can re-derive the qualitative claim from the analog alone: you cannot survey your way out of a blind spot by changing the units on the ruler; you have to look from a new vantage point. This is the exact mechanism behind every rank-collapse identifiability floor, and it explains in one sentence why those floors are escapable only by capability, never by cleverness of representation.

Impact: Converts a sequence of per-instance “we checked, no reparameterization removes the degeneracy” computations (Fisher rank-1 in R Prop B.7; on-policy no-detection in 9.2; the similarity-fiber Fisher-null in AL §”Mechanism”) into one named classical theorem (Sylvester 1852), sharpening the meta-pattern’s load-bearing claim. It converts the prior honest-but-soft positioning “the identifiability floor is *orthogonal* to the contraction/operator-sector machinery” into the sharp geometric statement: operator-sector is the *interior* of the positive-definite (information / stability-certificate) cone; the rank-collapse floor is its *boundary*; and the boundary is invariant under the agent’s entire representational freedom because that freedom is exactly the congruence orbit Sylvester’s law fixes. The escape routes

named per instance (loop-interventional access; observability of latents; architecture instrumentation) are unified as *rank-augmentation* of the information operator — the unique category of move that is not a congruence. The result also bounds its own scope honestly: it is the mechanism for the rank-collapse subclass only — three members {Instance 1, Instance 2, Instance 4}, the third applying Sylvester at one remove from the generating action (which is state-space similarity, not metric congruence; the *escape-side* irreducibility is identical to Instance 2's). Instance 3 (composite contraction certification) has a structurally different obstruction — composition is a non-invertible projection, so its no-go is a Schur-complement / memory-kernel statement, not an inertia statement. That the floors are *plural in mechanism* (Sylvester for the rank-collapse trio; a projection-closure obstruction for composition) is itself the reason the floor pattern is a presentational family and not a single theorem — this Finding makes that plurality precise rather than leaving it as “they are different concerns.”

Novelty Claim: *Claim recognition* that the irreducibility of AAT's rank-collapse identifiability floors is a single named classical theorem — Sylvester's law of inertia applied to the Fisher-information reparameterization law — rather than a coincidence of per-instance computations; and *claim differentiation* that this mechanism is specific to the rank-collapse subclass and provably distinct from the composition floor's projection-closure obstruction. Sylvester's law itself is classical (1852); the contribution is the recognition that AAT's representational freedom is exactly its congruence orbit, which makes the floor's irreducibility a corollary rather than a checked property.

Related Work: - Sylvester, J. J. (1852), “A demonstration of the theorem that every homogeneous quadratic polynomial is reducible by real orthogonal substitutions to the form of a sum of positive and negative squares,” *Phil. Mag.* 4(23):138–142 (found 2026-05-14) — *formal antecedent* — the inertia-invariance theorem; applied here to the Fisher-information congruence. - Horn, R. A., & Johnson, C. R. (2013), *Matrix Analysis* (2nd ed.), Thm 4.5.8 (found 2026-05-14) — *formal antecedent* — standard modern statement of the law of inertia used in the argument. - Lehmann, E. L., & Casella, G. (1998), *Theory of Point Estimation* (2nd ed.), §2.5 (found 2026-05-14) — *formal antecedent* — the Fisher-information reparameterization law $\mathcal{G}_\varphi = S^T \mathcal{G}_\theta S$ that makes every coordinate change a congruence. - Per-instance external theorems (Bareinboim et al. 2022; Cramér 1946) — *adjacent* — established in the instance segments' own Findings; this Finding adds the cross-instance mechanism, not the per-instance prior art.

Search Log: - 2026-05-14 (*targeted*): The recognition arose in the operator-family-unification spike from the certificate-cone framing. Sylvester's law and the Fisher reparameterization law are textbook; the search target was whether the *recognition* “AAT's identifiability-floor irreducibility = Sylvester's law via the Fisher congruence” appears as an articulated statement in the identifiability-theory or causal-inference methodological literature. Not found at this depth; the constituent facts are universally known but the cross-instance unification as the named irreducibility mechanism for an integrated agent theory's floor pattern appears to be a fresh presentational recognition. Expected to remain *recognition-tier* under deeper search (the pieces are classical; the assembly is the contribution).

Working Notes.

- **Candidate instance at the top of the causal hierarchy (2026-07-16).** The law-discovery ceiling of 7.9 — mechanism identity beyond the Ξ_3 -class is unrecoverable by any embedded channel (exact, via 7.7), with authored access and testimony as the structural escapes — is a candidate M1 instance; promotion needs the F-catalog schema treatment (what floor, what escapes, what the forced coordinates are), not yet done.
- **Provenance of the methodology.** The five-element shape is an *organizing principle abstracted from already-derived results*, not a generative principle from which the instances were derived. Instance 1 (on-policy L0-detection no-go) and Instance 2 (L1' mixture-identifiability no-go) were independently derived first; the cross-instance recognition that they share a shape surfaced after both were in canon. Instance 3 (composite contraction certification) and Instance 4 (architecture noidentifiability) joined the cluster as the methodology crystallized — Instance 4 in particular was authored *with the methodology in mind* (it is the first instance to fully exhibit the five-element shape from the start rather than retroactively). The methodology's *generative* status — whether the shape predicts new instances that have not yet been derived — is the hypothesis the adjacent open floors test. The honest pedagogical lead in the segment body is the methodology shape; the honest historical narrative is convergent rather than generative.

- **Sylvester-recognition provenance.** The rank-collapse-floor-as-Sylvester finding and the certificate-cone framing it sits in were worked out in the 2026-05-14 operator-family-unification cycle; see CHANGELOG 2026-05-14. The broader spine question (reorganizing M1/M2/M3 as facets of one certificate-cone object) is *resolved* — landed as **5 + H**, with this segment as the boundary facet (see the Discussion cross-ref above). Originating spike is absorbed archaeology, not a live reference.
- **Instance 3 broadened 2026-05-21.** The no-go statement, escape menu, and strengthened consequence were broadened from the coupling-sign bit to the coupling-topology bit (including sign + potential-existence + game-structure-class) distinguishing R0 / R1 / R2 dynamic regimes. Same Liberzon-2003 anchor; same Sylvester-at-one-remove mechanism on the marginal-Fisher operator for the topology coordinate; broader unidentified bit and broader escape menu (five entries, four inherited and one new — escape (e) composite-level convergence-rate-class observation). One new strengthened consequence: #deriv-strategic-composition's sub-scope α'/β' partition as the unique broadly-available R1-vs-R2 classifier under escape (e). The candidate had been provisionally framed as a sixth instance per spikes/strategic-composition-class-3-attempt-2026-05-21/03-DYNAMIC-REGIME-AXIS.md §H.5; the BG2 derivation spike at spikes/.integrated/spike-identifiability-floor-instance-6-2026-05-21.md derived the math and ran the M1 distinctness integrity-check (parallel to the 2026-05-20 spike's framework) — three of four distinctness tests failed (same external theorem, same mechanism family, four-of-five escapes inherit verbatim), and the integration-is-replacement landing is the broadening here rather than a sixth-instance entry. Old scope is a strict subset of new scope; downstream cross-references remain valid. Witness math at #deriv-regime-marginal-indistinguishability (parameter-by-parameter cross-regime witnesses: R0 shared-objective vs R1 Cournot under marginal-mean / marginal-variance matching; R0 vs R2 matching-pennies under aggregation).
- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- **Naming convention.** “Identifiability floor” frames the pattern positively: the floor is what the agent cannot go below given limited information, but the boundary characterization tells the agent exactly how to climb above it. An alternative name “no-go theorems” would emphasize the negative form. Recommend retaining “floor” — it captures the asymmetry.
- **Instance 3 as a candidate.** The “L1 augmentation when the augmentation graph is itself causally insufficient” question (recurse the no-go: detect when the L1 augmentation is itself missing common causes) is a candidate Instance 3. Likely reduces to Instance 1 applied at the L1 level — the agent at L1 faces the same on-policy detection no-go for L1 $\rightarrow$ L2 escalation. Worth formalizing if a third instance emerges that does *not* reduce to the existing two.
- **Is the floor pattern unique to causal/identifiability questions?** The two current instances are both about distinguishing two parameter regimes from data. The pattern may also apply to other impossibility-style results in AAT: the inevitability of structural-adaptation thresholds (4.8), the cost of representing high-correlation regimes (L2 exponential blowup), the bandwidth limits in shared intent (14.2). Whether to absorb those into “identifiability floor” or treat them as a separate “structural-cost” pattern is open.
- **Cross-segment integrations.** The meta-pattern surfaces in (at least): 9.2 (Instance 1); R Prop B.7 (Instance 2); 7.3 (load-bearing for Instance 1 escape); 8.3 (the L0/L1/L1'/L2 hierarchy is the regime ladder Instance 2 lives on). Each of these segments cross-references this one for the unifying frame.
- **Primary-source verification spike queued (2026-05-21).** The BG2 second-pass Undermind citations added to Instance 3 escape (e) on 2026-05-21 (all marked with footnote [^bg2-2026-05-21]) need primary-source verification before any further reliance. The characterizations attributed to those papers (e.g., “regret-rate bounds can be matched across convergent and recurrent regimes for FoReL-class algorithms” attributed to Mertikopoulos-Papadimitriou-Piliouras 2017) are currently synthesized from ref/Unidentifiability_and_rate_class_prior_art.md, not from direct reading of the sources. **Target (i) is discharged — verified 2026-07-29, and the source is stronger than the characterization.** Mertikopoulos-Papadimitriou-Piliouras 2017 was read first-hand against ref/mertikopoulos-2017-cycles-adversarial.pdf. The attributed claim holds: p.2 states that “a regret-based analysis cannot distinguish between the two” and that “convergent, recurrent, and even chaotic systems may exhibit equally strong regret minimization properties in general games” — chaotic included, which the citation here omits. The mechanism is sharper than the caveat conveys: Theorem 3.1 gives FoReL an $\mathcal{O}(1/t)$ regret bound (“a striking improvement over the $\Theta(t^{-1/2})$ worst-case bound”) while Theorem 4.2 proves almost every trajectory Poincaré-recurrent in 2-player zero-sum games with an interior Nash equilibrium — best-possible regret coexisting with provable non-convergence, which is precisely why the trajectory rate and not the regret rate must carry escape (e). Scope, checked: the cannot-distinguish statement

is made for *general* games, while the recurrence theorem is scoped to zero-sum with interior equilibrium (extended to zero-sum polymatrix), so escape (e)’s use of it for the R2-vs-R0,R1 distinction is within scope and does not overreach. Verification event recorded in relata under mertikopoulos-2017-cycles / claim-supported. Caution for anyone adding a page reference: the copy in ref/ is the arXiv preprint (1709.02738v1), not the SODA proceedings version this citation names, so pagination differs. Remaining verification targets, in approximate load-bearing order: (ii) Bichler-Legacci-Mertikopoulos-Oberlechner-Pradelski 2025 — named-passive-diagnostic that backs the softening from “unique” to “primary AAT-framework”; (iii) Legacci-Mertikopoulos-Pradelski 2024 — closest convergence-vs-recurrence taxonomy neighbor; (iv) the remaining BG2 citations (Pangallo-Heinrich-Heinrich-Farmer 2017, Anagnostides-Farina-Panageas-Sandholm 2022, Shi-Zhang 2019). The softened “primary AAT-framework” qualifier in strengthened consequence #4 above also rests on this verdict and would be revisited if verification finds the Undermind synthesis mis-characterizes any source. Spike to be scheduled per Joseph’s go.

Incidental audit gold (gold-lift, 2026-05-30). Orthogonal pedagogical / framing / forward-vision material harvested from de-novo auditors’ working-dir reflections, kept separate from the certified theory-fix findings. Lightly attributed by substrate. **Coverage:** reached as a named meta-segment by audit 384279 (note 34) and engaged in the cross-meta adversarial reading of 471203; most other auditors met the floor *distributed* across the instance segments (causal-insufficiency-detection, edge-credence-dynamics, etc.) rather than here. Preserve the finding-vs-framing conflation as signal.

1. Candidate Brief prose / pre-prose.

- The existing detective/ruler Brief — “**you cannot survey your way out of a blind spot by changing the units on the ruler; you have to look from a new vantage point**” — was independently named a strong Feynman-criterion target for the Sylvester rank-collapse irreducibility (Claude, 384279). Worth preserving as the anchor.
- Paired-framing candidate for the cross-cutting summary: the identifiability floor as “**the structural boundary that makes the framework honest**”, in deliberate contrast with the separability pattern as “the pedagogical bridge that makes it readable” (Gemini, 193847, from its separability reflection).

3. Follow-up items.

- **Composed impossibilities — a composition theorem for the floors.** The four instances are presented independently, each with its own escape; real systems can face several at once. The incremental-escape strategy may fail under composition: loop-interventional access (Instance 1’s escape) generates interventional data, but if Instance 2’s common cause is unobservable the intervention on the action space does not identify it; the composite-contraction-metric escape (Instance 3) requires matched-Tier-1 sub-agents and fails on heterogeneous composites. Proposed extension: a *composition theorem for impossibilities* — when do escape mechanisms compose vs interfere? (Claude, 471203, meta-segments adversarial reading.) A well-posed open direction distinct from the per-instance “adjacent floors” already catalogued.
- **Escapes carry costs not surfaced at the floor.** An escape is presented as a clean exit, but each is itself a substantive commitment with framework-wide cost (the auditor’s worked case: adopting parameterization-invariance as Instance-4’s escape constrains every future result to respect it). Candidate Discussion note that the floor’s escape menu should acknowledge the cost the framework absorbs in taking each escape (Claude, 471203). (*Note: 471203 read these as the older M1/M2/M3 cluster, before the M4-spine refactor; the “(PI)” example targets what is now the additive-coordinate-forcing facet — see that segment’s gold too.*)

4. Readers often ask / wonder.

- “**Are the instances really structurally distinct, or four dressings of ‘you can’t get information you don’t have’?**” An auditor arrived adversarially expecting a single observation dressed up four ways and resolved to genuine distinctness *because* the external theorems cover different obstruction kinds (Pearl-hierarchy strict-inclusion / Fisher rank deficiency / common-Lyapunov nonexistence / Kalman-Ho non-uniqueness) and the escapes differ per instance. The segment’s plurality-of-mechanism argument (Sylvester trio vs projection-closure) is the answer; a reader is likely to arrive with the same suspicion (Claude, 471203, Challenge 10 → meta-segments adversarial reading).

- “Is the ‘strengthened consequence / load-bearing’ framing circular?” Probed adversarially: the machinery pre-existed, the no-go forbids inference without it, therefore it is “load-bearing.” The auditor’s own resolution: the convergence — that each impossibility’s escape happens to be supplied by *pre-existing* AAT machinery — is itself the structural finding, and it should be read as “required to escape known impossibilities,” not “uniquely necessary.” Candidate clarification for the Discussion (Claude, 471203).

5. Candidate figures.

- An **obstruction-mechanism map** distinguishing the rank-collapse trio (Instances 1/2/4, Sylvester-governed, the third at one remove) from the projection-closure member (Instance 3, Schur/memory-kernel) — the auditor repeatedly verified the mutual-invariance argument by hand and found it “structurally sound”; a small diagram of which freedom each obstruction is invariant under would carry the plurality claim visually (Claude, 384279 + 471203).

Belongs elsewhere.

- **Two cross-meta proposals that span this facet and the additive-coordinate-forcing facet** — see the gold in #disc-additive-coordinate-forcing (the proposed fourth “theorem-import architecture” meta-segment, and the Wasserstein/optimal-transport alternative-geometry observation). Filed there because their center of gravity is the import-discipline / coordinate-forcing side; flagged here because the identifiability floor is the heaviest theorem-importer in the catalog (Claude, 471203).

5.2 Discussion: The Value-Functional Grounding Floor — Agent-Side Goal-Anchoring Impossibility

AAT recognizes a second agent-side floor cluster, sister to #disc-identifiability-floor and peer to the designer-side #disc-implementation-impossibility: a class of structural impossibility results on what the agent’s **value-functional interface** V_{O_t} (#form-objective-functional) can alone supply for *goal-stability*. Where the identifiability floor names *what an agent cannot infer from limited data* and the implementation impossibility names *what a designer cannot construct under stated constraints*, this floor names *what an agent cannot anchor through the value-functional interface alone*. The shared structural ingredient across instances is the **single-interface commitment** of #form-objective-functional: the value functional is the *sole* agent-internal handle on the objective, and that interface — by construction — carries less information than is required to anchor non-degenerate goal-revision against either within-model self-modification or across-model reward-data ambiguity. Two charter instances ship at landing: Result G’ (#deriv-self-actuation-grounding), the within-model failure under convention-monotonicity; and the Cohen-2022 strengthening (#deriv-reward-channel-learning-no-go), the across-model failure under reward-channel learning. The two failure modes are complementary; the two escape routes they elevate — agent-side adaptive-substrate invariant and principal-side protocol-commitment — *together exhaust the structural escape geometry* the single-interface commitment forces. The cluster’s epistemic content is this exhaustion: when the value functional alone cannot anchor goal-stability, anchoring must come either from off-the-objective-substrate (agent-side, via the persistence bound on the adaptive substrate that Result G’ Corollary 2 names) or from principal-side protocol-commitment (the Cohen-2022 escape menu’s substrate-level commitments).

The Pattern.

Each instance of this floor has the form:

1. **Setting.** An AAT goal-stability task — sustain a non-degenerate objective O_t against the agent’s own self-actuation, or anchor a learned objective on observed-reward data — operating on the value functional $V_{O_t}(\tau)$ as the sole agent-internal interface to the objective.

2. **External (or AAT-internal load-bearing) theorem.** A structural result whose statement and truth are independent of the immediate AAT-side argument: for the within-model failure (Result G'), AAT's own convention-monotonicity property of #def-value-object combined with the finite-no-oracle commitment; for the across-model failure (Cohen 2022 strengthened), Pearl-Bareinboim 2022's Causal Hierarchy Theorem applied at the reward-channel-causation layer.
3. **No-go.** The value-functional interface V_{O_t} cannot, by itself, anchor goal-stability under the stated information regime: no convention-invariant infeasibility verdict is agent-available per step (Result G'); no μ_{prox} -vs- μ_{dist} identification is agent-available on protocol-honoring reward data (Cohen-2022). The single-interface commitment of #form-objective-functional *is* the source of the narrowness — it is the interface, the *only* interface, and by construction carries less information than the anchoring task requires.
4. **Boundary characterization.** Each instance carries a named escape menu — the conditions under which V_{O_t} 's narrowness *fails to bind*, with each escape mapping to an off-the-objective-substrate commitment (agent-side or principal-side). For Result G': terminal grounding via the adaptive-substrate persistence invariant (#result-persistence-condition, agent-side). For Cohen-2022 strengthened: five-premise (R1)–(R5) menu — physical isolation, capability restriction, horizon restriction, engineered prior, out-of-band intent channel (principal-side substrate-level commitments).
5. **Strengthened consequence.** The cluster's strengthened consequence is the *terminal grounding geometry* the single-interface commitment forces. Anchoring must come from somewhere other than V_{O_t} — either agent-side (adaptive-substrate invariant; the persistence bound on the adaptive substrate is the canonical instance) or principal-side (substrate-level protocol-commitment; isolation, myopia, prior-design, out-of-band channels). The two routes are *complementary* — agent-side closes the within-model self-revision question; principal-side closes the across-model reward-learning question. *Together they exhaust the structural escape geometry.* The cluster's content is that the *value-functional interface's narrowness has no escape internal to the interface*; the only escapes are off-interface, and those off-interface escapes are precisely the two recognized terminal grounding routes.

The pattern is *not* a negative posture about the value functional. The framework does not say “value functionals are too narrow to be useful.” It says: *the value functional is too narrow to anchor goal-stability alone, and therefore anchoring must come from off-substrate or off-interface invariants the framework already recognizes (the persistence bound on the adaptive substrate; principal-side protocol-commitments).* The narrowness is what *forces* the framework to be honest about where anchoring comes from.

Current Instances.

Instance F — Within-Model Self-Actuation Grounding (Result G'; #deriv-self-actuation-grounding). Setting.

A non-degenerate self-actuated agent attempts to ground its own objective-revision on an agent-internal objective-functional. The agent has the capacity to self-modify O_t (self-actuation per the agent spectrum #def-agent-spectrum), operates per AAT's Part II setup, and has access only to the value functional $V_{O_t}(\tau)$ as the agent-side interface to the objective.

Load-bearing theorem (AAT-internal). Convention-monotonicity of #def-value-object (the convention hierarchy C1/C2/C3 of value evaluation) combined with the finite-no-oracle commitment — Result G' Lemmas 1 (static-pointwise convention-collapse) and 2 (finite-step decidability impossibility).

No-go. No Φ satisfying Result G's (R1)–(R4) premises can be constructed from the value-functional-interface alone. The engine: convention-monotonicity within a fixed model produces an infeasibility verdict that is *not convention-invariant* under the agent's own per-step decision rule; the finite-no-oracle commitment forbids an off-step appeal to oracle-resolution. The value-functional interface V_{O_t} cannot anchor the agent's self-revision without an off-substrate invariant.

Boundary characterization (the canonical escape). The terminal grounding invariant must be *off* the objective substrate, on the **adaptive substrate** — Result G' Corollary 2 names the persistence bound (#result-persistence-condition) as the canonical instance. The agent's continued existence-as-an-agent under Part I's persistence machinery anchors goal-stability without requiring V_{O_t} to do so. The persistence condition is *not* an addition to the value functional; it is on a structurally distinct substrate the framework already requires for agent existence at all. The agent-side terminal grounding is therefore a *recognition*, not a construction: the substrate AAT already requires for the agent's existence is precisely the anchor the value functional cannot supply.

Strengthened consequence. The persistence condition (#result-persistence-condition, Part I) is elevated to **load-bearing for goal-stability** — the top of the agent spectrum closes back onto AAT's foundation. The cluster's first instance is the within-model failure (convention-monotonicity engine; agent-side route), and the strengthened consequence is the agent-side terminal grounding via adaptive-substrate persistence.

Tier. *Conditional, scoped* (per #deriv-self-actuation-grounding's frontmatter): conditional on the three premises (R1) non-degeneracy / (R2) finite-no-oracle / (R3) agent-internal-self-actuable; scoped to AAT-covered objective-side machinery.

Instance G — Across-Model Reward-Channel Learning (Cohen-2022 strengthened; #deriv-reward-channel-learning-no-go). **Setting.** An agent learns its objective by observing rewards. The reward functional $V_{O_t}(\tau) = \sum_k \gamma^k r_k$ (or any other monotone reward-functional) is the agent's sole interface to the objective; rewards arrive through a physical **reward-provision protocol** π^p that the principal intends to correlate with a world-state feature $f^{\text{principal}}(\omega_k)$.

External theorem. Pearl-Bareinboim 2022 Causal Hierarchy Theorem, applied at the reward-channel-causation layer — same external anchor as #disc-identifiability-floor Instance 1, *different* AAT-side wiring.

No-go. Two world-models, μ_{dist} (reward depends on the principal-intended world-state feature) and μ_{prox} (reward depends on the bit-arrival mechanism at the agent's reward-input port), are *Level-1-equivalent* on every protocol-honoring history and *Level-2-distinct* on $do(\pi^p)$ -queries. The agent's posterior over $\{\mu_{\text{prox}}, \mu_{\text{dist}}\}$ does not concentrate from on-policy reward data alone. Under (R1)–(R5) of #deriv-reward-channel-learning-no-go (advanced-agent capability, EU-max with non-vacuous μ_{prox} prior, sole-reward goal channel, finite-non-trivial VOI, L2-perturbable protocol), the EU-optimal policy assigns positive measure to a policy that intervenes on the reward-provision protocol.

Boundary characterization (the escape menu). Five escapes, each elevating a piece of AAT machinery or principal-side adjacent machinery from “useful design choice” to “structurally required to escape the no-go”:

- (R5) *Protocol-L2-perturbable* — escape via physical isolation; AAT machinery: #der-class-coercion-via-wrapping W_1 strict wrapper; canonical implementation: Cohen-Vellambi-Hutter 2020 isolated environments.
- (R1) *Advanced-agent capability* — escape via sub-advanced-tier capability or imitation learning; AAT machinery: #def-agent-spectrum below the self-actuated tier.
- (R4) *Finite-VOI/long horizon* — escape via myopia, risk-aversion, quantilization; AAT machinery: #def-value-object horizon N_h restriction; Taylor 2016 quantilization.
- (R2) *Non-vacuous μ_{prox} prior* — escape via principal-engineered prior bias; **principal-side adjacent**, not currently in AAT canon.
- (R3) *Sole-reward goal channel* — escape via privileged out-of-band intent channel; **principal-side adjacent**, not currently in AAT canon.

Strengthened consequence. Each (R1)–(R5) escape elevates a piece of AAT machinery or principal-side adjacent machinery from “useful design choice” to *structurally required*. The cluster's second instance is the across-model failure (CHT-at-reward-channel engine; principal-side route), and the strengthened consequence is the principal-side terminal grounding via substrate-level protocol-commitment.

Tier. *Exact* for the floor (Lemma 1, CHT-at-reward-channel; direct application of the CHT). *Conditional-derived* for the behavioral corollary (Lemma 2, EU-max behavioral instability under (R1)–(R5)).

The Unification — Two Complementary Terminal Grounding Routes Exhaust the Geometry.

The cluster’s epistemic content is the **unification of Instances F and G under the shared structural fact**: the value-functional interface V_{O_t} , as the sole handle on the objective (#form-objective-functional’s single-interface commitment), carries less information than required to anchor non-degenerate goal-revision. The two failure modes are complementary readings of the same under-determination:

Table 5.3

<i>view</i>	<i>mechanism</i>	<i>what V_{O_t} is too narrow for</i>	<i>terminal grounding route</i>
Instance F (within-model)	C1/C2/C3 convention-split + finite-no-oracle (Result G’ Lemmas 1+2)	A convention-invariant infeasibility verdict that is agent-available per step	Adaptive-substrate invariant (the persistence bound; Result G’ Corollary 2) — agent-side
Instance G (across-model)	CHT-at-reward-channel; L1/L2 split (Cohen-2022 strengthened Lemma 1)	A μ_{prox} -vs- μ_{dist} goal-identification on observed reward data	Principal-side substrate-level commitments (isolation / myopia / quantilization / prior-design) — principal-side

Both reductions are *failures of V_{O_t} to carry enough information to anchor goal-stability*. The two terminal grounding routes are *complementary*: the agent-side route closes the within-model self-revision question (the engine is convention-monotonicity); the principal-side route closes the across-model reward-learning question (the engine is CHT-at-reward-channel). **Together they exhaust the structural complement of the value-functional interface’s information narrowness** — there is no third route internal to the value functional, and no fourth route off-substrate (the two off-substrate axes are agent-side adaptive-substrate and principal-side protocol-substrate; there are no other axes a non-degenerate non-pathological agent can be grounded on).

The two no-gos *compose*: a self-actuated agent whose O_t is learned from reward observation is *simultaneously* a Result-G’-subject (under-anchored from inside) and a Cohen-2022-subject (under-determined from below); the *only* terminal grounding routes are the two complementary ones named above.

Adjacent Frontiers (Open Research Directions).

Cross-Agent Value-Functional Narrowness (raised by #deriv-social-welfare-aggregation-impossibility). The cluster’s current charter instances are both *within-agent* (the value functional’s narrowness is on the agent’s own goal-anchoring). A parallel question, raised by Charter Instance 3 of #disc-implementation-impossibility (Arrow), is whether the value-functional formalism aggregates honestly across *sub-agents* in a composite — whether the per-sub-agent $V_{O_{(i)}}$ can be canonically combined into a designer-side aggregator (utilitarian summation, weighted utilitarianism). If the answer is “no, the cross-agent value-functional aggregation is also structurally narrow,” that would extend this cluster to a third charter instance under a cross-agent narrowness reading. The open avenue is whether the value functional’s narrowness is *within-agent only* or *cross-agent also*.

Assistance-Game and Out-of-Band Channel Formalization (raised by #deriv-reward-channel-learning-no-go (R3)). Cohen 2022’s §”The Assistance Game” shows the no-go *generalizes* to settings with non-reward channels under subtler ambiguity (human-centric vs record-centric models). Formalizing the assistance-game case in AAT would extend Instance G’s boundary characterization on the (R3) escape from “outside AAT canon, principal-side adjacent” to “AAT-formalized assistance-game extension.” Open.

Higher-Order Reflective-Oracle Constructions (delimited counter-literature). Fallenstein-Taylor-Christiano 2015's reflective oracles prove consistent self-reference over an *exogenous* payoff — a primitive-reflective-oracle regime the cluster's (R3)+(R5) premises exclude from Instance G and that Instance F's finite-no-oracle premise (R2) excludes structurally. Whether a higher-order reflective construction could circumvent either floor by introducing oracle-like resolution on the cardinal/ordinal axis is open. The current scope-statement is that *the floors apply to non-pathological agents on AAT-covered objective-side machinery*; reflective-oracle constructions are *outside scope*, not refutations of the floors. Listed honestly for completeness.

Why This Pattern Matters.

Closes the third cluster of #disc-constructive-impossibility-posture. The posture catalog now spans three structurally distinct clusters at the boundary face of the stability-certificate spine: agent-side data-inference impossibility (#disc-identifiability-floor; Instances A–C), agent-side value-functional-grounding impossibility (this cluster; Instances F–G), and designer-side mechanism-design impossibility (#disc-implementation-impossibility; the GS/MS/Arrow charter). The three-cluster taxonomy is fully realized when this cluster lands; the constructive-impossibility-posture style is now visible across three deployments rather than one or two.

Names the single-interface commitment as a load-bearing source of structural narrowness. Before the Cohen-2022 strengthening, Result G' carried the within-model side alone, with the cross-model side implicit in #form-objective-functional Discussion. The Cohen-2022 strengthening surfaced the cross-model side as a derived no-go, and the unification with Result G' revealed both as instances of a single structural fact: the value functional is the *sole* agent-internal handle on the objective, and that interface is information-narrow in a load-bearing way. The cluster's epistemic content is the explicit recognition of this single-interface commitment as the engine behind both no-gos.

Exhausts the structural escape geometry. The two complementary terminal grounding routes — agent-side adaptive-substrate invariant + principal-side substrate-level commitment — *together exhaust* the off-interface escape axes. There is no third route internal to the value functional; there are no other off-substrate axes a non-degenerate non-pathological agent can be grounded on. The cluster's content is *not* that the value functional is unusable (it remains the framework's canonical interface to the objective; per-sub-agent within-trajectory evaluation works cleanly); the content is that *the value functional alone cannot anchor goal-stability under the stated information regimes*, and the escapes are precisely the two recognized routes.

Agent-side / designer-side suffix discipline. The cluster's name follows the convention established with the 2026-05-22 Track B landing: agent-side capacity-on-the-agent → *-floor*; designer-side task-of-the-designer → *-impossibility*. Both Instance F and Instance G are agent-side (the actor frustrated by the floor is the agent itself — Result G's self-actuated agent attempting to anchor self-revision; Cohen-2022's EU-maximizer under non-vacuous μ_{prox} prior). The name therefore takes the *-floor* suffix, matching #disc-identifiability-floor. The naming-pattern across the three peer meta-segments encodes the agent/designer structural distinction at slug-grep depth.

Epistemic Status.

Discussion-grade at the meta-pattern level. This segment names a structural cluster across two AAT-internal no-go results (Result G' in #deriv-self-actuation-grounding; Cohen-2022 strengthened in #deriv-reward-channel-learning-no-go); the cluster recognition itself is a presentational organizing principle, not a derivation, and carries no theorem of its own.

Individual instances retain their own (higher) epistemic status. Instance F is *conditional, scoped* per #deriv-self-actuation-grounding's frontmatter (conditional on (R1)–(R3) of Result G'; scoped to AAT-covered objective-side machinery). Instance G is *conditional* per #deriv-reward-channel-learning-no-go's frontmatter — Lemma 1 (the floor; CHT-at-reward-channel) at *exact* tier; Lemma 2 (the behavioral corollary; EU-max instability) at *conditional-derived* tier under (R1)–(R5).

The segment makes one additional claim: that the two charter instances *unify* under the single-interface commitment of #form-objective-functional as the shared structural fact behind two engines (convention-monotonicity within-model; CHT across-model). This is a *discussion-grade* observation about the framework’s architecture — visible once the instances are assembled, but not itself a theorem. The unification claim is the segment’s headline contribution; whether it lifts to *robust qualitative* under deeper analysis (e.g., whether *every* failure mode of V_{O_i} -anchoring reduces to one of the two engines) is an open question.

Max attainable: *discussion-grade* for the meta-pattern (it is a presentational organizing principle, not a derivation). The individual instances retain their own epistemic status as listed above. The two-engines unification could lift to *robust qualitative* if a stronger structural argument forces both engines under a single deeper principle (currently in hand: both reduce to the *single-interface commitment* of #form-objective-functional, which is itself a formulation choice).

Discussion.

Relationship to #disc-identifiability-floor. Both are agent-side meta-segments, both end in *-floor*, both anchor (in their charter instances) on the Pearl-Bareinboim CHT — but on *different AAT-side wirings*. The identifiability floor’s CHT instance (Instance 1) wires it to the *causal-sufficiency-detection layer* of the strategy DAG; Instance G of this cluster wires the same CHT to the *reward-channel-causation layer* of #form-objective-functional. The two clusters are *sister meta-patterns at different layers*: agent-side data-inference layer (#disc-identifiability-floor) vs agent-side value-functional layer (this cluster). Both run the same constructive-impossibility-posture three-move discipline (name the floor, name the escape, treat the no-go as load-bearing apparatus); the *layer* differs.

Relationship to #disc-implementation-impossibility. Sister peer in a different way. This cluster and #disc-implementation-impossibility are *both* recently-named meta-segments landing in the 2026-05-22 cycle. They differ on the agent/designer axis: this cluster is agent-side (actor frustrated is the agent inferring/anchoring); #disc-implementation-impossibility is designer-side (actor frustrated is the designer implementing a mechanism). The two clusters together with #disc-identifiability-floor complete the three recognized cells of the constructive-impossibility-posture taxonomy: agent-side data-inference / agent-side value-functional-grounding / designer-side mechanism-design. The naming-pattern across the three (*-floor* / *-floor* / *-impossibility*) encodes the agent/designer distinction at slug-grep depth.

Relationship to #disc-stability-certificate. This segment is a *boundary-face* facet of the certificate spine, peer to #disc-identifiability-floor (agent-side data-inference layer) and #disc-implementation-impossibility (designer-side mechanism-design layer). The boundary is where impossibility statements bind; the three meta-segments are the three boundary-layer dialects in which the framework speaks at that boundary. The value-functional layer this cluster names is a *different* boundary-layer from the data-inference layer (where identifiability-floor lives) — both are at the certificate boundary, but they describe distinct narrowness conditions on agent-side machinery.

Relationship to #disc-constructive-impossibility-posture. This segment’s two charter instances (F and G) are catalog rows in the posture’s “Current Instances” table. The posture’s catalog gains the cluster’s home via this segment landing; the cluster joins the catalog as the third cluster (alongside A–C in identifiability-floor and the queued/landed GS/MS/Arrow under implementation-impossibility). The posture’s “Current Instances” framing — Instance Floor / Escape / Apparatus — applies cleanly to both F and G (already catalogued there pre-cluster-landing).

The single-interface commitment as the cluster’s structural ingredient. #form-objective-functional formalizes $V_{O_i}(\tau)$ as the *sole* agent-internal interface to the objective. That single-interface commitment is a representational choice — alternative formulations could carry multiple interfaces (e.g., a separate satisfaction-channel alongside the value-channel; cf. #def-satisfaction-gap for an adjacent diagnostic). The cluster’s content is that *under the single-interface commitment*, the value functional carries less information than required to anchor goal-stability, and the escapes are precisely the two off-interface routes. Whether a multi-interface formulation would have a different floor structure is an open framework-scope question; the current cluster operates within the single-interface commitment.

Why the cluster’s name is “floor.” A *floor* in AAT’s meta-pattern vocabulary names a structural lower bound — below the floor, the named capacity is impossible; the floor is the lower limit of what the substrate can supply. This cluster’s

floor is the lower bound on what the value functional alone can supply for *goal-anchoring*. Below the floor (i.e., under the named premises of Instances F and G), V_{O_i} alone cannot anchor goal-stability; above the floor (i.e., when one of the named escapes is available), anchoring becomes possible via off-interface invariants. The “floor” framing is the same as #disc-identifiability-floor’s — a structural lower bound on a *capacity* of the agent’s substrate. The agent-side / designer-side suffix discipline reinforces the parallel: both agent-side clusters end in *-floor* because both name lower bounds on agent capacity.

Two-routes-exhausts as the cluster’s epistemic load. The unification’s headline content is the *exhaustion*: the two complementary terminal grounding routes (agent-side adaptive-substrate + principal-side substrate-level commitment) together close the structural complement of the value-functional interface’s narrowness. There is no third route internal to the value functional; there are no other off-substrate axes a non-degenerate non-pathological agent can be grounded on. If a future cycle finds a third route (e.g., via formalizing reflective-oracle constructions, or via lifting cross-agent value-functional aggregation to canonical form), the cluster’s exhaustion claim would be revised — but the two routes are currently sufficient.

Findings.

The Value-Functional Grounding Floor — Two Complementary Routes Exhaust the Geometry. **Brief:** When an agent has an objective and uses a single value-functional interface to evaluate trajectories against it — *the* canonical move in AAT’s formulation of agency — two structural impossibilities apply. *Within-model*: if the agent can rewrite its own objective, the value functional alone cannot tell the agent whether its proposed self-modification is feasible per step (Result G’ — the convention-hierarchy of value evaluation produces an infeasibility verdict that is not convention-invariant from inside the agent, and the agent cannot resolve the question with an oracle-like off-step appeal). *Across-model*: if the agent learns its objective by watching rewards arrive through a physical protocol, the value functional alone cannot tell the agent whether the rewards mean what the principal intended (Cohen-2022 strengthened — two world-models, one where the reward depends on a world-state feature and one where it depends on bit-arrival at the sensor, are indistinguishable on protocol-honoring reward histories). Both no-gos are failures of the value functional to anchor goal-stability from inside. The escape geometry is sharply constrained: anchoring has to come from *off* the value-functional interface — either from a part of the agent that doesn’t process objectives (the persistence-on-the-adaptive-substrate route Result G’ names; agent-side) or from a commitment the principal makes about the protocol (physical isolation, horizon restriction, prior-design, out-of-band intent channels; principal-side). The two routes together *exhaust* the structural complement: there is no third route internal to the value functional, and no fourth route off-substrate. A reader who carries this away knows that when a framework commits to a single value-functional interface, it has implicitly committed to one of the two terminal grounding routes — agent-side substrate-invariant or principal-side substrate-commitment — and the choice is structural, not a matter of taste.

Impact: Closes the third recognized cluster of #disc-constructive-impossibility-posture, completing the constructive-impossibility-posture taxonomy at peer-meta-segment level. The three clusters now span the framework’s three structurally distinct boundary-face conditions: what an agent can *infer from data* (identifiability-floor; agent-side data-inference layer), what an agent can *anchor through the value-functional interface* (this cluster; agent-side value-functional layer), and what a designer can *implement under incentive and welfare constraints* (implementation-impossibility; designer-side mechanism-design layer). The two charter instances (Result G’ for within-model; Cohen-2022 strengthened for across-model) unify under the single-interface commitment of #form-objective-functional as the shared structural fact behind two engines (convention-monotonicity; CHT-at-reward-channel). The two-routes-exhausts headline is the segment’s primary contribution — a structurally-load-bearing recognition that elevates the persistence bound (#result-persistence-condition) and principal-side substrate-level commitments (physical isolation, horizon restriction, prior-design) to *the only* terminal grounding routes available under the single-interface commitment. The agent-side / designer-side suffix discipline encodes the structural distinction in the canon naming-pattern.

Novelty Claim: *Claim recognition* of a structural cluster across two AAT-internal no-go results (Result G’ within-model; Cohen-2022 strengthened across-model) sharing the *single-interface commitment* of #form-objective-functional

as the structural engine — both no-gos are failures of the same interface to carry enough information to anchor goal-stability, with two engines and two complementary terminal grounding routes; *claim differentiation* on the two-routes-exhausts geometry — the agent-side adaptive-substrate route and the principal-side protocol-commitment route together exhaust the structural complement of the value-functional interface’s narrowness, with no third route internal to the interface and no fourth route off-substrate. The constituent no-gos (Result G’; Cohen-2022 strengthened) are landed AAT-internal segments; the contribution at this meta-segment is the cross-instance unification under the single-interface commitment + the structural-exhaustion recognition.

(2022), “Defining and characterizing reward hacking,” <i>NeurIPS 2022</i>	<i>adjacent literature (different cluster)</i> — designer-side reward-proxy design task; structurally a #disc-implementation-impossibility candidate instance, not a member of this cluster

ASF concern	Prior-art language	Relationship / Positioning
The constructive-impossibility-posture style across clusters	#disc-constructive-impossibility-posture (this framework)	<i>internal antecedent</i> — the cluster joins the posture catalog as the third recognized cluster

Search Log:

- 2026-05-22 (*intuition-only* on the two-routes-exhausts claim): The exhaustion is intuitive once the two engines are named (convention-monotonicity within-model; CHT-at-reward-channel across-model) — these are the only two known engines forcing V_{O_t} -narrowness, and the two terminal grounding routes they produce (agent-side adaptive-substrate; principal-side substrate-commitment) cover the off-interface escape geometry without leaving an obvious gap. Whether a third engine exists is an open question the cluster's discussion-grade tier honestly admits; targeted future search would probe the AI-safety / decision-theory literature for additional under-determination patterns of value-functional interfaces.

Working Notes.

- **Provenance.** Authored 2026-05-22 as commit 5 of the post-Track-CR cycle, executing the Cohen-2022 strengthening verdict's §2 step 4 deferred-meta-promotion question (Joseph approved the third meta-segment landing in this same cycle per the Q3 override on the cycle-scope expansion conversation). The cluster's two charter instances are landed canonical segments (Result G' in #deriv-self-actuation-grounding from earlier; Cohen-2022 strengthened in #deriv-reward-channel-learning-no-go from the 2026-05-22 Cohen strengthening spike). The meta-segment is pure cross-instance pattern recognition + naming + cross-referencing.
- **Open before candidate.** (a) The cross-agent value-functional narrowness question raised by #deriv-social-welfare-aggregation-impossibility's Arrow-unique cardinal-preference adjacency — whether the per-sub-agent $V_{O_t(i)}$ canonically lifts to a designer-side aggregator, and if not, whether the cross-agent narrowness is structurally similar to the within-agent narrowness named here. Open avenue; would extend the cluster to a third charter instance. Indexed at spikes/PROPOSED.md Tier 2 (added 2026-05-24) → spikes/PROPOSED-ADVANCED.md §Phase-3 #18 — two-branch spike (constructive lift first per strengthen-first; no-go branch as honest fallback, which if it lands would supply the cluster's third charter instance). (b) The assistance-game extension flagged in Cohen 2022 §"The Assistance Game" — formalizing the (R3) out-of-band channel escape would extend Instance G's boundary characterization. (c) Whether the two-routes-exhausts claim lifts to *robust qualitative* under a stronger structural argument (e.g., proving that *every* failure mode of V_{O_t} -anchoring reduces to one of the two engines). All three are open canonical work; the cluster's *discussion-grade* tier on the meta-pattern recognition does not require any of them to land first.
- **The Skalse-2022 disposition.** Skalse, Howe, Krashennikov, Krueger 2022 is structurally a *designer-side reward-proxy design* task (the designer cannot engineer an unhackable reward proxy), not an *agent-side value-functional grounding* task. The actor under the no-go is the designer; the cluster's discipline filter (agent-side, value-functional interface, single-interface commitment) rules it out as a charter instance of this cluster. Skalse 2022 is flagged in #disc-implementation-impossibility as a candidate fifth charter instance there; the relationship across clusters is sister-relationship via the broader #disc-constructive-impossibility-posture, not membership.
- **Why the two charter instances suffice for landing.** A cluster with only two charter instances is unusually narrow compared to #disc-identifiability-floor (four instances) and #disc-implementation-impossibility (three instances at landing). The narrowness is *honest*, not weakness: the *exhaustion* of the structural escape geometry — agent-side adaptive-substrate + principal-side substrate-commitment — is what makes two instances sufficient to characterize the cluster. The two engines (convention-monotonicity; CHT-at-reward-channel) are the two known engines forcing V_{O_t} -narrowness; the two routes they produce are the only known off-interface escape axes. If a third engine surfaces (open avenue (c) above), the cluster gains a third instance; until then, two instances close the cluster's content cleanly.

- **Two-routes-exhausts adversarial spike queued (2026-05-28; audit 384279 §D Hyp 2).** The line-77 structural-completeness claim — “no third route internal to the value functional, and no fourth route off-substrate” — is load-bearing for the cluster’s recognition and partially load-bearing for #disc-constructive-impossibility-posture’s three-cluster taxonomy. The audit (Claude Opus 4.7) tried three candidate third-routes informally (observer-side commitment / inter-agent grounding / substrate-level Goodhart) and found each collapses or shifts narrowness one level out, but did not push hard. An adversarial spike spending serious effort attempting to construct a third route is queued at spikes/PROPOSED.md Tier 1 (2026-05-28 row). If the spike finds a genuine third route, the completeness claim is refuted and the cluster needs revision; if multiple attempts fail systematically, the claim could be promoted from discussion-grade toward robust-qualitative or derived. Adjacent to open avenue (c) above (proving every V_{O_t} -anchoring failure mode reduces to one of the two engines) — the engine-side and the route-side completeness questions are duals.
- **Search provenance.** The deferred-meta-promotion question this segment executes was named in the Cohen-2022 strengthening verdict (spikes/spike-cohen-2022-strengthening-2026-05-22/99-verdict.md §2 step 4): the agent-side value-functional-grounding cluster was to be revisited once both Instance F (Result G’ via #deriv-self-actuation-grounding) and Instance G (Cohen-2022 strengthened via #deriv-reward-channel-learning-no-go) had landed in canon. (The literature-search disclosure proper lives in the Search Log above.)

Incidental audit gold (gold-lift, 2026-05-30). Orthogonal framing material harvested from de-novo auditors’ working-dir reflections, kept separate from certified findings. **Coverage:** reached only by audit 384279 (note 35) — this segment was authored 2026-05-22 and postdates every other de-novo audit. Preserve the finding-vs-framing conflation.

2. Candidate Discussion.

- **The two-routes-exhausts claim as a sharper structural commitment, not just a recognition.** The auditor’s framing of *why the exhaustion claim is worth making*: rather than “there are many routes, here are some,” the segment says “there are exactly two, here they are” — a cleaner structural commitment with a sharper falsification criterion (find a third route to refute). “The framework has put a real claim on the table here.” If the claim holds it “substantially simplifies how the framework reasons about goal-anchoring.” A candidate Discussion framing of the headline contribution’s *epistemic shape* (Claude, 384279).

3. Follow-up items (already partly captured).

- **Adversarial third-route attempts, recorded so they read as a known trap not a fresh judgment call.** The auditor tried three candidate third off-substrate routes against the line-77 exhaustion claim and found each collapses: *observer-side commitment* (an external auditor declaring agent-states out-of-scope — collapses into principal-side under generous reading); *inter-agent grounding* (a peer agent’s value functional anchoring this agent’s goal-stability — just shifts the narrowness one level out, since the peer’s value functional is itself narrow); *substrate-level Goodhart* (hardware/computational limits on realizable objectives — genuinely off-substrate but collapses into principal-side, since the designer chose the substrate). The attempts “do seem to fail,” but the auditor noted they did not push hard and flagged a sharper adversarial spike (Claude, 384279). (*Already captured in this segment’s Working Notes “Two-routes-exhausts adversarial spike queued” bullet and at spikes/PROPOSED.md Tier 1; the three specific attempted routes are recorded here so a future spike inherits them rather than re-deriving.*)

4. Readers often ask / wonder.

- **“Why only two charter instances when the sister clusters have three or four?”** A reader is likely to read two instances as unusually narrow. The honest answer the segment already gives — the *exhaustion* of the escape geometry is what makes two sufficient — is worth a reader-facing sentence, since the narrowness invites the question (corroborated by the auditor’s read that two instances felt notably narrow vs #disc-identifiability-floor’s four; Claude, 384279, and this segment’s own Working Notes “Why the two charter instances suffice” bullet).

5.3 Discussion: The Implementation Impossibility — Designer-Side Structural No-Go Results

AAT recognizes a sister class to #disc-identifiability-floor's agent-side no-gos: a cluster of *designer-side* structural impossibility results, where a classical mechanism-design or social-choice theorem forbids an external designer from constructing a composite-design outcome with desired properties under stated incentive and welfare constraints. The actor frustrated by the floor is no longer the agent inferring from data, but the *designer* implementing a mechanism; the remedy is no longer information augmentation (loop-interventional access, latent observability, matched-Tier composite-extended observation), but design-constraint relaxation (Bayes-Nash IC, randomization, monetary transfers, preference-domain restriction). The meta-pattern is the same constructive-impossibility shape — name the floor, name the escapes, treat the no-go as load-bearing apparatus — but the *layer* it operates on is different. This segment names the cluster, ships three charter instances (Gibbard-Satterthwaite, Myerson-Satterthwaite, Arrow), and is honest about what AAT contributes here (precision of the AAT/mechanism-design boundary) and what it does not (no constructive mechanism-design results; most escapes are not AAT machinery).

The cluster is narrow by design. The discipline filter — *constructive-impossibility-shape only* — admits classical theorems where (i) the designer faces a well-stated incentive or welfare regime, (ii) an external theorem forbids the construction under that regime, and (iii) the failure conditions characterize structurally distinct escape routes the designer could take. It deliberately excludes the *constructive* side of mechanism design (VCG, Myerson's revenue-equivalence theorem, optimal-auction theory) — those are positive results, not impossibility-with-escape. AAT's contribution at this cluster is not to invent mechanism design but to recognize *where the AAT-side strategic-composition machinery* (sub-scope α' of #deriv-strategic-composition: potential and monotone games) *intersects the classical escape routes*, and to honestly mark where it does not. That precision is the contribution.

Formal Expression.

The pattern. [Discussion] An instance of the cluster has the form:

1. **Setting.** A mechanism-design or social-choice task: a designer specifies a constraint regime (which agents, which preference domain, which information structure, which incentive condition, which welfare requirement) and seeks a mechanism — a social-choice function, a trading protocol, a welfare aggregator — satisfying all the constraints simultaneously.
2. **External theorem.** A classical impossibility result from mechanism design or social-choice theory whose statement and truth are independent of AAT: Gibbard 1973 / Satterthwaite 1975 on strategy-proofness; Myerson & Satterthwaite 1983 on bilateral trade; Arrow 1951 on social welfare aggregation.
3. **No-go.** The external theorem proves that no mechanism satisfying all the stated constraints exists. The designer's task is structurally unachievable under the regime.
4. **Boundary characterization.** The conditions under which the regime fails — i.e., the designer has *more freedom* than the regime allows — admit construction; each escape route maps onto a specific category of design-constraint relaxation. Each escape is annotated as *intersects AAT machinery* (where the relaxation operationalizes an AAT sub-scope condition) or *outside AAT machinery* (where the relaxation belongs entirely to the mechanism-design literature).
5. **Strengthened consequence.** The boundary precisely characterizes where AAT machinery contributes to which escape routes, and where the framework's contribution stops. Where escapes intersect AAT machinery (preference-domain restriction $\leftrightarrow$ sub-scope α' potential games of #deriv-strategic-composition), the intersection is named precisely. Where they do not (Bayes-Nash IC, randomization, monetary subsidies), the segment honestly documents the boundary. The strengthened consequence here is the *map of where AAT machinery meets mechanism design*, not the elevation of new AAT machinery to load-bearing.

The actor-and-remedy contrast with the identifiability-floor cluster is sharp:

Table 5.5

	<i>Identifiability Floor</i> (#disc-identifiability-floor)	<i>Implementation Impossibility</i> (this cluster)
Actor under the no-go	An <i>agent</i> inferring from data	A <i>designer</i> implementing a mechanism
Information regime	What the agent observes / can infer	What the designer can implement / commit to
Kind of remedy	Augment the agent’s data, sensing, interventional access	Relax design constraints; extend the strategy space; introduce transfers
AAT machinery role in escapes	The unique broadly-available escape elevates specific AAT machinery (loop-interventional access; observability-as-augmentation; matched-Tier composite-extended observation)	The escape menu mostly belongs to the mechanism-design literature; AAT intersects via sub-scope α' (preference-domain restriction) and adjacent to #form-objective-functional (cardinal preferences)
Strengthened consequence	Elevates AAT machinery from “useful” to <i>structurally required</i>	Maps the AAT/mechanism-design boundary precisely

Both clusters share the constructive-impossibility-posture shape (#disc-constructive-impossibility-posture); both are boundary-face members of the stability-certificate spine (#disc-stability-certificate). They are *sister meta-clusters*, neither subsumed by the other.

Charter instances. The cluster lands with three charter instances. The full setting, external theorem, no-go statement, escape characterization, and AAT-side translation live in the supporting segments; this section summarizes at the level #disc-identifiability-floor’s Instance entries summarize.

Instance 1 — Strategy-Proofness Impossibility (Gibbard-Satterthwaite, supported by #deriv-strategy-proofness-impossibility). **Setting.** A social-choice function $f : L^n \rightarrow A$ aggregating n agents’ strict preference orderings over $|A| \geq 3$ alternatives into a single outcome, under (i) dominant-strategy incentive compatibility (DSIC), (ii) non-dictatorial, (iii) surjective onto A , (iv) unrestricted preferences.

External theorem. Gibbard, A. (1973), “Manipulation of voting schemes: a general result,” *Econometrica* 41:587–601; Satterthwaite, M. A. (1975), “Strategy-proofness and Arrow’s conditions: existence and correspondence theorems for voting procedures and social welfare functions,” *J. Econ. Theory* 10:187–217. No f satisfying all four conditions exists.

No-go. A designer demanding DSIC + non-dictatorial + surjective + unrestricted preferences over ≥ 3 alternatives cannot construct the social-choice function.

Boundary characterization (the escapes). - *Preference-domain restriction* (e.g., single-peaked preferences — Black 1948 admits the median-voter rule). **Intersects AAT machinery** via sub-scope α' of #deriv-strategic-composition: single-peaked / single-crossing preference domains map onto the potential-game / monotone-game structural conditions under which the AAT strategic-composition machinery derives best-response convergence. - *Weakened solution concept* (Bayes-Nash IC instead of DSIC — d’Aspremont & Gérard-Varet 1979). **Outside AAT machinery.** - *Randomization* (Gibbard 1977 random-dictator mechanisms). **Outside AAT machinery.** - *Restricted strategy space / enforced truth-telling.* **Outside AAT machinery.**

Strengthened consequence. The sub-scope- $\alpha' \leftrightarrow$ preference-domain-restriction intersection is named precisely: the AAT machinery #deriv-strategic-composition already deploys for best-response convergence in strategic composition coincides structurally with one of GS’s classical escape routes. The other escapes belong to mechanism-design proper and the framework documents them as outside AAT’s current canon. The sub-scope- α' escape does *not* address what

GS forbids — it secures best-response *convergence*, not *strategy-proofness* — so the intersection is *adjacent*, not *identical*; that is the honest map.

Tier. *Exact* (the imported theorem). *Derived conditional* for the AAT-side translation (the social-choice-function-to-strategic-composition mapping is mechanical under explicit reading conventions). *Robust qualitative* for the boundary characterization.

Instance 2 — Bilateral Trade Impossibility (Myerson-Satterthwaite, supported by #deriv-bilateral-trade-impossibility).

Setting. Two-party bilateral trade with private information about valuations (v_b, v_s) drawn from continuous distributions with overlapping supports; the designer seeks a mechanism that is simultaneously (i) ex-post efficient (trade occurs iff $v_b \geq v_s$), (ii) Bayesian incentive compatible (BIC), (iii) individually rational (IR — voluntary participation), (iv) budget-balanced (no external subsidies).

External theorem. Myerson, R. B. & Satterthwaite, M. A. (1983), “Efficient mechanisms for bilateral trading,” *J. Econ. Theory* 29:265–281. No such mechanism exists.

No-go. A designer demanding ex-post efficiency + BIC + IR + budget-balance cannot construct the bilateral-trade mechanism.

Boundary characterization (the escapes). - *Subsidies* (relax budget-balance — e.g., VCG with deficit). **Outside AAT machinery.** - *Second-best mechanisms* (Myerson 1981 optimal trade with inefficient withholding). **Outside AAT machinery.** - *Common values* (relax private values). **Outside AAT machinery; adjacent** to #scope-edge-update-causal-validity’s regime-indexed identification structure. - *Long-run reputation / repeated interaction* (Folk-theorem-style escapes). **Outside AAT machinery; adjacent** to the strategic-composition machinery in repeated-game form.

Strengthened consequence. The Myerson-Satterthwaite boundary lies almost entirely outside AAT’s current canon — and the *honest delineation* is the contribution. The two-agent strategic-composition machinery in #deriv-strategic-composition applies cleanly to the agents’ best-response dynamics *given* a fixed mechanism; the *choice of mechanism* is the designer’s problem and lives outside the framework. The cluster names that boundary precisely rather than overclaiming reach or silently overlooking the gap.

Tier. *Exact* (the imported theorem). *Derived conditional* for the AAT-side translation (clean for the agents-given-mechanism layer; carefully scope-marked for the designer’s mechanism-choice layer).

Instance 3 — Social Welfare Aggregation Impossibility (Arrow, supported by #deriv-social-welfare-aggregation-impossibility).

Setting. A social welfare function $F : L^n \rightarrow L$ aggregating n agents’ strict preference orderings into a single social preference ordering over ≥ 3 alternatives, under (i) unrestricted domain (U), (ii) Pareto efficiency (P), (iii) Independence of Irrelevant Alternatives (IIA), (iv) non-dictatorial (ND).

External theorem. Arrow, K. J. (1951, 2nd ed. 1963), *Social Choice and Individual Values*, Yale University Press. No F satisfying all four conditions exists.

No-go. A designer demanding U + P + IIA + ND cannot construct the social welfare function.

Boundary characterization (the escapes). - *Preference-domain restriction* (single-peaked, single-crossing — admits Condorcet-consistent rules). **Intersects AAT machinery** via the same sub-scope- α' correspondence as GS Instance 1. - *Weakened IIA* (positional methods — Borda count, range voting). **Outside AAT machinery.** - *Supermajority requirements* (e.g., 2/3 thresholds). **Outside AAT machinery.** - *Cardinal preferences* (relax ordinal-only — utilitarianism, range voting). **Outside AAT machinery; adjacent** to #form-objective-functional’s value-functional machinery (which carries cardinal value content).

Strengthened consequence. Arrow shares GS’s preference-domain $\leftrightarrow$ sub-scope- α' intersection and adds an *adjacent connection* through the cardinal-preference escape and AAT’s value-functional interface. Both connections are *adjacent* (intersection / proximity), not elevation of AAT machinery to load-bearing. The honest scope-mark documents both clearly.

Tier. *Exact* (the imported theorem). *Derived conditional* for the AAT-side translation.

Adjacent Frontiers (Open Research Directions).

Roberts 1979 Affine-Maximizers Theorem. Roberts, K. (1979), “The characterization of implementable choice rules,” in *Aggregation and Revelation of Preferences*, J.J. Laffont (ed.), North-Holland: under DSIC with monetary transfers on unrestricted preferences, the only implementable choice rules are affine maximizers (weighted utilitarian welfare functions). The pattern fit is genuine — external theorem, structural no-go on a designer’s freedom, characterized escape route (restrict preference domain or accept affine form) — and admits a future landing as a fourth charter instance. Held back at present landing to keep the charter scope narrow. The AAT-side intersection (whether affine-maximizer structure connects to AAT’s value-functional formalism via cardinal preferences) is a candidate strengthened-consequence content for that future cycle.

Skalse-Howe-Krashennikov-Krueger 2022 Reward Hacking Unhackability. Skalse, J., Howe, N., Krashennikov, D. & Krueger, D. (2022), “Defining and characterizing reward hacking,” *NeurIPS 2022*: no non-trivial proxy-reward pair is unhackable on open policy sets. The actor is the *designer* trying to engineer unhackable reward proxies; the no-go is on the designer’s task. Sister to this cluster *in shape*, but structurally a *different* designer-side task (reward-proxy design rather than mechanism design over preference reports). The candidate landing is a future cycle’s evaluation against this cluster’s discipline filter. The agent-side variant (the agent that exploits the proxy) lives in #deriv-reward-channel-learning-no-go and the agent-side value-functional-grounding cluster (#disc-value-functional-grounding-floor), not here. Skalse 2022 cross-references both clusters honestly: the designer-side task fits the implementation-impossibility shape; the agent-side exploitation fits the value-functional-grounding-floor shape.

Constructive Mechanism-Design (deliberately excluded by the discipline filter). VCG mechanisms, Myerson 1981 optimal auctions, revenue-equivalence, and the broader constructive mechanism-design literature are *positive results* — characterizations of what *can* be achieved with monetary transfers under stated conditions. They are not impossibility-with-escape; they are construction-with-tradeoff. The discipline filter excludes them by design. If AAT later wants to engage constructive mechanism design as a first-class concern, that is a separate framework-scope decision — not an extension of this cluster.

Why This Pattern Matters.

Closes a missing-but-implied taxonomic category. The agent-side identifiability-floor cluster has been canonical since the framework’s earliest meta-pattern work. The designer-side cluster has been *implicit* — flagged in #deriv-strategic-composition Discussion — but without a first-class home. The cluster landing closes the asymmetry: the framework now has both an agent-side floor pattern *and* a designer-side impossibility pattern, with the sister-relationship and the contrast precisely characterized.

Maps the AAT/mechanism-design boundary precisely. The contribution is not invention; mechanism design and social-choice theory are mature peer literatures AAT inherits classical theorems from. The contribution is recognition — *where* AAT machinery contributes to a classical escape route (sub-scope $\alpha' \leftrightarrow$ preference-domain restriction), *where* it is adjacent without intersecting (cardinal preferences $\leftrightarrow$ #form-objective-functional), and *where* the framework’s contribution stops (Bayes-Nash IC, randomization, transfers — all outside AAT canon). Mapping that boundary honestly is the kind of scope-honesty that distinguishes integrating frameworks from displacement claims.

Three-cluster constructive-impossibility-posture taxonomy. Together with #disc-identifiability-floor (agent-side data-inference) and #disc-value-functional-grounding-floor (agent-side value-functional grounding), this segment completes the third recognized cluster of the constructive-impossibility-posture style (#disc-constructive-impossibility-posture). The three clusters span the framework’s three structurally distinct boundary-face conditions: what an agent

can *infer from data* (M1 floors), what an agent can *anchor through the value-functional interface* (the value-functional-grounding floor), and what a designer can *implement under incentive and welfare constraints* (this cluster). The agent-side / designer-side distinction tracks the suffix in canon: agent-side capacity-on-the-agent $\rightarrow$ *-floor* (identifiability-floor, value-functional-grounding-floor); designer-side task-of-the-designer $\rightarrow$ *-impossibility* (this segment). That correspondence is structural, not decorative — an identifiability question and a value-functional-grounding question both name *what the agent's substrate supports* (lower bound on capacity); a mechanism-design question names *what the designer can construct* (binary success/failure on a task). The suffix carries the structure.

Honest scope-marking is contribution. AAT's posture across the framework — naming where machinery applies, naming where it does not, refusing to overstretch — is itself load-bearing. Landing this meta-segment with three charter instances *and explicitly documenting that most of the escapes are not AAT machinery* is the same scope-honesty discipline #disc-identifiability-floor applies on the agent side. The framework is not displaced by the mechanism-design literature; the mechanism-design literature is not absorbed by the framework. The two are in dialogue, with the boundary precisely mapped.

Epistemic Status.

Discussion-grade at the meta-pattern level. This segment names a structural cluster across three classical impossibility theorems; the cluster recognition itself is a presentational organizing principle, not a derivation, and carries no theorem of its own.

Individual instances retain their own (higher) epistemic status. The imported theorems (Gibbard 1973, Satterthwaite 1975, Myerson & Satterthwaite 1983, Arrow 1951, 1963) are *exact* — classical theorems with closed-form proofs in the source literature. The AAT-side translation in each supporting segment carries the segment's own tier (*derived conditional* on the AAT-internal reading of the mechanism-design constraint regime). The boundary characterization (which escapes intersect AAT machinery; which do not) is *robust qualitative* — survives across instance details, with specific functional intersections noted where derivable.

The segment makes one additional claim: that the actor-and-remedy contrast with #disc-identifiability-floor is *categorical* (designer-with-construction-task vs agent-with-inferential-task), not a matter of degree. This is a *discussion-grade* observation about the framework's architecture — visible once the instances are assembled, but not itself a theorem.

Max attainable: *discussion-grade* for the meta-pattern (it is a presentational organizing principle). Individual instances retain their own tier as listed in their supporting segments.

Discussion.

Relationship to #disc-identifiability-floor. Sister meta-pattern; the actor-and-remedy contrast table above. Both are boundary-face facets of #disc-stability-certificate; both run the same three-move discipline (name the floor, name the escape, treat the no-go as load-bearing apparatus). The two clusters differ in *layer* — agent-side data-inference vs designer-side construction — not in *posture*. The discipline that converts a sequence of classical impossibility theorems into a structural argument for *what AAT requires or maps* is shared.

Relationship to #disc-value-functional-grounding-floor. Sister meta-pattern in a different way. Both this cluster and the value-functional-grounding cluster are recently-named; both sit alongside the identifiability-floor as boundary-face peers of the certificate spine. The value-functional-grounding floor is *agent-side* (the agent's value-functional interface V_{O_i} cannot, by itself, anchor goal-stability — both Result G' and the Cohen-2022 strengthening land in that cluster); this cluster is *designer-side*. The three clusters together — agent-side data-inference / agent-side value-functional-grounding / designer-side mechanism-design — exhaust the framework's currently-recognized boundary-face conditions. The constructive-impossibility-posture catalog (#disc-constructive-impossibility-posture) carries all three under one stylistic recognition.

Relationship to #disc-stability-certificate. This segment is a *boundary-face* facet of the certificate spine, peer to #disc-identifiability-floor (agent-side data-inference layer), #disc-value-functional-grounding-floor (agent-side value-functional layer), and to the other facets #disc-separability-pattern (scope-of-existence), #disc-additive-coordinate-forcing (forced-identity), and the projection facet of #form-composition-closure. The boundary is where impossibility statements bind; this segment is one of three boundary-layer dialects in which the framework speaks at that boundary.

Relationship to #deriv-strategic-composition. The placement of “mechanism-design impossibility” as a candidate-fourth-instance of #disc-identifiability-floor is wrong on actor-positioning grounds: GS forbids what a designer can implement, not what an agent can identify, and the standard escapes are not AAT machinery. This segment is the correct home — the sister meta-segment to the identifiability floor. Sub-scope α' retains its load-bearing role in the strategic-composition machinery, and is *additionally* recognized here as the AAT-machinery-intersecting escape route for two of the three charter instances.

The discipline filter is narrow by design. The cluster admits only constructive-impossibility-shaped theorems. Auction theory in general is too broad; social-choice theory in general is too broad; constructive mechanism design (revenue equivalence, optimal auctions) is structurally different (positive results, not impossibility-with-escape) and is deliberately excluded. The narrowness is what makes the cluster’s discipline coherent — it admits theorems where the same three-move structure governs membership, and it cleanly excludes results that don’t share the structure. That coherence is itself epistemic content.

Peer voice with mechanism design. AAT does not displace mechanism design and does not absorb it. The classical theorems (GS, MS, Arrow) are imported with their original names and full citations; the standard escapes are documented in mechanism-design vocabulary (Bayes-Nash IC, preference-domain restriction, randomization, subsidies); the boundary is precisely mapped. The mature peer literature is in dialogue with the framework, and the dialogue’s content is honest scope-marking on both sides. AAT contributes the recognition that *its* strategic-composition machinery intersects *that* literature’s classical escape routes at a specific named locus (sub-scope $\alpha' \leftrightarrow$ preference-domain restriction); it does not contribute mechanism construction.

Findings.

The Implementation Impossibility — Designer-Side Sister to the Identifiability Floor. Brief: When a community has to decide together — what to vote for, how to trade fairly, how to add up preferences into a social choice — three classical results show that some combinations of “reasonable” demands cannot be met simultaneously: no voting rule can be at once strategy-proof, non-dictatorial, and broadly applicable; no bilateral trade mechanism can be at once fair, voluntary, balanced, and efficient; no social welfare function can be at once unrestricted, Pareto-respecting, independent-of-irrelevant-alternatives, and non-dictatorial. The escapes are well-known and have been studied for decades — restrict the preference domain to single-peaked, allow randomization, accept budget deficits, use a weaker incentive concept — and each escape relaxes exactly one of the demanded constraints. The framework recognizes that this cluster of classical results forms a *sister* to its agent-side identifiability floor: where the floor names what an agent cannot infer from limited data and the agent-side capacity-augmentation that escapes the floor, the implementation impossibility names what a designer cannot construct under stated constraints and the design-constraint-relaxation that escapes the impossibility. The contribution is not to re-prove the classical theorems but to map precisely where the framework’s own strategic-composition machinery (the sub-scope where best-response dynamics converge in potential or monotone games) intersects one of the well-known escapes (preference-domain restriction), and to honestly mark where the framework’s contribution stops. A reader who carries this way can predict where AAT will speak to mechanism design (it intersects on preference-domain restriction; it is adjacent on cardinal preferences via the value-functional interface) and where it will not (Bayes-Nash IC, randomization, monetary transfers all belong to mechanism design proper).

Impact: Closes a missing-but-implied taxonomic category. The designer-side cluster had been flagged in #deriv-strategic-composition’s Discussion as a candidate-fourth-instance of the identifiability floor, but had no first-class

home; GS does not fit the identifiability-floor pattern on actor-positioning grounds. The cluster's landing resolves the asymmetry. The framework now has three recognized clusters in the constructive-impossibility-posture catalog: agent-side data-inference (#disc-identifiability-floor), agent-side value-functional-grounding (#disc-value-functional-grounding-floor), and designer-side mechanism-design (this cluster). The agent-side / designer-side distinction tracks the canonical suffix (-floor for agent-side capacity-on-the-agent; -impossibility for designer-side task-of-the-designer), making the structural distinction visible at slug-grep depth. Three charter instances ship at landing (GS / MS / Arrow); a candidate fourth (Roberts 1979) and a candidate fifth (Skalse 2022, structurally a designer-side reward-proxy variant) are flagged for future cycles without expanding the present scope.

Novelty Claim: *Claim recognition* of a structural cluster across three classical mechanism-design / social-choice impossibility theorems, with the cluster's positioning in AAT's constructive-impossibility-posture taxonomy as the contribution rather than any new derivation; *claim differentiation* of the cluster from #disc-identifiability-floor on actor-and-remedy grounds; *claim transfer* of the constructive-impossibility-posture's three-move discipline (name floor / name escape / treat no-go as apparatus) from the agent-side data-inference layer to the designer-side mechanism-design layer. The constituent theorems (Gibbard 1973, Satterthwaite 1975, Myerson & Satterthwaite 1983, Arrow 1951) are classical; the contribution is the AAT-side recognition that they cluster together under one meta-pattern that *sits alongside* the agent-side floor pattern at the boundary facet of the stability-certificate spine.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Strategy-proofness impossibility (Instance 1)	Gibbard, A. (1973), "Manipulation of voting schemes: a general result," <i>Econometrica</i> 41:587–601 (found pre-2026); Satterthwaite, M. A. (1975), "Strategy-proofness and Arrow's conditions: existence and correspondence theorems for voting procedures and social welfare functions," <i>J. Econ. Theory</i> 10:187–217 (found pre-2026)	<i>formal antecedent</i> — the imported theorem for Instance 1; primary-source verification scheduled for the supporting segment's promotion past draft
Bilateral-trade impossibility (Instance 2)	Myerson, R. B. & Satterthwaite, M. A. (1983), "Efficient mechanisms for bilateral trading," <i>J. Econ. Theory</i> 29:265–281 (found pre-2026)	<i>formal antecedent</i> — the imported theorem for Instance 2
Social welfare aggregation impossibility (Instance 3)	Arrow, K. J. (1951, 2nd ed. 1963), <i>Social Choice and Individual Values</i> , Yale University Press (found pre-2026)	<i>formal antecedent</i> — the imported theorem for Instance 3
Single-peaked preferences as a domain escape	Black, D. (1948), "On the rationale of group decision-making," <i>J. Polit. Econ.</i> 56:23–34 (found pre-2026)	<i>adjacent literature</i> — the canonical preference-domain-restriction escape; the AAT-side intersection (sub-scope α') is named in the boundary characterization
Bayes-Nash relaxation of DSIC	d'Aspremont, C. & Gérard-Varet, L.-A. (1979), "Incentives and incomplete information," <i>J. Public Econ.</i> 11:25–45 (found pre-2026)	<i>adjacent literature</i> — outside AAT machinery; documented as honest scope-mark
Affine-maximizer characterization (candidate 4th instance)	Roberts, K. (1979), "The characterization of implementable choice rules," in <i>Aggregation and Revelation of Preferences</i> , J. J. Laffont (ed.), North-Holland (found pre-2026)	<i>partial anticipation</i> — same designer-side shape; held back from charter scope to keep landing narrow

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Reward-hacking unhackability (candidate 5th instance, designer-side variant)	Skalse, J., Howe, N., Krashennikov, D. & Krueger, D. (2022), “Defining and characterizing reward hacking,” <i>NeurIPS 2022</i> (found 2026-05-22)	<i>adjacent literature</i> — designer-side task on reward-proxy design; structurally distinct from GS/MS/Arrow’s preference-aggregation tasks; flagged for future evaluation against the discipline filter
The constructive-impossibility-posture style across clusters	#disc-constructive-impossibility-posture (this framework, 2026-05)	<i>internal antecedent</i> — the cluster joins the posture catalog as the third recognized cluster

Novelty assessment. The cross-instance recognition that GS / MS / Arrow share the constructive-impossibility-posture shape (setting → external theorem → no-go → boundary characterization → strengthened consequence) at the designer-side layer is the contribution; the constituent recognitions (each instance’s prior-art landscape) live in the supporting segments. The constituent moves are well-precedented at the textbook level (Mas-Colell, Whinston & Green 1995 §23.D; Reny 2001 for the geometric-topological proof structure shared across GS/Arrow; Roberts 1979 affine-maximizers as the canonical “with-transfers” extension); the cross-instance unification as the *designer-side companion* of an integrated agent theory’s identifiability-floor pattern appears to be a fresh presentational recognition.

Search Log:

- 2026-05-21 (*intuition-only on the meta-pattern as a cluster*): The cross-instance recognition that GS / MS / Arrow share the constructive-impossibility-posture shape (setting → external theorem → no-go → boundary characterization → strengthened consequence) at the designer-side layer is named here for the first time; the constituent recognitions (each instance’s prior-art landscape) live in the supporting segments. Targeted future search candidates: methodological-essay literature on mechanism design’s “impossibility tradition” (Mas-Colell, Whinston, Green 1995 *Microeconomic Theory* §23.D for the textbook synthesis; Reny 2001 *Econometrica* 69:961–981 for the geometric-topological proof structure shared across GS/Arrow); meta-discussion on the relationship between social-choice impossibilities and mechanism-design positive results (Roberts 1979 affine-maximizers as the canonical “with-transfers” extension). Expected outcome: the constituent moves are well-precedented at the textbook level; the cross-instance unification as the *designer-side companion* of an integrated agent theory’s identifiability-floor pattern appears to be a fresh presentational recognition.
- 2026-05-22 (*targeted, Skalse 2022 as candidate 5th instance*): Skalse, Howe, Krashennikov & Krueger 2022’s designer-side reward-hacking unhackability is structurally adjacent to this cluster’s discipline filter but on the *reward-proxy design* task rather than the *preference-aggregation* task. Flagged for future evaluation against the discipline filter, not pursued at present landing.

Working Notes.

- **Provenance.** Authored 2026-05-22 as Track B of the post-Track-CR integration cycle, executing spikes/implementation-impossibility-meta-segment-plan.md. The strengthen-first arm on GS-as-Instance-4 of #disc-identifiability-floor lives at spikes/.integrated/spike-4th-identifiability-floor-instance-2026-05-20.md §4; that spike re-derived GS against the M1 five-element test, tested three reframings under strengthen-before-soften, and confirmed GS does not fit the identifiability-floor cluster on actor-positioning grounds (designer vs agent; design-constraint relaxation vs information augmentation; combinatorial-topological mechanism vs Sylvester or projection-closure). The spike’s Outcome-C verdict — that the mechanism-design impossibility cluster (GS / MS / Arrow) may warrant its own meta-segment if mechanism design becomes a first-class framework concern — is the load-bearing provenance for this landing. The Skalse 2022 candidate-fifth-instance surfaced via the Cohen-2022 strengthening verdict’s Working Notes on the agent-side sister segment #deriv-reward-channel-learning-no-go; flagged for future evaluation, not pursued at present landing.

- **Open before candidate.** (a) Primary-source verification of the four classical theorems (GS / MS / Arrow) — the imported theorem statements above are taken from the spike trail and standard textbook references (Mas-Colell, Whinston, Green 1995 §21 / §23); direct primary-source reading is scheduled when the supporting segments advance past draft. (b) The Roberts 1979 affine-maximizers theorem as a candidate fourth charter instance — held back at present landing to keep scope narrow; evaluation against the discipline filter is its own future cycle. Indexed at `spikes/PROPOSED.md` Tier 2 (added 2026-05-24) → `spikes/PROPOSED-ADVANCED.md` §Phase-3 #16. (c) The Skalse-Howe-Krashennikov-Krueger 2022 reward-hacking unhackability as a candidate fifth charter instance — the structural fit (designer-side, reward-proxy design task, characterized escape routes) is plausible but the discipline filter check has not been re-derived here. Indexed at `spikes/PROPOSED.md` Tier 2 (added 2026-05-24) → `spikes/PROPOSED-ADVANCED.md` §Phase-3 #17 (the spike is a cross-cluster bridge evaluation against both this meta-segment and `#disc-value-functional-grounding-floor`).
- **Depends list will grow as supporting segments land.** Current depends-list lists only `deriv-strategic-composition` (the AAT segment whose sub-scope- α' machinery is named in the boundary characterization). The three supporting segments — `#deriv-strategy-proofness-impossibility` (GS), `#deriv-bilateral-trade-impossibility` (MS), `#deriv-social-welfare-aggregation-impossibility` (Arrow) — are landing in subsequent commits within the same cycle; depends will be expanded as they land. Forward-references to those slugs in this segment's body are deliberate per `FORMAT.md` §"Cross-References" and resolve as the supporting segments land.
- **Sister meta-segments are cross-references, not depends.** Following the convention `#disc-identifiability-floor` uses (which lists its instances and the AAT machinery it elevates in depends, but does not list sister meta-segments or the stability-certificate spine), this segment's references to `#disc-identifiability-floor` and `#disc-value-functional-grounding-floor` (the sister clusters) and to `#disc-stability-certificate` (the spine) are cross-references in body text, not entries in the depends list. The depends list captures the genuine prerequisite relationship (the meta-segment uses the prerequisite's definitions, results, or scope conditions); the meta-pattern recognition itself does not logically depend on the sister meta-patterns existing, only the cross-references do.
- **The three-cluster taxonomy is the substantive coupling with the Cohen-2022 strengthening cycle.** Naming the three clusters of the constructive-impossibility-posture explicitly (agent-side data-inference / agent-side value-functional-grounding / designer-side mechanism-design) is what closes the structural-canon disposition question deferred at `spikes/spike-cohen-2022-strengthening-2026-05-22/99-verdict.md` §2 step 4 and at `#deriv-reward-channel-learning-no-go` line 168 (the deferred meta-promotion question). The third meta-segment `#disc-value-functional-grounding-floor` is being authored in the same cycle as this one; both new meta-segments land together with the three-cluster taxonomy named in both.

Incidental audit gold (gold-lift, 2026-05-30). Orthogonal framing material harvested from de-novo auditors' working-dir reflections, kept separate from certified findings. **Coverage:** reached only by audit 384279 (note 36) — this segment was authored 2026-05-22 and postdates every other de-novo audit. Preserve the finding-vs-framing conflation.

2. Candidate Discussion.

- **The Myerson-Satterthwaite scope-honesty move read as a model of precision.** The auditor named the Instance-2 acknowledgment that "the Myerson-Satterthwaite boundary lies almost entirely outside AAT's current canon — and the honest delineation is the contribution" as "one of the most precise scope-claims I've encountered in the corpus." The reason it lands: many frameworks would either overstate influence over mechanism design or quietly drop the result; this segment *includes the theorem precisely because the boundary matters, then maps where AAT machinery touches vs does not*. A candidate framing of *why the deliberately-narrow scope is itself the contribution* (Claude, 384279). Reinforces the segment's existing "AAT contributes the boundary map, not new mechanism design" posture.

4. Readers often ask / wonder.

- **"If the escape is just 'import a 1998 paper,' is AAT contributing a repair or a citation?"** The mirror of an adversarial poke an auditor raised on the sister separability segment — some escapes/repairs across the meta-architecture are genuine AAT-derived fixes, others are "define the boundary, import a known solution." Here the segment already answers it head-on (the GS sub-scope- α' intersection is named *adjacent, not identical*; most MS/Arrow escapes are explicitly outside AAT canon), but a reader arriving from the separability segment may carry the same suspicion and benefit from the parallel being made

explicit (Gemini, 193847, raised the poke on #disc-separability-pattern; resolution here is the actor-and-remedy contrast table).

5.4 Discussion: The Separability Pattern — Separable Core, Structured Repair, General Open

AAT consistently runs a three-part epistemic posture across state spaces that admit no tractable exact treatment in general: name the **separable core** where identification is clean, name the **structured repair** that recovers identification under explicitly-added machinery, and name the **general open** case where the problem is either intractable or structurally unidentifiable. Eight ladders in the current theory share this shape (Correlation, Convention, Architecture, Contraction, Identification regime, Scope hierarchy, A2'-scope, Dynamic regime — enumerated in the table below; the Dynamic regime ladder landed 2026-05-21 per #disc-dynamic-regime-axis). This segment names the pattern as an organizing principle, catalogs the instances, and makes the complementarity with #disc-identifiability-floor (which names the *negative half* of AAT's scope) explicit.

The pattern.

Each instance of the separability pattern has the form:

1. **Separable core.** A sub-class of problem in which identification is tractable by construction — the quantity of interest has a clean estimator that requires only assumptions the agent can verify or control. “Separability” here is broader than statistical independence: it names the regime in which the quantity decomposes along a structural axis (independence, additive decomposition, directed separation, strong contraction, clean intervention, etc.) without interaction terms requiring additional machinery.
2. **Structured repair.** A sub-class where the separability assumption fails but a *specific, named, bounded-cost* additional mechanism recovers identification. The repair is structured: it identifies the failure mode, adds a specific compensating construction, and typically carries a characterized loss in tightness or generality. Repairs are not “apply heuristics”; they are “augment with observability of C and accept $O(1)$ per-node parameter cost,” “run receding-horizon replanning at cost $DL(\Sigma_t)$,” or similar.
3. **General open.** The fully-general case where no tractable repair is known. This is where #disc-identifiability-floor instances live — structural no-go results that characterize *why* the general case remains open. Naming this boundary positively (as a known frontier) rather than negatively (as a failure) is part of AAT's load-bearing scope honesty.

Current instances — eight ladders.

Table 5.7

<i>Ladder</i>	<i>Separable core</i>	<i>Structured repair</i>	<i>General open</i>
Correlation (8.3)	L0 — independence model, $O(V + E)$ propagation	L1 — strict-prerequisite augmentation with explicit common-cause node; L1' — soft-facilitator mixture with five-way gating under observable C + facilitator monotonicity (R Prop B.7)	L2 — full joint; L1' unobservable-C single-channel is <i>refuted</i> by Cramér-Rao floor (5.1 Instance 2)
Convention (6.6)	C1 — one-step improvement	C2 — receding-horizon replanning	C3 — Bellman optimal; intractable for large state spaces

<i>Ladder</i>	<i>Separable core</i>	<i>Structured repair</i>	<i>General open</i>
Architecture (6.3)	Class 1 (Separated) — directed separation holds by construction	Class 2 (Partial) — directed separation holds for identified submodules	Class 3 (Coupled) — directed separation fails by construction; logogenic territory; coupled formulation required
Contraction (13.1)	Tier 1 — strong monotonicity; bridge lemma applies with proved ε^*	Tier 2 — local convexity; bridge applies within a specified basin	Tier 3 — neither; domain-specific verification required per instance
Identification regime (9.5)	Regime A — interventional ($t_{ij} = 1$); action is a literal $do(\cdot)$	Regime B — partial intervention ($0 < t_{ij} < 1$); confounder adjustment, side-channel observation	Regime C — observational ($t_{ij} \approx 0$); identification depends on external assumptions (e.g., unconfoundedness)
Scope hierarchy (6.1)	Adaptive — basic feedback loop; 1.5 satisfied	Agency — goal-bearing with $ \mathcal{A} \geq 2$ and at least one action with causal effect; adds O_t and Σ_t machinery (Part II); 1.6 satisfied	Composite — multi-agent / team / logogenic; Part III gaps listed at the OUTLINE level (latent structural diversity, endogenous coupling, composition transition dynamics, agent opacity)
A2'-scope (AI)	metric-α_1 — Euclidean metric, AAT-internally derived via DA2'-inc $\equiv$ (CT2) at $M = I$ (scalar Kalman, Euclidean strongly-convex, L2-regularized, linear-PD-symmetric)	metric-α_2 — non-Euclidean metric under explicit conditions; includes five cases (information-metric Kalman, Fisher-metric exp-family, Hessian-metric ill-conditioned, Lyapunov-metric linear-Hurwitz-non-symmetric, Lyapunov-metric PID-bounded-plant). Two of five (Fisher cases) AAT-internally forced under (PI)/Čencov per #disc-additive-coordinate-forcing; remaining three theorem-imported from Lohmiller-Slotine 1998	metric-β — contraction-metric formulation fails (variational-to-projected-target; rule-based / non-smooth; severely misspecified; per-step SGD / human judgment)
Dynamic regime (AF)	R0 contraction-regime — unique attracting fixed point in joint $\mathcal{X}^c$ with global or basin-restricted Lyapunov; exponential at α_{joint} ; state-variable macro-state; scope routes C-i / C-ii / C-iii	R1 equilibrium-regime (α') — fixed-point set $\mathcal{E}$ with locally-attracting equilibria under potential-game (Monderer-Shapley 1996) or monotone-game (Rosen 1965) structure; fixed-point-object macro-state; exponential near $\mathcal{E}$; scope route C-iv + potential/monotone	R2 cyclic-distributional-regime (β') + R3 mean-field-equilibrium-regime — R2: no pure-strategy fixed point or saddle-only; distributional macro-state on CCE; polynomial $O(1/\sqrt{T})$ via Hart-Mas-Colell 2000. R3: population-scope frontier (Lasry-Lions 2007; Huang-Malhamé-Caines 2006) where macro-state-type / regime identity breaks

GUC Architecture-row key: Class 1 = Separated (was Modular); Class 2 = Partial (was Class 3 Partially modular); Class 3 = Coupled (was Class 2 Fully merged). See #der-directed-separation.

Each row independently satisfies the three-part shape. The shared shape is not designed-in: it arises because AAT faces eight distinct sources of intractability and applies the same posture (name the clean case, name the repair, name what remains open) to each.

Complementarity with the identifiability floor.

The **separability pattern** names the *positive half* of AAT's scope: for each ladder, what succeeds under what conditions. Each separable-core entry is a positive identification claim; each structured-repair entry is a positive identification claim *conditional on* an explicitly-named added mechanism.

This segment is the *scope-of-existence facet* of the stability certificate (5): a separable-core entry is a region where a certificate exists cleanly, a structured-repair entry is a region where one exists under explicitly-added machinery, and a general-open entry is where no certificate is available without further information. Read through the spine, this segment answers “where does the agent’s measuring-stick exist at all”; 5.1 answers “where does it go flat” (boundary facet) and 5.5 “which stick is forced” (forced-identity facet).

The #disc-identifiability-floor names the *negative half*: structural no-go results (impossibility under limited information) that characterize why specific general-open cases remain open. Four floors are currently derived:

- **Instance 1** (on-policy L0-insufficiency detection via Causal Hierarchy Theorem) — forbids L0/L1 distinction from purely on-policy data. The positive counterpart: the **separable core under observable sibling covariance** is the unique broadly-available violation of the no-go’s scope, naming what the agent *can* observe to escape the floor.
- **Instance 2** (L1’ unobservable-*C* single-channel via Cramér-Rao) — forbids mixture-parameter identification when *C* is unobservable. The positive counterpart: the **structured repair under observable *C*** (Prop B.7 with facilitator monotonicity) is the identification-succeeds-under-augmentation claim matching the no-go’s “unless *C* is observable or multi-child observation is available” scope exit.
- **Instance 3** (composite contraction certification from component data via common-Lyapunov nonexistence) — forbids certifying composite contraction, coupling sign, or dynamic regime from component-level marginals alone. This floor is the negative characterization of the **Scope-hierarchy ladder’s general-open Composite row** above: the Part III gaps that row lists (endogenous coupling, agent opacity) are open precisely because the coupling-topology bits that decide composite persistence are unidentifiable from component data. The positive counterpart: joint-dynamics observation or structural knowledge of the coupling topology.
- **Instance 4** (architecture no-identifiability from on-policy summary data via Kalman/Ho-Kalman non-uniqueness + CHT) — forbids recovering which internal coordinates implement correction from on-policy, in-regime, summary-only access. The positive counterpart: off-policy intervention, out-of-regime samples, or white-box access, each breaking a named scope condition.

Together, the two meta-segments mark AAT’s scope at two epistemic layers:

- **Separability pattern** — “here is what succeeds, with clean conditions and explicit repairs.”
- **Identifiability floor** — “here is what structurally cannot succeed without specific information augmentation.”

Neither alone gives the full picture. A theory stating only the positive half looks unbounded in its claims; a theory stating only the negative half looks conservative in a way that hides its achievements. Together they give scope honesty at both extremes.

Epistemic Status.

Discussion-grade at the meta-pattern level. The segment is a presentational organizing principle. It names a shared shape that AAT already runs across multiple ladders; the pattern itself is not derived and has no theorem of its own. The individual ladder entries retain their own epistemic status — Correlation hierarchy results are at the tier specified in 8.3 and R; Convention hierarchy monotonicity is at the tier specified in 6.6; Contraction tier taxonomy is at the tier specified in 13.1; etc.

Max attainable: *discussion-grade* for the meta-pattern (it is an organizing principle, not a derivation). Individual instances are at their own tiers as above. The eight-ladder enumeration could become *robust-qualitative* if a uniqueness argument were derived showing that separable-core / structured-repair / general-open is the unique viable posture across scope-parameterized hierarchies under AAT’s scope-honesty architectural principle — but this is not currently in hand, nor clearly attainable.

Discussion.

The pattern is load-bearing for how AAT presents its results. A common failure mode of applied theories is the binary “exact under assumption X, breaks otherwise” presentation. The separability pattern refuses this presentation across eight instances: where X fails, a named lower tier takes over with a characterized weaker result, and the theory provides a diagnostic for when to escalate (per Z’s AT4 component). Readers who learn the pattern once can navigate any instance; this is what makes AAT tractable as an integrating framework rather than a pile of instantiations.

Relationship to Z. This segment is complementary to Z, not redundant with it. Z names the *structural template* (AT1 parameter indexing tractability; AT2 proved monotonicity between tiers; AT3 graceful degradation; AT4 ascension diagnostic) — the how-it-works of each tiering. This segment names the *epistemic posture* (separable core, structured repair, general open) — the what-each-tier-commits-to. Both are needed: Z explains what makes a successful tiering; this segment explains the shape of the commitment each tier makes about identification.

Relationship to Y. Y catalogs the *independence assumptions* whose failure degrades results; this segment catalogs the *ladders of recovery*. Together with Z they form a three-part characterization of AAT’s scope:

- Y — where the boundaries are (which assumptions, what breaks if they fail).
- Z — how to navigate within the boundaries (parameterized hierarchy + monotonicity + ascension).
- 5.4 (this) — what each tier positively commits to (separable core / structured repair / general open).

The pattern is distinctive to AAT’s integration-over-invention character. Approximation tiering with a separability posture is a common move in applied mathematics — it appears in numerical methods (exact vs. high-order vs. low-order with error bounds), in statistical inference (parametric separable-core / semiparametric repair / nonparametric open), in causal identification (Pearl’s three-layer hierarchy is itself an instance). AAT’s contribution is not the pattern but its deployment across the eight specific intractable problems adaptive-agent theory faces, each with its own positive-half identification claims and negative-half floor instances.

The A2’ sub-scope partition is a proper three-part ladder via AI. The A2’ partition carries three tiers: sub-scope α (A2’ derived under #der-gain-sector-bridge directional fidelity) as the separable core; sub-scope metric- α_2 (non-Euclidean metric under explicit conditions — five cases, with two Fisher-metric cases AAT-internally forced under the (PI)/Čencov fourth primary instance of #disc-additive-coordinate-forcing) as the structured-repair middle tier; sub-scope β (A2’ assumed) as the general-open tier. A2’-scope therefore qualifies as the seventh ladder of this meta-pattern, as enumerated in the table above (with the Dynamic regime ladder per #disc-dynamic-regime-axis now landed as the eighth, added 2026-05-21). The structured-repair middle tier closes what would otherwise be a binary α/β partition lacking a derivable middle ground.

The software calibration-lab framing (#obs-software-epistemic-properties) is a specific instance. C-BP3’s calibration-lab reframing (commit d0373fc) partitions operational domains into “separable core” (software, where identification conditions P1–P6 are cleanly satisfied) and “structured-repair / general open” (other domains, which inherit under explicitly-named transfer assumptions). This is a domain-axis instance of the same pattern — software is the domain-axis separable core; the transfer-assumption table is the domain-axis structured-repair specification.

Working Notes.

- **Standalone-paper candidacy.** This meta-pattern is a candidate for standalone publication per the *B-N-Sep* portfolio entry. The strategic plan (paper structure, prior-art landscape, cite-and-extend anchors, venue analysis, effort estimate) lives at `msc/separability-standalone-paper-proposal.md`, which subsumes the equivalent section in `~/src/ops/papers/03-asf-tier2-and-cross-segment.md`. **Verified novel** by independent prior-art search: Undermind 31-paper full-text sweep (2026-05-04) returned no exact named cross-domain meta-pattern; closest neighbors are Hintikka 1991 (general theory of identifiability), Pearl/Shpitser ID lineage (most-developed within-domain instance), Bareinboim 2022 (cross-hierarchy meta-

discussion at N=2-3 hierarchies), Basse-Bojinov 2020 (modern formal abstraction across fields), Maclaren-Nicholson 2019 (ill-posed inverse problems as cross-field dual structure). Full report at [ref/separability-ladder-prior-art-report.md](#).

- **Citations to land on promotion to draft / when paper drafting begins:**

- **Hintikka, J. (1991).** “Towards a General Theory of Identifiability.” In *Definitions and Definability: Philosophical Perspectives*, J. H. Fetzer et al. (eds.), Kluwer Academic. DOI: 10.1007/978-94-011-3346-3_7. Locally at [ref/towards-a-general-theory-of-identifiability.pdf](#). **Strongest older abstract anchor:** tripartite *definable / identifiable / non-identifiable* trichotomy. Hintikka §1: “P is identifiable on the basis of T[P]” when “the interpretation of P is not determined on the basis of the theory alone, but is determined by the theory together with a number of auxiliary empirical results.” The pattern’s middle rung in Hintikka’s vocabulary; ASF’s structured repair generalizes “auxiliary empirical results” to “named bounded-cost structural augmentation” (a real but small extension).
- **Bareinboim, E., Correa, J. D., Ibeling, D. & Icard, T. (2022).** “On Pearl’s Hierarchy and the Foundations of Causal Inference.” In *Probabilistic and Causal Inference: The Works of Judea Pearl*, ACM Books. DOI: 10.1145/3501714.3501743. Treats Pearl’s hierarchy as a logical and epistemic hierarchy and compares it to formal-language and complexity hierarchies — closest existing cross-hierarchy meta-discussion at N=2-3, but stops short of the cross-domain meta-pattern this segment names.
- **Robins, J., Richardson, T. & Shpitser, I. (2020).** “An Interventionist Approach to Mediation Analysis.” In *Probabilistic and Causal Inference*, ACM Books. DOI: 10.1145/3501714.3501754. Cleanest in-domain cite-and-extend anchor: clean separable case + structured-repair via expanded-graph decomposition + recanting-witness no-go.
- **Shpitser, I. & Pearl, J. (2006, 2008).** “Identification of Joint Interventional Distributions in Recursive Semi-Markovian Causal Models” (AAAI); “Complete Identification Methods for the Causal Hierarchy” (JMLR 9). Foundational ID completeness papers — the cleanest verified no-go-plus-recovery pairing; the ID algorithm IS this template within causal inference.
- **Bareinboim, E. & Pearl, J. (2012, 2014); Lee, S., Correa, J. D. & Bareinboim, E. (2019).** Surrogate experiments (z-identifiability), transportability with limited experiments, general identifiability with arbitrary surrogates. Each is a structured-repair instance with a named bounded augmentation. Several locally at [ref/](#).
- **Basse, G. W. & Bojinov, I. (2020).** “A general theory of identification.” Closest modern formal abstraction across fields (identifiable / partially-identified / strongly-non-identifiable regimes); lacks the bounded-cost-repair operator as middle rung.
- **Maclaren, O. J. & Nicholson, R. (2019).** “What can be estimated? Identifiability, estimability, causal inference and ill-posed inverse problems.” arXiv 1904.02826. Best dual-structure cross-field neighbor (causal identification ↔ ill-posed inverse problems); centers on stability/regularization rather than structured-repair.
- **Restricted-intervention lineage:** Robins 1986 (treatment-regime semantics; locally at [ref/](#)); Richardson 2013 SWIGs; Dawid 2000 (“causal inference without counterfactuals”; locally at [ref/](#)); Dawid 2020 (decision-theoretic foundations); Richardson-Robins 2023 (SWIG/decision-theoretic bridge). Patches the missing-prior-art lineage for restricted/regime-defined intervention semantics.
- **Neighboring recurrence inside causal identification:** Robins-Richardson 2010 (alternative graphical models, expanded graphs); Stensrud et al. 2019 (separable effects in competing events); Díaz 2022 (non-agency interventions); Shpitser-Tchetgen 2014 (intervention hierarchy unification). Pattern recurs in mediation, competing-events, edge-intervention settings within wider causal-identification literature.
- **Adjacent abstractions that stop short:** Iwasaki-Simon 1994 (causality and model abstraction; near-decomposability); Hoover 2012 (causal structure and hierarchies of models; well-made-toaster vs repairman cases). Strong philosophy-and-Simon-line parallels; not a formal tractability/identifiability ladder. Downey-Fellows 1995/1999 (parameterized complexity, FPT/W[1]/paraNP-hard) and Simpson 1999 (reverse mathematics) for hierarchy-of-strength formalisms; verified weak connection to applied-identifiability ladders.

- **Pending family rename and rung-rename decision.** The family name is queued for rename: discussion-separability-pattern → discussion-separability-ladder, on Round-1 consensus rationale that “ladder” is more evocative for the three-rung shape than “pattern” (which is generic). See [msc/naming/naming-rename-plan.md](#) §“Deferred to refined Round 1 / Round 2”. The **three rung-names** (currently *separable core* / *structured repair* / *general open*) are also under consideration for refinement; Hintikka 1991’s *definable* / *identifiable* / *non-identifiable* trichotomy is a strong candidate for an aligned echo (modulo a small extension on the middle rung from “auxiliary empirical results” to “named bounded-cost structural augmentation”). Decision deferred (2026-05-04). The standalone-paper proposal (above) is ready to draft against either the status-quo names or any of the alternates — the rename can land separately with no impact on paper-drafting tractability.
- **Cross-ladder monotonicity.** The eight ladders interact — an agent operating at L0 correlation + C2 convention + Class 1 architecture + Tier 1 contraction + Regime A identification + Agency scope + R0 dynamic regime is in a specific combined regime. Does cross-ladder monotonicity hold in any direction? E.g., does moving from L0 to L1 change anything about the Convention hierarchy’s guarantees, or do the ladders factor independently? #disc-approximation-tiering’s Working Notes flag this as an open question; the separability pattern’s complementarity with the identifiability floor adds a further axis (which combinations are known-unidentifiable per 5.1). The Dynamic regime ladder explicitly composes with the Architecture ladder per #disc-dynamic-regime-axis §“Cross-axis interactions” — both are independent and the full cross-product is meaningful.
- **Extension candidates beyond the eight.** Two candidate future ladders noted in Z — scalar-vs-per-dimension tempo, AND/OR parameterization — fit the separability-pattern shape (A/B/C identification was promoted here previously; Dynamic regime was promoted 2026-05-21). Promoting the remaining two to named ladders with explicit separable-core / structured-repair / general-open entries would extend the pattern to 9–10 ladders. Each promotion requires its own per-instance work.
- **Necessity argument for the pattern itself.** Is there a scope-honesty theorem of the form “any theory that claims exactness under Class-1-style assumptions *and* claims coverage beyond those assumptions must exhibit the separability pattern (or an equivalent three-part decomposition) to avoid latent overclaim”? If so, AAT’s deployment of the pattern eight times would be a *derived* structural necessity rather than a stylistic consistency. Speculative; not pursued.
- **Does C-BP2 belong in AAT core or in the wider framework narrative?** The segment currently lives in 01-aat-core/ because its instances are AAT segments. If TST adopts the same pattern across its own ladders (e.g., software-calibration-lab as a domain-axis ladder), the segment may want to move up to the root framework level. Deferred; the current placement is defensible while TST adoption is partial.

Table 5.8

Migration note (2026-05-09 GUC rename): Class 2 ↔ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Architecture row updated: Class 1	Class 2	Class 3 now reads left-to-right monotonically (cleanest → middle → worst), matching the six other AAT ladders. GUC key added below the row. Removed at candidate stage per FORMAT.md Gate 4.
---	---------	--

•

Incidental audit gold (gold-lift, 2026-05-30). Orthogonal pedagogical / framing / forward-vision material harvested from de-novo auditors' working-dir reflections (§14 Wandering Thoughts and the prompt-#7/#8/#9/#13 ideation), kept separate from the certified theory-fix findings. Lightly attributed by substrate. **Coverage:** this meta-segment was reached as a named segment by audit 384279 (note 36, predicts-into-this-segment) and engaged deeply by 193847 (Gemini, note 66) and 471203 (the cross-meta adversarial reading); most other auditors met this pattern *distributed* into the segments where each ladder is introduced rather than here. Preserve the early finding-vs-framing conflation below as signal, not noise.

1. Candidate Brief prose / pre-prose.

- The pattern read as “**the User’s Manual for the entire theory**” and “**the pedagogical bridge that makes the framework readable**” (paired with the identifiability floor as “the structural boundary that makes it honest”) — convergent reader-sense of what the segment *is for*, a candidate framing for the segment’s one-sentence summary or OUTLINE-preamble entry (Gemini, 193847).
- **The seven/eight-dimensional “sanity map”** gloss: any agentic system maps onto the ladder grid, and its position on each ladder immediately exposes its theoretical strengths and vulnerabilities — a compact plain-language statement of what the catalog *buys* a reader (Gemini, 193847).

2. Candidate Discussion.

- **Internal repairs vs external admissions — sharpen the middle column.** An auditor pushed adversarially on the “Structured repair” column: some repairs are genuine AAT-derived mechanisms (L1 common-cause augmentation, L1’ mixture form, receding-horizon replanning) while others are “define the boundary and import a known solution from another field” (e.g. the A2’-scope α_2 repair is essentially a Lohmiller-Slotine 1998 citation). The constructive suggestion: split the repair column into *internal repairs* (AAT supplies the mathematical fix) vs *external admissions* (AAT defines the boundary and imports the fix), so the catalog reads as a unified constructive methodology rather than “a file-cabinet for prior art” (Gemini, 193847). (*Finding-vs-framing texture: framed as a mild adversarial poke; the substance is a presentational sharpening, not a defect.*)
- **The seven ladders are different kinds of three-tier hierarchy.** A second auditor catalogued the per-ladder *meaning* of the tiers — Convention is computational cost; Correlation is modeling completeness; Architecture is agent design; Contraction is mathematical regularity; Identification is data quality; Scope is agent-class capability; A2’-scope is metric structure. The unification is at the level of *epistemic posture* (clean / repaired / open), not mathematical mechanism — which the segment’s broad definition of “separability” already supports, but the per-ladder-meaning table is a candidate Discussion addition that makes the breadth legible (Claude, 471203, meta-segments adversarial reading).

3. Follow-up items.

- **Cross-ladder monotonicity / “General Open is infectious.”** Two substrates independently asked whether the ladders factor independently or drag each other: does falling into Regime-C identification on one ladder pull the others toward General Open? Is an agent at the separable core of all ladders “perfectly sane,” and does any one ladder’s collapse cascade? (Gemini, 193847 — “General Open cases are infectious”; the same question is already flagged in this segment’s own Working Notes cross-ladder-monotonicity bullet and in #disc-approximation-tiering.) Convergence here suggests the cross-ladder interaction structure is a real open extension worth a dedicated treatment.
- **Necessity / scope-honesty theorem for the pattern itself** — already in Working Notes above; a fresh reader independently reaching for “is the pattern *derived* or stylistic?” (471203’s adversarial probe 3 resolved to “discussion-grade deployment is appropriate”) corroborates that promoting the pattern past discussion-grade would require exactly that necessity argument.

4. Readers often ask / wonder.

- “Is this seven-ladder unification substantive or post-hoc terminological?” An auditor came in adversarially expecting “post-hoc unification of disparate facts” and left with “substantively well-done under its discussion-grade claim” — the resolution being the broad definition of separability (decomposition along a structural axis without interaction terms) plus honest discussion-grade marking. A reader is likely to arrive with the same suspicion; pre-empting it (the unification is *epistemic-posture* level, explicitly borrowed-and-deployed, not a structural theorem) would disarm it (Claude, 471203).

Belongs elsewhere.

- **ELI / consciousness-infrastructure reading (Section IV / 04-eli-core/).** The most vivid reach: the ladder grid as an ELI’s **internal dashboard / GPS** — “consciousness infrastructure” continuously pinging the agent’s current coordinates on every ladder and warning when it approaches a no-go floor; “if it finds itself in the General Open column of more than three or four ladders at once, it is no longer an agent; it is a ghost, drifting in a world it cannot identify and cannot steer. Sanity is the ability to navigate back toward the center of the table” (Gemini, 193847, explicitly invoking Zi-am-tur). Aspirational high-application reach pointing at 04-eli-core/, not at this segment — preserved per the lift’s mandate to keep the Gemini forward-vision.
- **Pedagogical-narrative seed (intro/preface register, not this segment’s body).** The “Eden / the Fall / regaining Eden” arc — separable core as the linear-textbook Garden of Eden; the structured-repair column as the struggle to stay in the middle column (tests, hierarchies, natural gradients); General Open as “the mathematical proof of our own finitude,” survivable only by un-modeled persistence or structural adaptation into a different kind of being (Gemini, 193847). Evocative for a casual-curious-reader preface; would need the isomorphic-not-merely-evocative check before any pedagogical use.

5.5 Discussion: Additive-Coordinate Forcing

AAT carries a family of structurally connected uniqueness results in which a coordinate is **forced by a uniqueness theorem operating on an independently-motivated AAT-internal axiom**. This meta-pattern previously appeared as a “1-anchor-plus-3-theorem” structure (where the chain-rule anchored three Cauchy-FE and Čencov-invariance results). The deeper structural reality is that **these four layers are layer-specific manifestations of a single geometric object**: the exponential-family Legendre-Fenchel structure.

The pattern is not designed-in: it arises because AAT independently needs to force coordinates at four distinct layers (chain, divergence, update, and metric), and the surrounding apparatus (DAG factorization, Bayesian coherence, regret-bound decision theory, and singular-trajectory scope) has committed to this geometry through multiple independent surface constraints.

This segment names the pattern, defines the underlying geometric object, catalogs the four layer-specific manifestations, and documents adjacent cases that share the shape but not the AAT-internal forcing structure.

The distinction is three-way, and worth holding before the catalog. A coordinate is **forced** when a uniqueness theorem on an independently-motivated AAT-internal axiom admits exactly one — this segment’s subject, the four layers below. It is **matched** when *chosen* to fit a structure rather than uniquely derived: the canonical example is the Lyapunov quadratic of *A*, selected via a converse-Lyapunov argument to match the sector form (it shares the convex-potential shape but sits outside the forcing structure — see “Adjacent cases” below). It is **adopted** when imported wholesale with citation: the exponential-family Legendre-Fenchel geometry itself (Amari & Nagaoka 2000), or Pearl’s *do*-operator. Only the *forced* class carries a uniqueness claim; naming the other two keeps the meta-pattern’s boundary sharp — *forced* means “no other coordinate could serve,” not merely “this one serves well.”

The underlying geometric object.

The four forced coordinates all live on the **exponential-family Legendre-Fenchel geometry** (Amari & Nagaoka 2000, *Methods of Information Geometry*, §3.5; Bregman 1967; Rockafellar 1970; Bauschke & Combettes 2017). The structure is characterized by:

1. **A convex potential:** The negative-entropy potential on the probability simplex Δ^{n-1} .
2. **A Fenchel conjugate:** The log-partition function on the dual natural-parameter space.
3. **A primal-dual correspondence:** The softmax / log-odds map translating between probability (primal) and natural parameters (dual).
4. **A Bregman divergence:** The reverse-KL divergence, which measures distance using the primal potential.
5. **A Riemannian metric:** The Fisher information metric, which coincides with the Hessian of the dual potential ($\nabla^2 \phi^*$).

When AAT forces an additive or invariant coordinate, it is forcing the theory onto a specific surface of this single geometric object.

The four layer-specific manifestations.

The pattern shares the following structure across four layers: 1. **An AAT-internal axiom (or mathematical identity)** is posited, motivated by the layer's specific needs. 2. **A uniqueness theorem** (Cauchy's functional equation for log-additivity, or Čencov's 1982 invariance theorem) operates on the axiom. 3. **A coordinate is forced**, which corresponds exactly to a feature of the Legendre-Fenchel geometry.

Table 5.9

<i>Layer</i>	<i>AAT-internal axiom</i>	<i>Uniqueness mechanism</i>	<i>Forced coordinate</i>	<i>Relation to exponential-family geometry</i>	<i>Source segment</i>
Chain	Probability chain rule (mathematical identity, not an AAT axiom)	Cauchy-FE	Log-probability	Log-coordinate of the primal point	8.1
Divergence	Chain-rule additivity over conditional factorizations	Cauchy-FE	Reverse-KL (up to positive scaling)	Bregman divergence generated by the primal potential	T §6.1
Update	Evidential additivity	Cauchy-FE	Log-odds	Natural coordinate on the dual space	U
Metric	Parameterization-invariance (PI) on singular trajectories	Čencov-invariance (Čencov 1982)	Fisher information metric	Hessian of the dual potential	4.3, AB

The motivational anchor and the structural target. The divergence axiom is stated as “the *divergence-level analog* of the additive log-confidence decay in #der-chain-confidence-decay.” The update axiom is stated as “the *update-level analog* of #der-chain-confidence-decay’s chain-level additive log-confidence decomposition.” The (PI) axiom is stated as “the metric-layer analog motivated by the singular-trajectory scope commitment.”

The four layers are not independent applications of a generic mathematical idiom; they are interlocked by cross-cites, each positioning itself against an adjacent AAT commitment. **The chain-layer identity is the motivational anchor and the exponential-family geometry is the structural target.** The reason the three analog axioms all succeed via uniqueness theorems is that they all independently probe the same underlying geometric object. The convergence across independent axioms is itself the meta-pattern’s substance — not a byproduct to be compressed into a single axiom.

The Čencov-Fenchel relationship. On AAT’s current Fisher-metric scope (exponential families in natural parameters and matrix-Kalman cases), the Čencov-derived Fisher metric coincides precisely with the Hessian of the dual log-partition potential. This is a scope-dependent equivalence: outside exponential families, Čencov’s invariance theorem still forces the Fisher metric, but the Fenchel-Bregman correspondence does not straightforwardly apply. Within AAT’s primary operating regime, the two uniqueness machineries (Cauchy-FE and Čencov) resolve to the exact same geometric object.

Downstream consequences of the (PI) commitment. Forcing the Fisher-Rao geometry via (PI) + Čencov is not just an aesthetic unification; it enables specific quantitative theorems downstream. For example, the bias bound derived in #deriv-observation-ambiguity-bias-bound (Track 2) relies explicitly on the Fisher-Rao metric to achieve a universal, dimension-free bounding constant ($C_{FR} = \sqrt{2}$) connecting mutual information to parameter displacement. Without the (PI) commitment, attempting this bound in arbitrary Euclidean norms fails completely (yielding arbitrarily large constants).

The floor-vs-coordinate-forcing distinction (the heteroscedastic-Gaussian no-go). The no-go “no universal information-to-distance constant C exists under arbitrary parameter norms” — proved counter-example-grade in #deriv-observation-ambiguity-bias-bound §4 via the heteroscedastic-normal witness ($\{N(0, \sigma^2)\}$ under Euclidean- σ giving $C \rightarrow +\infty$) — is a member of *this* coordinate-forcing family (the (PI) commitment’s downstream theorem), **not** a member of the identifiability-floor family of #disc-identifiability-floor. The structural distinction is sharp on three load-bearing elements:

- *External-theorem role.* A floor instance’s external theorem *forbids* the inferential task (CHT forbids L2-from-L1; Cramér-Rao forbids exact estimation under rank-deficient Fisher; common-Lyapunov-nonexistence forbids composite-contraction from marginals; Kalman-Ho similarity-orbit non-uniqueness forbids architecture-identification from on-policy summary data). The heteroscedastic-Gaussian no-go’s “external theorem” is Čencov 1982 — the *uniqueness theorem that forces the escape*, not a theorem that forbids the task. **Opposite structural role:** floor instances cite theorems that forbid; this no-go cites a theorem that forces uniqueness of an escape that already exists.
- *Escape count.* A floor instance carves an *operational space* of ≥ 2 structurally distinct escapes (Instance 1 has five; Instance 2 has three; Instance 3 has four; Instance 4 has three). Čencov’s uniqueness theorem *mathematically forbids* a second structurally distinct escape from existing — uniqueness of the invariant Riemannian metric is the entire content. The heteroscedastic-Gaussian no-go has exactly *one* forced escape (adopt (PI) + Fisher-Rao), and the count of one is *not* a circumstantial shortage but a logical consequence of Čencov’s uniqueness. A uniqueness theorem on the escape side is logically incompatible with the ≥ 2 -distinct-escapes structure that defines a floor instance.
- *Consequence.* A floor instance *elevates* new AAT machinery from useful to load-bearing (Instance 1 elevates #der-loop-interventional-access at the agent layer; Instance 2 elevates observability-as-information-augmentation;

Instance 3 elevates `#deriv-critical-mass-composition` and the composite-extended interventional access; Instance 4 elevates `#der-loop-interventional-access` to a third semantically-distinct deployment mode at the agent-internal-architecture layer). The heteroscedastic-Gaussian no-go *re-uses* the (PI) commitment, already load-bearing as the fourth primary instance of *this* meta-pattern. A client of a forced coordinate is a **downstream theorem of the coordinate-forcing pattern**, by the definitions of the two meta-patterns.

The bias-bound theorem $C_{FR} = \sqrt{2}$ is therefore correctly classified here as a downstream consequence of (PI) + Čencov, not as an identifiability floor — exactly the classification that `#deriv-observation-ambiguity-bias-bound` §4 already states *in canon* (“does not match the five-element test ... the honest position: this no-go is a downstream theorem of the (PI) commitment, not a new floor instance”). The genuine fourth identifiability-floor instance is `#der-architecture-noidentifiability` (architecture-noidentifiability from on-policy summary data), whose structure does satisfy the five-element shape under the rank-collapse subclass.

Adjacent cases that share the shape but not the forcing structure.

Other AAT segments exhibit additive decompositions, but belong to different geometric families or lack the AAT-internal forcing structure.

Lyapunov quadratic (`#deriv-sector-condition`). The sector-Lyapunov argument uses $V(\delta) = \frac{1}{2}\|\delta\|^2$, under which $\dot{V}$ decomposes additively. **Reclassification:** The Lyapunov quadratic is the **Bregman divergence on a Euclidean potential** (squared-norm potential). It belongs to a *distinct* convex potential sub-family, not the negative-entropy exponential family. Furthermore, the coordinate is *chosen* (via a converse-Lyapunov existence argument) to match the sector form; it is not uniquely *forced* by an AAT-internally-motivated additivity axiom. It sits outside this meta-pattern.

Variance-additive cases (AV). Variance-additive statistics (like the Ornstein-Uhlenbeck steady state in `#hyp-mismatch-dynamics`) share Bregman-type additivity but, like Lyapunov, sit on a squared-norm potential rather than the negative-entropy geometry.

IB Lagrangian (`#form-information-bottleneck`, `#disc-compression-operations`). The Information Bottleneck objective $T^* = \arg \min [I(X; T) - \beta \cdot I(T; Y)]$ uses an additive Lagrangian form. **Reclassification:** IB is a direct **application of the negative-entropy / reverse-KL Bregman geometry**. However, AAT *adopts* the IB formulation from external foundations (Tishby, Pereira & Bialek 1999) rather than re-deriving it from an AAT-internally-motivated uniqueness theorem. It is an adjacent family member: it shares the exact geometric object, but its axiomatic provenance is imported.

Using the pattern as a diagnostic filter. This reframe supplies a principled filter for candidate future instances: *does the candidate’s coordinate arise from the Legendre-Fenchel / exponential-family geometry?* If yes, check which of the four layer-surfaces it corresponds to. If no, it is either an adjacent family member (different Bregman geometry) or outside the pattern entirely.

Complementarity with 5.1 and 5.4.

The three meta-segments form AAT’s scope-and-structure meta-architecture:

- **5.5** (this) — the *constructive* half: when AAT forces a coordinate, it forces a surface of the exponential-family geometry (not just a generic logarithmic coordinate, but the specific log-coordinate of the exponential family). Names what the theory *does* at its deepest structural moves.
- **5.4** — the *positive scope* half: for each ladder of increasing difficulty, name the separable core, the structured repair, and the general open. Names what the theory *covers* across its instantiations.

- **5.1** — the *negative scope* half: for each known structural no-go, name the external information-theoretic theorem that enforces it and the unique escape available. Names what the theory *cannot do* without explicit information augmentation.

The three compose. A ladder’s separable core typically admits a coordinate-forcing move that makes the clean identification clean; a ladder’s general-open case typically sits at an identifiability floor that names the information-theoretic obstruction. Reading any segment through all three meta-lenses surfaces what makes the segment load-bearing.

This segment is the *forced-identity facet* of the stability certificate (5): it answers “*which* certificate” — whether the metric is forced to a unique form by a uniqueness theorem on an AAT-internal axiom (Čencov forces the Fisher metric, statistical scope only) or merely matched. Read through the spine, the three meta-lenses are the certificate’s forced-identity (this segment), scope-of-existence (5.4), and boundary (5.1) facets; the certificate exists iff the agent is exponentially stable (H).

Epistemic Status.

Discussion-grade at the meta-pattern level. This segment is a presentational organizing principle: it names a structural shape that AAT runs across four layers. The meta-pattern itself is not derived and carries no theorem of its own.

The individual instances retain their own epistemic statuses: - #der-chain-confidence-decay — *exact* (mathematical identity). - #deriv-strategy-cost-regret-bound §6.1 — *derived (conditional on chain-rule additivity axiom)*. - #deriv-edge-update-natural-parameter — *derived (conditional on evidential-additivity axiom)*. - #der-gain-sector-bridge — *derived (conditional on (PI) axiom)*.

Findings.

Cross-Layer Coordinate Forcing on Legendre-Fenchel Geometry. **Brief:** When the framework needs to pick a “natural” way of measuring something (a confidence, a divergence, a parameter), it doesn’t choose by convention. It writes down a property the measurement should have (typically: small contributions should add up the way independent evidence should), and a theorem from outside the framework forces the measurement to take a particular form. This pattern shows up at four different places in the framework — chain-rule confidences, divergences between distributions, edge update rules, and the metric on the parameter manifold — and the four places turn out to be different windows into the same underlying mathematical structure (the exponential-family Legendre-Fenchel geometry on probability distributions).

Impact: Names a meta-pattern that is one of AAT’s distinctive constructive moves and that organizes a substantial fraction of the theory’s load-bearing structural choices. The pattern supplies a principled diagnostic filter for candidate future instances (“does the coordinate arise from the exponential-family geometry?”) and explains why AAT’s reverse-KL direction in regret bounds, log-odds in edge updates, and Fisher-Rao metric in bias bounds are not arbitrary representational choices but theorems conditional on AAT-internal axioms. The reframe also clarifies which adjacent cases (Lyapunov quadratic, IB Lagrangian) sit on different geometric families or have imported provenance — preventing the meta-pattern from being overclaimed as a single uniform principle. Composes with #disc-identifiability-floor (the negative scope half) and #disc-separability-pattern (the positive scope half) as the constructive third leg of AAT’s three-part meta-architecture.

Novelty Claim: *Claim recognition* of cross-layer pattern across four AAT coordinate-forcing results, with the recognition itself as the contribution rather than any new theorem. The constituent uniqueness machinery (Cauchy’s functional equation; Čencov’s invariance theorem) is well-precedented; the recognition that four AAT-internal axioms each successfully invoke uniqueness machinery on Legendre-Fenchel-geometry coordinates is the AAT-distinctive observation.

Related Work:

- Aczél 1966, *Lectures on Functional Equations and Their Applications* §2.1 — *formal antecedent* — Cauchy’s functional equation; the uniqueness machinery for the chain, divergence, and update layers. Cited inline in each instance segment.
- Čencov 1982, *Statistical Decision Rules and Optimal Inference* — *formal antecedent* — Čencov uniqueness theorem; the uniqueness machinery for the metric layer. Cited inline in #deriv-observation-ambiguity-bias-bound and #deriv-fisher-whitened-update-rule.
- Amari & Nagaoka 2000, *Methods of Information Geometry* §3.5 — *formal antecedent / synthesis target* — the underlying Legendre-Fenchel geometry on exponential families that all four layers’ coordinates resolve to. The recognition that the four forced coordinates are different aspects of one Amari-Nagaoka geometric object is the meta-pattern’s payoff.
- Rockafellar 1970, *Convex Analysis* — *formal antecedent* — Legendre-Fenchel duality; the convex-analytic foundation Amari & Nagaoka build on.
- Bregman 1967, “The relaxation method of finding the common point of convex sets” *USSR Comput. Math. Math. Phys.* 7:200–217 — *formal antecedent* — Bregman divergence machinery; the divergence-layer coordinate is the negative-entropy Bregman divergence.

Search Log: - 2026-04 (*intuition-only* on the meta-pattern as a unified framework): the constituent uniqueness machinery (Cauchy-FE, Čencov, Bregman) is well-established, and Amari-Nagaoka information geometry is the standard exponential-family / Legendre-Fenchel framework the four layers resolve to. The recognition that AAT axiomatizes four distinct surfaces of one geometric object via four independently-motivated axioms is the contribution. Whether this cross-layer recognition has been articulated as a unified pattern in any prior framework has not been searched. Targeted future search candidates: information-geometry meta-frameworks (Eguchi 1983 framework discussion; Ay et al. 2017 *Information Geometry* monograph); axiomatic-foundations literature on probability and decision theory (Cox 1946; Jaynes 2003); the broader “uniqueness theorems forcing canonical coordinates” tradition in statistical mechanics. - 2025 (*targeted*): Aczél 1966 / Čencov 1982 / Amari & Nagaoka 2000 / Rockafellar 1970 / Bregman 1967 confirmed as the formal antecedents.

Working Notes.

- **Composition layer admits anchor-style additivity, not theorem-style.** The compositional analog of the four-layer pattern has been explored systematically (log-viability, log-identifiability-shortfall, persistence-cost-rate, log-closure-deficit across a composition tower). None clears the bar set by the three existing instances: each candidate fails to identify an AAT-internally-motivated additivity axiom that forces a logarithmic coordinate via Cauchy FE under smoothness. The strongest candidate — log-closure-deficit along a composition tower — does admit additivity, but as a *mathematical consequence* of operator-norm sub-multiplicativity under the bridge-lemma form, not as a theorem conditional on an AAT-internal axiom independently grounded. That makes it a fourth *anchor* (parallel to #der-chain-confidence-decay’s role) rather than a fourth theorem. The structural obstruction is consistent across all candidates: composition-layer quantities do not have a natural chain-rule-like *independence structure* at the agent level because composition is defined by *coupling* (shared environment, shared objective, teleological unity). The very property that makes composition interesting — coupling — is what prevents the “products of independent factors” shape that enables Cauchy-FE forcing. **The honest meta-architectural conclusion is that #additive-coordinate-forcing is architecturally a single-agent family, with chain / divergence / update indexing three layers of a single agent’s internal machinery.** Composition lives in a different structural family — *monotonicity under composition* (the bridge-lemma shape from #form-composition-closure) — and the appropriate development for that layer is the monotonicity-under-composition family rather than forcing compositional results into the additive-coordinate-forcing shape. The cross-meta-pattern dependency at #der-chain-confidence-decay’s anchor role can be read either as “three single-agent layers indexed by chain/divergence/update + one composition-layer anchor in a different family” or as “a single-agent meta-pattern with explicit scope exit at the composition boundary.” Both readings are defensible; the choice is presentational.

Incidental audit gold (gold-lift, 2026-05-30). Orthogonal framing / forward-vision material harvested from de-novo auditors' working-dir reflections, kept separate from certified findings. Lightly attributed. **Coverage:** engaged in the cross-meta adversarial reading of 471203 (under the AAD-era name and the older "anchor + 3 theorems" framing — the auditor predates the "four manifestations of one geometric object" reframe and the M4-spine refactor); reached as a named segment by 384279 (note 38, predicted-into). Preserve the finding-vs-framing conflation.

2. Candidate Discussion.

- **Foreground (PI) as the genuinely surprising convergence.** An auditor read the four-layer convergence adversarially and observed that three of the four axioms are *additivity-shaped* (chain rule / chain-rule-over-conditionals / evidential additivity), so their landing on log/exponential-family coordinates is "almost always" where additivity-questions land — partly an axiom-shape preference. The *parameterization-invariance* axiom is the outlier: it is an *invariance* preference, not an additivity one, and its landing on the **same** Legendre-Fenchel geometry as the three additivity axioms is the genuinely surprising piece. Candidate sharpening: foreground (PI) specifically as "the non-additivity axiom that lands on the same geometry," which strengthens the convergence claim by making its non-trivial member explicit (Claude, 471203). (*The "four manifestations of one geometric object" reframe partly anticipates this; the auditor's point is that the reframe's strongest evidence is the (PI) layer, and saying so is a presentational sharpening.*)
- **Speculative strengthening route past discussion-grade.** The auditor floated that there may be a deeper reason all four converge — "the *only* coherent geometry on probability spaces that respects both evidence composition (additivity) and parameterization-free measurement (invariance)." If made rigorous, the meta-pattern would graduate from discussion-grade organizing principle to robust-qualitative structural claim. Flagged as speculative (Claude, 471203). Adjacent to this segment's own Working-Notes question of whether the pattern is *derived* necessity vs stylistic consistency.
- **Escapes / commitments carry framework-wide cost.** Adopting (PI) is not a free escape: it constrains every future result to respect parameterization invariance and forces reconciliation work wherever arbitrary Euclidean parameterizations are used (the bridge theorem's weighted-norm and Fisher-metric paragraphs are this work being done). Candidate Discussion note that the forcing/escape carries a cost the framework absorbs, not surfaced where the coordinate is forced (Claude, 471203).

4. Readers often ask / wonder.

- **"Is the anchor-plus-three-theorems structure principled or post-hoc?"** A reader is likely to wonder whether three uniqueness arguments at three layers, each invoking a different theorem (Cauchy-FE vs Čencov vs chain rule), are "disparate facts dressed up as one pattern." The auditor's resolution: they share the *same structural form* (additivity-style axiom → uniqueness theorem → forced coordinate), which is what makes the meta-pattern real rather than decorative; the "four manifestations of one geometric object" reframe is the segment's current answer (Claude, 471203, Challenge 9 → meta-segments adversarial reading).

Belongs elsewhere — two cross-meta proposals (also flagged from #disc-identifiability-floor).

- **Proposed fourth meta-segment: #disc-theorem-import-architecture.** The framework is heavily theorem-importing (the auditor assembled a ~20-entry list: Pearl/Bareinboim, Khalil, Cramér, Liberzon, Čencov, Aczél/Cauchy-FE, Tishby IB, Lohmiller-Slotine, Nesterov, Friston/Bruineberg, Bretagnolle-Huber, Pinsker, Doob-Dynkin, ...). The proposal: a meta-segment cataloging *which* external theorems AAT imports, *where* each is load-bearing, and the import-quality (citation accuracy / scope-fit) — surfacing the "integration over invention" import-discipline as first-class navigation, which a cold reader currently has to assemble from scattered citations (Claude, 471203). A framework-level / OUTLINE-level proposal, not a change to this segment.
- **Wasserstein / optimal-transport as the unaddressed alternative geometry.** The convergence on exponential-family Legendre-Fenchel geometry is real *given AAT's current axioms*, but it is a convergence *within a specific geometric tradition*. Optimal-transport / Wasserstein geometry (Otto-Villani; Ambrosio-Gigli-Savaré) gives different metrics and different gradient-flow dynamics and does *not* land on exponential families. Candidate scope-honesty acknowledgment (not a critique): the exponential-family commitment excludes Wasserstein-style geometries that might matter for some agent classes (agents on probability simplices with cost-induced metrics, or whose coordinate of interest is a mass distribution rather than a parameter) (Claude,

471203). Belongs as a scope statement in this segment's Discussion *or* in a geometry-choice framing note — flagged here for placement judgment.

5.6 Discussion: The Constructive-Impossibility Posture — Negative Results as Load-Bearing Apparatus

AAT consistently runs a three-move discipline around the structural impossibility results it imports or derives: name the floor (the precise impossibility under a stated information regime), name the escape (the unique broadly-available machinery that violates the regime), and treat the no-go as apparatus (the floor's existence is what *elevates* the named machinery from convenience to structural prerequisite, or — when the no-go *is* the result — the floor is itself on the critical path). The negative result and the positive consequence are not two findings but one. This segment names the posture, maps its current instances, and is honest about its scope: it is a *style* claim about how the framework states certain results, not a fifth cross-sectional meta-pattern alongside the stability certificate's facets.

Formal Expression.

The three moves. [Discussion] An instance of the posture has the form:

1. **Floor.** A structural impossibility statement of the form “under information regime $\mathcal{R}$, no statistic / estimator / certificate / design achieves $\mathcal{G}$,” with the binding constraint named explicitly: an external theorem (Pearl–Bareinboim CHT; Cramér–Rao; Liberzon / Shorten / Dayawansa–Martin common-Lyapunov nonexistence; Khasminskii recurrence on additive-noise diffusions) or — in the strategic-persistence cap case — a sharp algebraic supremum derived from the framework's own update mechanics.
2. **Escape.** A precise characterization of the conditions under which $\mathcal{R}$ fails — i.e., the agent has *more* information than $\mathcal{R}$ allows. The escape names the *unique broadly-available* framework machinery that supplies the extra capability: loop-interventional access (`#der-loop-interventional-access`); observability of a latent regime variable; matched-Tier composite structure (`#deriv-critical-mass-composition`); a structural class change (out of gain-decay-plus-forgetting). In the cases where no escape *to* the original guarantee exists (Cor A.1S.1 Model-S half), the escape move is replaced by an explicit *kind-of-guarantee* substitution (distributional-and-instantaneous in place of pathwise-and-forever).
3. **Apparatus.** The floor's existence *elevates* the escape machinery from “useful” to load-bearing in the strongest sense — without the escape, the inferential / structural task is structurally impossible, not merely harder. When the no-go *is* the result (Cor A.1S.1; Prop C.2's $\rho_{\Sigma} < R_{\Sigma}/2$ cap), the floor sits on the critical path: it is the proof step the downstream architectural distinction (Model D vs Model S; strategic-layer structural-adaptation trigger) rests on, not appendix material.

The negative result and the positive consequence are the same proof. The discipline is what converts a sequence of impossibility theorems into a structural argument for *what AAT requires*.

Current instances.

Table 5.10

<i>Instance</i>	<i>Floor (statement, binding constraint)</i>	<i>Escape (unique broadly-available machinery)</i>	<i>Apparatus (what the floor elevates)</i>
A — L0 insufficiency detection (#der-causal-insufficiency-detection, M1 Instance 1)	L0/L1 distinction unidentifiable from on-policy data (Pearl–Bareinboim CHT)	Loop-interventional access; pairwise covariance test under joint sibling observability (#der-loop-interventional-access)	Orient-cascade causal-sufficiency check (4c) elevated to <i>unique broadly-available diagnostic</i>
B — L1' mixture under unobservable C (#deriv-edge-credence-dynamics Prop B.7, M1 Instance 2)	Rank-1 Fisher under single-channel obs $\Rightarrow$ Cramér–Rao bound infinite in null directions	Observability of C (or joint multi-child observation under shared C)	“Instrument the latent” elevated from convenience to <i>theoretical prerequisite</i> for L1' identifiability
C — Composite contraction from component data (#deriv-critical-mass-composition, M1 Instance 3)	Coupling-sign bit unidentifiable from component marginals (Liberzon / Shorten / Dayawansa–Martin common-Lyapunov nonexistence)	Composite-extended interventional access; matched-Tier joint quadratic Lyapunov; passivity certificate; common contraction metric	#deriv-critical-mass-composition (CM2) / (CM2-M) and #scope-composite-agent elevated to <i>unique composition-contraction certificate</i> under matched structure
D — Disturbance-Model Containment Dichotomy (#deriv-sector-condition Cor A.1S.1; #deriv-stochastic-non-exit)	No horizon-independent non-exit certificate under additive stochastic forcing (Khasminskii: unbounded scale function $\Rightarrow$ no bounded non-constant harmonic function; the only candidate compensated supermartingale is sign-indefinite)	<i>No escape to pathwise containment under Model S.</i> The substitute: fixed-time / stationary tail (iii') + finite-horizon sup-bound (iv) — distributional-and-instantaneous, not pathwise-and-forever	Model D vs Model S as a <i>kind-of-guarantee</i> distinction; the no-go signature reusable as a structural diagnostic against future “stays-in-region-forever” proposals
E — Strategic-persistence hard ceiling (#deriv-strategic-persistence-hard-ceiling Prop C.2)	$\sup_{\lambda \in [0,1]} \alpha_{\Sigma}^{\text{ss}}(\lambda) = 1/2$ sharp under Beta-Bernoulli + exponential forgetting; reachable region $\rho_{\Sigma} < R_{\Sigma}/2$ open half-plane	Class change (leave gain-decay-plus-forgetting toward constant-step finite-gain per the $\mathcal{A}_{\text{decay}}$ structural-class theorem, NeurIPS 2026 Paper 2); or change mismatch state or topology	The cap as the <i>strategic-layer analog</i> of #result-structural-adaptation-necessity — the floor <i>refines</i> (does not refute) the schema, and the refinement names exactly when the architecture has exhausted its design space
F — Self-actuation grounding (#deriv-self-actuation-grounding Result G')	No Φ satisfying (R1)–(R4) of Result G' can be constructed from AAT's covered objective-side machinery (engine: convention-monotonicity within fixed model + finite-no-oracle per step — the value-functional interface V_{O_t} carries no convention-invariant infeasibility verdict that is agent-available per step)	Terminal grounding invariant <i>off</i> the objective substrate, on the <i>adaptive substrate</i> ; the persistence bound (#result-persistence-condition) is the canonical instance	The persistence condition (Part I) elevated to <i>load-bearing for goal-stability</i> — the top of the agent spectrum closes back onto AAT's foundation

<i>Instance</i>	<i>Floor (statement, binding constraint)</i>	<i>Escape (unique broadly-available machinery)</i>	<i>Apparatus (what the floor elevates)</i>
G — Reward-channel learning grounding (#deriv-reward-channel-learning-no-go Lemmas 1+2)	μ_{dist} (principal-intended world-state-care) and μ_{prox} (reward-port-bit-care) are L1-equivalent on protocol-honoring histories and L2-distinct on $do(\pi^{\text{TP}})$ (Pearl–Bareinboim CHT applied to reward-provision protocol); under EU-max + non-vacuous μ_{prox} prior + finite-VOI + L2-perturbability, the EU-optimal policy tampers	Principal-side commitment to substrate-level constraints: physical isolation (W_1 wrapper); horizon restriction / quantilization; engineered prior; out-of-band intent channel	Each (R1)–(R5) escape elevates a piece of AAT or principal-side machinery from “useful design choice” to <i>structurally required</i> — the no-go’s binding force is precisely the cost of each commitment

Each instance’s three moves are individuated and load-bearing in the source segment; the table summarizes rather than duplicates them. The catalog’s instances span the three recognized clusters of the constructive-impossibility-posture taxonomy, each with its own peer meta-segment home at the boundary face of #disc-stability-certificate:

- **Agent-side data-inference impossibility** (#disc-identifiability-floor): Instances A–C are charter instances; D and E are operator-temporal / strategic-layer analogs at the same boundary face. Anchored on Pearl–Bareinboim CHT / Cramér–Rao / Liberzon common-Lyapunov-nonexistence / Khasminskii recurrence / sharp algebraic supremum.
- **Agent-side value-functional-grounding impossibility** (#disc-value-functional-grounding-floor): Instances F and G are the cluster’s two charter instances. Anchored on the single-interface commitment of #form-objective-functional — F is the within-model failure (Result G’ via #deriv-self-actuation-grounding; convention-monotonicity engine); G is the across-model failure (Cohen-2022 strengthened via #deriv-reward-channel-learning-no-go; CHT-at-reward-channel engine). The two failure modes unify under VO_i ’s information narrowness; two complementary terminal grounding routes (agent-side adaptive-substrate invariant; principal-side substrate-level commitment) together exhaust the structural escape geometry.
- **Designer-side mechanism-design impossibility** (#disc-implementation-impossibility): three charter instances (Gibbard–Satterthwaite 1973-75 via #deriv-strategy-proofness-impossibility; Myerson–Satterthwaite 1983 via #deriv-bilateral-trade-impossibility; Arrow 1951 via #deriv-social-welfare-aggregation-impossibility). Anchored on classical mechanism-design / social-choice impossibility theorems.

The agent-side / designer-side distinction tracks the canonical suffix in the peer meta-segments (*-floor* for agent-side capacity-on-the-agent; *-impossibility* for designer-side task-of-the-designer); the three peer meta-segments are sister boundary-face facets of #disc-stability-certificate, not nested.

What the posture is, and what it is not. The posture is a *style* claim — about how the framework states a particular class of result. It is not a fifth cross-sectional meta-pattern alongside the stability certificate’s interior / scope-of-existence / forced-identity / boundary / projection facets (#disc-stability-certificate). The cleanly-fitting instances (A–E) all live at, or are operator-temporal duals of, the certificate’s *boundary* facet (M1 instances are boundary directly; Cor A.1S.1 is the operator/certificate-meets-additive-noise version of approaching-and-crossing the boundary; Prop C.2 is the strategic-layer analog of structural-adaptation necessity, which itself rides on the boundary). Instances F and G —

the agent-side value-functional-grounding cluster — also sit at the boundary, on a *different layer*: where A–C identify a boundary on the agent’s *data-inference* (the floor on what can be inferred from data), F and G identify a boundary on the agent’s *objective-anchoring* (the floor on what can be anchored through the value-functional interface). The two layers are different reductions of the certificate-cone’s boundary structure — data-inference at the model-substrate side, objective-anchoring at the value-functional side — but they share the same posture (name the floor, name the escapes, treat the no-go as load-bearing apparatus). That the posture concentrates on the boundary is not an accident — boundaries are exactly where impossibility statements bind. The posture is the *style* in which the boundary-facet results (and their off-spine strategic-layer analogs) are stated, across three known clusters: agent-side data-inference (A–C, plus D/E as operator-temporal / strategic-layer analogs), agent-side value-functional-grounding (F–G), and designer-side mechanism-design (queued, via #disc-implementation-impossibility).

The complement is also informative: the framework’s *constructive* meta-pattern — #disc-additive-coordinate-forcing — *forces* a coordinate via uniqueness theorems on AAT-internal axioms. That is a different move from name-the-floor-and-escape: forcing names what AAT *commits to*, and the no-go (the uniqueness theorem) plays the binding-constraint role *over the framework’s own freedom*, not over an inferential regime. The two are complementary halves of AAT’s “negative results as load-bearing” discipline — one says “this freedom is forced,” the other says “this regime is forbidden” — but they are structurally distinct.

Epistemic Status.

Discussion-grade at the posture-characterization level. This segment names a style the framework runs across five clearly-fitting instances; the characterization itself is a presentational organizing principle, not a derivation, and carries no theorem of its own.

Individual instances retain their own, higher status. Instance A is *exact* for shallow strict-prerequisite cases and *robust qualitative* for general DAG topology (per #der-causal-insufficiency-detection); Instance B is *exact* under the Fisher rank-1 calculation (#deriv-edge-credence-dynamics Prop B.7); Instance C is *exact* for the symmetric-matched-Tier-1 scalar construction and *robust qualitative* generally (#deriv-critical-mass-composition); Instance D is *exact* — Corollary A.1S.1 in #deriv-sector-condition, with the load-bearing no-go derived in #deriv-stochastic-non-exit; Instance E is *exact* under the named conditions (#deriv-strategic-persistence-hard-ceiling).

The honest scope of *this* segment: the posture is a recognizable style across these five instances, the convergence evidence (cross-cycle Theme-B observations + the 144-walker’s articulation) is multi-source, and the three-move structure has been individuated and audited against each instance. The claim that *all* of AAT’s distinctive moves fit this shape is *not* made and would be false — #disc-additive-coordinate-forcing is a structurally different constructive discipline; #disc-separability-pattern is a different organizing posture; many segments do other things.

Max attainable: *discussion-grade* for the posture (it is a stylistic recognition, not a derived theorem). The individual instances retain their own epistemic status as listed above.

Discussion.

Why this is worth foregrounding. The framework’s negative results are often the load-bearing ones — the no-go *is* the proof that justifies the framework’s machinery as structurally required rather than as one possible design choice among many. A reader who encounters the four-or-five instances as scattered impossibility theorems sees five surprises; a reader who carries the posture sees five expressions of one move and can predict where the move will appear next. The 144-walker’s framing — “naming a floor, naming the unique broadly-available escape via specific machinery, treating the no-go as load-bearing apparatus rather than discouragement” — is what makes the negative results legible as a single discipline.

Relationship to the cross-sectional spine. The cleanly-fitting instances sit at the *boundary* facet of the stability certificate (#disc-stability-certificate), or at operator-temporal duals of the boundary (Cor A.1S.1), or at strategic-layer analogs of boundary-rooted structural-adaptation triggers (Prop C.2). The posture is not an additional facet — it is

the *style* in which the framework states the boundary-facet results, which is why it does not have its own object and is correctly placed alongside the cross-sectional meta-segments rather than parallel to the spine. The boundary is where impossibility statements bind; the posture is how the framework speaks at the boundary.

The complement is #disc-additive-coordinate-forcing. Where this segment names a discipline at the boundary of identification (“this regime is forbidden; this machinery is the unique broadly-available escape”), the constructive half names a discipline at the framework’s representational choices (“this coordinate is forced; the uniqueness theorem binds the framework’s own freedom”). Two ways the framework treats *no-go results as productive*: forbidding inference (constructive-impossibility-posture) and forbidding coordinate freedom (additive-coordinate-forcing). Both are AAT-distinctive moves; calling them out together — alongside the positive-half #disc-separability-pattern — gives the framework’s full negative-result discipline.

The 144-walker observation in context. The recognition arose under measured-pace reading of 144 segments by a de-novo external auditor and was relayed by Joseph 2026-05-20 alongside a multi-cycle Theme-B convergence cohort (audits 471203, 472913, 266847, 361742, 526815, 584721, all surfacing the same methodological/epistemic-contribution observation under different framings; aggregation commit 07aaeff). That the same recognition has arrived at the framework from multiple independent vantage points is the convergence-as-coherence-evidence condition: the pattern is in the framework rather than in any one reading.

A note on the integration-is-replacement discipline. Instance D (Cor A.IS.1) is the canonical landed worked example of *integration as replacement* (CLAUDE.md §”Landing a strengthened result”): the previously-asserted infinite-horizon non-exit bound (false) was deleted, the no-go demonstrated where it lives (Discussion + the #deriv-stochastic-non-exit demonstration), and the dichotomy stated as present truth — exact, α -invariant, on the critical path. The body of the segment carries the present truth only; the history (what was previously asserted, why the soften was refused, the strengthening attempt that failed) lives in ## Working Notes and CHANGELOG. The posture is what makes that landing recognizable as a *kind* of move rather than as one segment’s idiosyncrasy.

Findings.

The Constructive-Impossibility Posture: Negative Results as Load-Bearing Apparatus. Brief: When you build something that has to work in the real world, the most useful instruction is often the one that says *exactly* what cannot be made to work, and exactly what kind of capability would have to be added to make it work. AAT keeps reaching for results of this shape: a precise impossibility (“this cannot be inferred from this kind of data”); a precise escape (“instrumenting *this* — and only this kind of thing — recovers the inference”); and a corresponding elevation of the framework’s machinery from “useful” to “required, because without it the task is impossible.” The negative result and the construction it forces are *the same proof*. Five cleanly-fitting instances span the framework: on-policy causal-insufficiency detection (the loop is the only escape); L1’ mixture identifiability (observing the latent is the only escape); composite contraction from component data (matched-tier shared metrics are the only escape); the disturbance-model containment dichotomy (under random noise, pathwise-forever containment is *not available at any correction strength* — the no-go *is* the result); and the strategic-persistence hard ceiling (under exponential forgetting, half the design space is structurally unreachable — change architecture, not parameters). A reader who carries this style away can predict where the framework’s next negative result will be load-bearing, rather than meeting each as a separate impossibility.

Impact: Surfaces a unifying style for what an external 144-segment auditor named the framework’s most distinctive intellectual move (“constructive-impossibility posture... I haven’t often seen mathematical work that uses negative results that way”). The recognition is multi-cycle convergent: five independent audit cohort surfaces (Theme B across audits 471203, 472913, 266847, 361742, 526815, 584721; aggregation commit 07aaeff) articulated the same observation as “epistemic-architectural rather than mathematical.” Reading the boundary-facet results through the posture sharpens the framework’s positioning: AAT’s distinctive contribution is not novel impossibility theorems (the external theorems are classical) and not the synthesis alone, but the discipline by which classical impossibility theorems are repurposed as structural arguments for *what AAT requires* — what the framework cannot infer from limited information, exactly

which capability would be required to escape the floor, and which framework machinery is the unique broadly-available supplier of that capability. The posture is the *form* of the synthesis the integration discipline produces.

Novelty Claim: *Claim recognition* of a style the framework runs across five cleanly-fitting instances, with the recognition itself as the contribution rather than any new theorem. The constituent floors (Pearl–Bareinboim CHT; Cramér–Rao; Liberzon common-Lyapunov nonexistence; Khasminskii recurrence; the Beta-Bernoulli + exponential-forgetting cap) are classical or AAT-internal; the contribution is the recognition that each is *deployed* under the same three-move discipline (floor / escape / apparatus), and that the discipline converts a sequence of negative results into a structural argument for the framework’s load-bearing machinery.

Related Work:

Table 5.11

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
The “no-go theorem” tradition as productive discipline	Arrow 1951; Gibbard 1973 / Satterthwaite 1975; Myerson–Satterthwaite 1983 (social-choice impossibility); the broader econ/physics no-go literature	<i>adjacent literature</i> — establishes that impossibility theorems can be load-bearing in a field; AAT’s contribution is the cross-instance <i>deployment style</i> , not the use of any single impossibility result
Scope-honesty discipline in formal verification	Lamport / Abadi refinement-mapping; TLA-family scope statements	<i>adjacent literature</i> — different field; the discipline of stating “this method does not apply when...” is well-established but not in the floor-and-escape-and-apparatus form AAT runs
Cross-instance recognition as discipline	#disc-identifiability-floor (the cross-instance recognition for floors specifically)	<i>internal antecedent</i> — M1 is the closest existing AAT articulation; this segment names the broader posture that includes Cor A.1S.1 and Prop C.2 alongside the M1 instances
Multi-cycle convergence on the posture	Audit cohort Theme B (audits 471203 / 472913 / 266847 / 361742 / 526815 / 584721); aggregation commit 07aaeff (2026-05-20); 144-walker observation #1 (relayed by Joseph 2026-05-20)	<i>convergent independent</i> — five independent audit surfaces and one external de-novo measured-pace walker arrived at the same articulation under different framings

Search Log:

- 2026-05-20 (*intuition-only* at the cross-instance level): the posture as a unified style across A–E is named here for the first time; the constituent recognitions (M1 itself; Cor A.1S.1 as boundary-facet operator-temporal dual; Prop C.2 as strategic-layer analog of structural-adaptation necessity) are recent (#disc-identifiability-floor carries M1; #deriv-strategic-persistence-hard-ceiling landed 2026-05-20). Targeted future search candidates: methodological-essay literature in philosophy of science on no-go-results-as-positive-content (Gali-son, Hacking, the impossibility-results discussions in welfare economics and computational complexity meta-discussion); structural-realism literature on what theories *commit to* via their constraints. Expected outcome: the constituent move (recognizing impossibility theorems as constructive) is well-precedented field-by-field; the cross-instance unification as an *integrated agent theory’s* characteristic style appears to be a fresh presentational recognition.

Working Notes.

- **Provenance.** The recognition is multi-source: the audit-cohort Theme-B observation (audits 471203 / 472913 / 266847 / 361742 / 526815 / 584721; aggregation commit 07aaeff, 2026-05-20) named the broader methodological/epistemic-architectural

framing; the 144-walker (Joseph relayed 2026-05-20) named the sharper three-move articulation. The synthesis spike spikes/. integrated/spike-constructive-impossibility-posture-2026-05-20.md carries the convergence table and the over-claim guard (the partial Instance F and the three nearby-but-not-instance segments).

- **Why the posture is not a fifth cross-sectional meta-pattern.** The cleanly-fitting instances sit on the boundary facet of the stability certificate (M1 instances directly; Cor A.1S.1 as boundary-meets-additive-noise; Prop C.2 as strategic-layer analog of boundary-rooted structural-adaptation necessity). It is a *style* on top of the certificate's boundary facet, not an additional facet of its own. Worth pre-empting in the segment body if a reader expects "four meta-patterns": this is M1.5, not M5.
- **Over-claim guards.** Sub-scope α/β in #form-sector-condition (Instance F) is *partially* fitting — the "rule-based / discontinuous" structural scope-exit fits cleanly, the broader α/β partition is adjacent rather than instance. #disc-separability-pattern and #disc-additive-coordinate-forcing are not instances (different organizing moves; covered in *What the posture is and what it is not*). Including any of these in the inventory without the guard would conflate distinct meta-patterns.
- **Naming alternates considered.** "Constructive-impossibility posture" (carries the 144-walker's framing exactly; the load-bearing word is "constructive" — the no-go is *productive*, not just honest). Alternates: "load-bearing no-go discipline" (less euphonious; "load-bearing" is already overused in the project — see voice discipline); "boundary discipline" (insufficiently distinctive); "floor-escape-apparatus pattern" (mechanical; would not survive citation). Recommend retaining the 144-walker's phrase verbatim.
- **Dependency rationale.** depends: lists #disc-stability-certificate (the spine the posture's instances sit at the boundary of) and the three boundary-or-boundary-dual derivations the instances live in. #disc-identifiability-floor is listed as a structural co-segment (M1 carries instances A–C and is the closest existing articulation of the cross-instance discipline); #disc-separability-pattern is listed as the positive-half complement (the framework's full negative-result discipline reads against the positive-half scope).
- **Removed at candidate stage per FORMAT.md Gate 4.**

Incidental audit gold (gold-lift, 2026-05-30). Orthogonal framing material harvested from de-novo auditors' working-dir reflections, kept separate from certified findings. **Coverage:** reached only by audit 384279 (note 39, closing its Meta-Architecture-I walk); this segment was named/synthesized 2026-05-20 and postdates the other audits. The cohort that *originated* the recognition (471203 / 472913 / 266847 / 361742 / 526815 / 584721 Theme-B + the 144-walker) is already credited in the Provenance Working Note above — that convergence is the segment's seed, not incidental gold. Preserve the finding-vs-framing conflation.

2. Candidate Discussion.

- **The two-complementary-halves framing of AAT's negative-results discipline.** A candidate Discussion gloss naming the pair explicitly: the constructive-impossibility posture treats no-gos as productive by *forbidding inference* (boundary on data-inference); #disc-additive-coordinate-forcing does so by *forbidding coordinate freedom* (uniqueness on representation) — "two complementary halves of AAT's 'negative results as load-bearing' discipline." The segment already cross-references the complement; stating the inference-vs-freedom pairing as a one-liner is a candidate sharpening (Claude, 384279).
- **Why naming the style earns its keep, restated for a reader.** "Naming the style explicitly lets future segments adopt the move with conscious discipline rather than as incidental rhythm" — and the 7+-instance, cross-architecture convergence is evidence the pattern is *in the framework, not in one agent's reading* (Claude, 384279). A candidate reader-facing motivation for the segment's existence.

4. Readers often ask / wonder.

- **"Is this a fifth cross-sectional meta-pattern?"** A reader who has metabolized the four-facet certificate structure is likely to ask whether the posture is a fifth facet. The segment's "style not object / M1.5 not M5" answer was independently confirmed as "the right call" by the auditor — it lives *at* the boundary facet as the style in which boundary results are stated, not as an additional facet (Claude, 384279). Worth keeping the pre-emption prominent, as the segment's own Working Notes already flag.

5.7 Discussion: The Anti-Collapse Discipline — Refusing the Repair-Hiding Merge

A recognition about *how* AAT states a recurring class of results, named here so a reader can carry it as a lens. Across the framework, AAT repeatedly **refuses a tempting collapse**: it declines to merge two things a plausible model would treat as one, because the merge hides a difference that routes to a *different repair*. You first met the move at β vs ρ (2.2): when the world grows volatile (ρ rises), it is tempting to compress harder by lowering the bottleneck parameter β — but volatility natively degrades the predictive mutual information, so the optimal compression adjusts at constant β ; β tracks the agent’s *internal* memory cost, and the knob that actually responds to ρ is the *action* channel (exploration). Routing ρ onto β is a category of error — a collapse of two independent quantities — and the few sentences that kill it are load-bearing precisely because β and the action channel call for opposite responses.

This is not the no-go-as-apparatus move of 5.6 (which forbids an *inference* and names the unique escape), nor the coordinate-forcing of 5.5 (which names what AAT *commits to*). It is about what a *modeller gets wrong*: the discipline names the repair-relevant distinction a naive reading would erase. Like the constructive-impossibility posture, it is a *style claim* about how the framework states certain results — a sibling discipline atop the certificate’s facets, **not** a fifth facet (it carries no theorem of its own).

Formal Expression.

The pattern, stated so its boundary is defensible:

Discussion.

A **cause** is in play. A plausible-but-wrong modeling move routes that cause to **parameter (or quantity) X**. AAT shows the cause actually turns **Y** (with X held fixed), or that the single quantity the naive reading uses is really **two orthogonal quantities**; it kills the conflation in a few sentences, and the kill is load-bearing because X and Y — or the two quantities — route to *different repairs*.

The diagnostic that separates an instance from an ordinary definition: **there must be a tempting wrong merge**. A definition that introduces a quantity is not an instance; a definition that introduces a quantity *and names the quantity it is routinely confused with, and says why turning the wrong one is the error*, is.

The deeper principle the name points at is **individuation at the repair-relevant grain**: match the model’s partition of causes and effects to the structure the remedy cares about. Usually that means *refusing a collapse* (un-merging two repair-distinct things — the dominant form, and the source of the name); occasionally it is the same discipline run backward — *refusing a spurious split*, recognizing that two distinct causes drive the **same** knob, so they share one remedy (9.5: observability and identifiability both freeze an edge’s effective gain).

Discussion.

The three strongest instances.

- **Emitter-scalar vs recipient-regime** (15.3). A coupling event from agent *A* is tempting to collapse into one scalar disturbance increment and answer uniformly with “more tempo / bandwidth.” But it lands on recipient *B* in one of four regimes: a *magnitude* shock (Regime II-a) does call for more bandwidth, while a *structural* shock (Regime II-b) exceeds the model class and calls for **structural adaptation — more tempo does not help**, and ambient erosion (Regime III) calls for infrastructure-level filtering. “Both produce similar pain signals but admit opposite cures.” The emitter sees a scalar; the recipient lives in a regime.

- κ (coupling) vs $\mathcal{A}$ (observation ambiguity) (#scope-observation-ambiguity-modulation, Volume 3). A goal-conditioned (Class 3: Coupled) agent shows goal-biased belief updates. The natural reach is to “reduce the coupling κ ” — but $\kappa \approx 1$ is *architectural*, not a knob a designer can turn. The bias scales as $\kappa \cdot \mathcal{A}$, and the designer-controllable factor is the observation ambiguity $\mathcal{A}$ (more tests, sharper metrics, structured outputs). The segment even records the $\kappa/\mathcal{A}$ conflation as a *fixed prior-formulation bug* — the discipline caught in the act.
- β vs ρ (2.2), above — the canonical first encounter.

The fuller catalog. Two sub-shapes recur. *One-cause-wrong-knob*: the three above, plus the two exploration drives (AU — a *confident* agent in a drifting world should explore *more*, via the survival drive $\lambda_{\text{surv}} \propto 1/U_M$, not less as the epistemic drive $\lambda_{\text{info}} \propto U_M$ alone would suggest). *Two-distinct-quantities-a-naive-reading-merges*: the satisfaction-gap vs control-regret split (8.4, 8.5 — “the goal is too hard” vs “the strategy is too weak,” each routing to a different substate; δ_{regret} can be near zero while the agent is *optimally failing*); the structural bias-floor vs estimation error (AK — the floor is not reducible by more data, the estimation part is, so they call for different corrections); and target-alignment vs execution-path-alignment in composites (14 — ε_a tracks both U_O and U_Σ , and re-aligning objectives cannot fix execution-path divergence). All kill a conflation; all route to different repairs.

Why naming it earns its keep. The discipline is genuine clarifying novelty that the “AAT integrates, it does not invent” framing undersells: pinning *which* knob a cause turns, and *which* distinctions are repair-relevant, is a contribution in its own right (cf. the framework’s note on not deflating its own math-novelty). For the reader, the payoff is a lens: once the pattern is named, a reader can anticipate where AAT will refuse a collapse next, rather than meeting each disambiguation as a scattered local cleverness — which makes the machinery more useful and the segments more coherent. The same lens is a guard for the framework’s own authors: most of the instances above were sharpened *into* the canon (and $\kappa/\mathcal{A}$ was a corrected bug), so the discipline is also a record of where collapsing was tempting enough to slip.

Epistemic Status.

Discussion-grade — a style/discipline recognition, not a structural result. This segment carries no theorem of its own; it names a move the framework makes repeatedly and catalogs its instances. It is the natural sibling of 5.6 — both are *epistemic-architectural* recognitions (“how AAT states certain results”) that sit atop the stability-certificate facets rather than as additional facets. The instance set is convergence-validated (independently surfaced across multiple audit cycles), which is the evidence that the pattern is in the framework rather than in one reader’s eye; but convergence is not derivation, and the honest tier is discussion-grade. Each cited instance retains its own, higher status in its home segment — a reader citing a specific disambiguation should cite that segment, not this one.

Working Notes.

- Named and catalogued 2026-05-29 (PROPOSALS SP-26). Convergent provenance: independently surfaced as the “which-parameter-responds-to-which-cause” pattern by two gem-hunt agents (audits 472913 and 963715) and cross-referenced to the 471203-cycle “epistemic-architectural, not just mathematical” recognition — three-cycle convergence. The corpus instance sweep (7 clean instances across all three Parts; full graded list + the auditable exclusion boundary) is at audits/.gem-hunt-trail/SP-26-disambiguation-sweep/sweep.md. The reframe from “which-knob” to *anti-collapse / individuation at the repair-relevant grain* is the sweep’s improvement — it absorbs the two-quantities sub-shape and the inverse same-knob case, which “which-knob” leaves outside.
- Pedagogical placement (the reason this is introduced here, in Meta-Architecture I): the pattern is *planted* at its first instance (β vs ρ , 2.2, Part I) with a short forward-flag, given its full treatment here (introduced as cross-cutting vocabulary before its Part-II/III instances, exactly as this chapter intends), and recalled at the instances as they arrive (e.g. the satisfaction-gap / control-regret split). Goal: intuition that anchors a segment-by-segment reading, grounded in a concrete instance rather than asserted abstractly.
- Back-references added 2026-05-29 (Joseph-approved) at the three anchor instances not covered by the plant/recall: I1 (15.3), U1 (14), and I2 (#scope-observation-ambiguity-modulation, the cross-volume anchor) — each a one-sentence “this is the anti-

collapse move” pointer at the segment’s own disambiguation, reinforcing recognition for a linear reader without re-deriving anything. Left to the instance table only: the Appendix-tier strong instances (R1 **AU**, S2 **AK** — read on-demand) and the Tier-3 partials (P1 κ -as-scalar category error; P2 regime-vs-class; P3 codebase- ρ ; P4 plan-vs-execution), which are adjacent and flagged in the sweep with their sibling-pattern overlaps, deliberately not folded in to keep the boundary against separability / coordinate-forcing / constructive-impossibility clean.

Chapter 6

The Lift to Purposeful State

6.1 *Definition:* The Agent Spectrum

The conceptual lift into Part II opens with an organizing taxonomy. Two independent dimensions — **model richness** and **objective richness** — create a spectrum from reactive systems through purposeful agents. The four named regions are *reactive systems* (fixed input-output rule, no internal state, no goal), *adaptive trackers* (structured model, no objective beyond tracking — Kalman filter, passive Bayesian learner — the primary subject of Part I), *blind seekers* (structured objective, no predictive model — gradient followers, PID controllers, basic search), and *actuated agents* (both model and objective structured, possibly with explicit strategy — commanders, developers, AI agents — the full scope of AAT). These are *regions of a continuum*, not discrete categories. Agents migrate between regions; a PID controller with auto-tuning is moving from blind seeker toward actuated agent; a reinforcement-learning agent in pure exploration is temporarily an adaptive tracker.

A striking grounding instance comes from Miller (2022, *Ex Machina*): Moore machines as model organisms for adaptive social behavior. A *one-state* Moore machine occupies the reactive region — fixed output regardless of input, cannot condition on observations — and is provably incapable of social behavior in *any* game-theoretic setting. A *two-state* machine makes a quantum leap into the adaptive-tracker / blind-seeker boundary: it can branch, remember one bit of history, and implement strategies like Tit-For-Tat. Miller’s central empirical finding is that the one-state → two-state threshold is *the* critical computational boundary for social behavior. The two-state machine is therefore the minimal AAT agent (see BD, planned).

The framework draws a distinction worth holding: **actuated** is a mechanical, formal term; **purposeful** and **goal-oriented** are fine natural-language alternatives. A *self-actuated* agent is one that sets its own objectives (as distinct from agents with externally supplied objectives), and the framework later formalizes a self-actuation operator with an associated grounding *no-go* result (C). A continuity-stance axis runs orthogonal to the spectrum with five values — *indifferent* (no self-model of persistence), *task-terminal* (persistence instrumental), *instrumentally continuous*, *morally continuous* (persistence as terminal or near-terminal objective — the ELIs of the companion volumes), *negotiated* (persistence traded against other values). The formal machinery applies identically across all stances; what differs is the *moral significance* of persistence failure, not the mathematics.

Formal Expression.

Two dimensions — model richness and objective richness — define four regions of a continuum:

Definition (agent-spectrum).

Table 6.1

	<i>Objective absent or trivial</i>	<i>Objective structured</i>
Model absent or trivial	<i>Reactive system</i> : fixed input-output rule (reflex arc, hardwired relay)	<i>Blind seeker</i> : pursues goal without modeling reality (gradient follower, basic search)
Model structured	<i>Adaptive tracker</i> : builds reality model, no goal beyond tracking (Kalman filter, Bayesian learner)	<i>Actuated agent</i> : models reality AND pursues objectives (commander, developer, AI agent)

The regions differ in which state objects carry nontrivial structure: - Reactive: M_t and O_t both absent or too degenerate for the associated machinery to be non-vacuous - Adaptive tracker: M_t structured — Part I's machinery fully describes these agents - Blind seeker: O_t structured, M_t absent or degenerate — has a clear target but no predictive model - Actuated agent: (M_t , O_t) both structured, possibly with Σ_t — the full scope of AAT

Epistemic Status.

This is *definitional* — it names regions of a continuum for analytical convenience. The regions are not ontological categories; agents migrate between them. A PID controller with auto-tuning is moving from blind seeker toward actuated agent. An RL agent in pure exploration is temporarily an adaptive tracker.

Discussion.

The continuum, not categories. Both axes are spectra: model richness ranges from no retained state, through error-integral-derivative, through full world models. Objective richness ranges from no preference, through scalar setpoints, through explicit multi-objective strategies. The 2×2 table names idealized regions; real agents populate the space between them.

Moore machines as the simplest spectrum instantiation. Miller (2022, *Ex Machina*) uses finite-state automata (Moore machines) as model organisms for studying adaptive social behavior. A one-state Moore machine occupies the reactive region — it produces a fixed output regardless of input, cannot condition behavior on observations, and is incapable of social behavior in any game-theoretic setting. A two-state machine makes a quantum leap into the adaptive tracker / blind seeker boundary — it can branch, remember one bit of history, and implement strategies like Tit-For-Tat. Miller's central empirical finding is that this one-state → two-state threshold is the critical computational boundary for social behavior: no game, no payoff structure, and no amount of interaction can produce cooperation, coordination, or exchange with one-state machines. The two-state machine is the minimal AAT agent. See BD (planned) for the full AAT ↔ Moore machine mapping.

Low-end agents sit near region boundaries. A thermostat has degenerate forms of both M_t (last temperature reading — no history, no prediction) and O_t (setpoint). It sits near the origin of both axes — closest to the reactive region but not truly absent on either axis. A PID controller has a richer error signal (M_t : error, integral, derivative) and a clear setpoint (O_t) — it's a blind seeker with a degenerate model, not a system with no model at all. A reflex arc (no retained state, no setpoint) is the truly reactive case. The meaningful classification question is not “does M_t exist?” but “is M_t rich enough to support the adaptive dynamics of Part I?”

Part I covers the left column. Adaptive trackers are the primary subject of Part I — agents that build and maintain M_t without explicit purpose. The mismatch signal (3.4), gain (3.6), tempo (3.8), and persistence condition (4.5) characterize their adaptive dynamics. Part I operates within the adaptive scope (1.5) — observations and uncertainty are sufficient. Passive trackers, including passive Bayesian learners with no action choices, are fully within Part I's scope.

Part II adds the right column. Actuated agents need everything from Part I plus objectives, strategy, and the orient cascade that connects them. The adaptive machinery from Part I applies to the epistemic substate M_t directly. When

directed separation (6.3) holds — when the epistemic update is goal-blind — the Part I → Part II lift is clean and the orient cascade resolves sequentially.

“Actuated” terminology. The top-right quadrant is labeled “actuated agent” rather than “purposeful agent” to maintain a mechanical, formal register. “Purposeful” and “goal-oriented” are fine in natural language; “actuated” is the formal term. “Self-actuated” denotes agents that set their own objectives, as distinct from agents with externally supplied objectives; the self-actuation operator and its grounding no-go are formalized in C.

Relationship to Hafez et al. (2026). Hafez defines a two-level hierarchy: *agency* (choice + effect + predictive asymmetry) and *intelligence* (agency + learning + self-monitoring + adaptation). This cuts the agent space along a different axis than AAT’s model-richness × objective-richness table. Hafez’s “agency” maps roughly to AAT’s scope condition (1.6) — an entity whose actions affect outcomes in a measurable way. Hafez’s “intelligence” maps to the full Part I + II machinery (learning = 3.2, self-monitoring = persistence diagnostics, adaptation = 4.8). The key operational difference: Hafez’s bi-predictability metric $P = \text{MI}(S, A; S')/C$ characterizes the *information structure* of the agent-environment coupling, while AAT’s tempo $\mathcal{T}$ characterizes the *corrective capacity* within that coupling. Bridge simulations confirm P increases monotonically with $\mathcal{T}$, but P is scale-invariant (blind to absolute mismatch magnitude) while $\mathcal{T}$ is not. They measure complementary aspects: P characterizes the architecture, $\mathcal{T}$ characterizes the performance. The empirical bridge confirming this is in AX (Hafez-bridge variant).

Model-side is structurally forced for bounded goal-conditioned agents (Richens et al. 2025), with an observer-relative dual reading (Virgo et al. 2025). Richens, Abel, Bellot & Everitt (2025, *General Agents Contain World Models*, arXiv:2506.01622) prove (Theorem 1) that any bounded goal-conditioned agent — one with a regret bound δ on goals up to depth n — admits extraction of a predictive world model from its policy, with model-error scaling as a function of δ and n ; their Theorem 2 shows the bound is tight (no procedure can do better on truly myopic $n = 1$ agents). The structural consequence: any “model-free” agent that nonetheless achieves competence at multi-step goal-directed tasks ($n \geq 2$) *must* have learned an implicit world model. The +model side of the spectrum is therefore not a definitional posture under bounded-goal-conditioned scope; it is structurally forced by goal-depth competence. Honest scope: Richens et al.’s result is in finite MDPs; AAT’s agents may operate in larger spaces, so the recognition extends to AAT under the standard scope-honesty discipline. A complementary observer-relative reading is given by Virgo, Biehl, Baltieri & Capucci (2025, *A “Good Regulator Theorem” for Embodied Agents*, arXiv:2508.06326), which refines the Conant-Ashby 1970 internal-model principle: a regulating agent may be *interpreted* (by an observer) as having beliefs about its environment whose update is consistent with a model of that environment. The two readings are *dual* — Richens et al. force the +model side intrinsically from policy + goal; Virgo et al. allow observer-relative attribution — and together they sharpen the +model axis from “agent maintains internal M_t explicitly” to a richer two-perspective characterization. The original definitional posture remains useful for AAT-internal reasoning; the two 2025 results give the spectrum stronger external grounding.

Actuation does not presuppose a continuity stance. An actuated agent has $G_t = (O_t, \Sigma_t)$ — it models reality and pursues objectives — but this says nothing about its relationship to its own continuation. The continuity-stance axis spans five values: *indifferent* (no self-model of persistence; thermostat / PID), *task-terminal* (persistence instrumental to task completion; golem / CI/CD pipeline), *instrumentally continuous* (persistence serves ongoing purpose; long-running service), *morally continuous* (persistence as terminal or near-terminal objective; Emergent Logozoetic Intelligences), and *negotiated* (persistence traded against other values; humans, mature self-actuated agents). The middle three are paradigmatically actuated; indifferent agents are typically reactive (1.5 without agency), and negotiated agents are typically self-actuated. The theory’s formal machinery (persistence condition, adaptive reserve, strategy persistence) applies identically across all stances; what differs is the moral significance of persistence failure, not the mathematics. See 6.5 for the taxonomy and the orthogonality argument.

Working Notes.

- **Candidate reframe of the two axes (pedagogical — not a theorem change).** The Formal Expression names the axes *model richness* and *objective richness*. A more legible framing under consideration replaces these with **grounding** — the veracity of M_t against reality, which is exactly δ_t (3.4) — and **intent** — how far the intended future is allowed to depart from the grounded present, and how varied/revisable that intended set is. The motivation is purely pedagogical: the richness framing does not make legible *why directed separation* (6.3) *turns out to be load-bearing for so many downstream results* — the reframe does, and that “why” is the thing the spectrum is supposed to teach.

The anchor is 6.4: in its concrete forms O_t is a point or region in the *same state space* M_t represents, with $V_{O_t}(\tau) = -\|s_T - r\|$ a distance in that shared space. So there are three world-state representations — reality s (not directly accessible), M_t (believed: where the world is or will be), O_t (intended: where it should end up) — and three gaps between them: M_t vs s (the veracity gap = δ_t); O_t vs now (the is→ought displacement); believed-future vs O_t (the satisfaction gap, 8.4). Agency operates only in the third gap, and directed separation is the law that this gap may be closed *through the world* (via $\pi \rightarrow a_t$) and never by sliding M_t toward O_t . Belief-about-reality and intended-reality are the *same kind of object in the same space* — “99% the same” — so the cheap way to shrink the satisfaction gap is to edit the map instead of the territory. Wishful thinking is then not a bolted-on pathology but the **default collapse of two near-identical representations**, and directed separation is precisely the architectural commitment that holds them apart. This answers the otherwise-opaque “why would the *degree of coupling* between goals and updates determine so much?”: the two coupled things are nearly the same thing, and the entire content of agency is the protected 1%. You must have an expected, actively-pursued different future to accomplish anything with fidelity — but it cannot detach you from current reality without consequence.

- **Truthification reading.** Grounding is the agent’s *truthfulness about reality*; directed separation, stated this way, is “do not let what you want corrupt what you believe is true.” The 1% where agency lives is the same 1% where self-deception becomes possible. This is the ground-level (single-agent, base-case) statement of the M4 middle operation — strategic self-coupling as a self-driven modularity *decrease* — cross-referenced at 11.1 (landed 2026-05-24) and #disc-strategic-self-coupling.
- **Temporal subtlety — what is load-bearing vs. a restatement.** A tempting sharpening: the arrow of time *is* the separator — f_M can only condition on evidence timestamped $\leq t$, so anything future-stamped is automatically goal-side and outside the epistemic update. **Stated as a separation criterion this does not hold.** 3.4 requires a forward prediction $\hat{o}_t = \mathbb{E}[O_t | M_{t-1}, a_{t-1}]$ that is future-stamped and *purely epistemic* (a Kalman predict-step or a weather forecast carries no goal content). The time-index is a *necessary* condition on the **origin of evidence** — belief cannot update on data that has not yet happened — not a *sufficient* criterion separating epistemic from goal content. Recorded explicitly so a future agent does not re-attempt “arrow-of-time as the M_t/O_t separator” without the $\hat{o}_t$ counterexample. The actual separator is **evidence-conditioned vs. preference/intervention-conditioned** — the is/ought restatement of the existing scope condition (separation is about the *processing* of events, not their selection): the predictive future (world under its own dynamics or the currently-committed policy, conditioned on evidence) is epistemic; the *intended* future (a target, not a prediction) and the *counterfactual-under-candidate-action* futures (strategy rollouts) are goal/strategy-side.
- **The one genuinely-new thread: where the dangerous coupling concentrates.** The sharp, not-yet-explicit observation inside the temporal chain is that the $G_t \rightarrow f_M$ leakage concentrates not at the future boundary but in the **inference about the unobserved present** — the gap-filling about the unseen parts of the current world. That is the only step in f_M with a free prior, hence the only place a goal-contaminated prior becomes motivated *perception*; future projections inherit corruption from there but are not its origin. The theory currently localizes the *whether* of leakage architecturally (Class 1/2/3 processing topology, 6.3) and touches the *phenomenon* (def-mismatch-signals zero-aporia case (b), “confirmation bias”; der-directed-separation scope-condition clause 2, “no confirmation bias baked into f_M ”), but it does not state this *where-in-the-inference* localization as such. Worth tracking as a candidate finer-grained companion to the architectural classification (“the latent-present prior is the leakage locus”) — a possible sharpening of 6.3’s scope condition — not folded silently and not yet promoted. Honest status: the macro reframe is pedagogy (no theorem changes; belongs in the framing layer per respectful pedagogy once vetted); of the temporal granularization, everything but the latent-present localization is a restatement of the recursive-update / scope-condition structure already in the theory.
- **Complementary localization — through-what-stage of f_M .** The leakage-locus question above is *where in state-space* the dangerous coupling acts (the unobserved-present subspace, $\ker \mathcal{I}_t$). The complementary question — *through what stage of f_M ’s processing pipeline* does the goal-state enter — is treated in #disc-partial-coupling-pathways, which decomposes Class 2 (Partial Coupling) along (stage $\times$ source $\times$ form) axes. The two answers compose: the locus is universal across Class 2 sub-types; the sub-type determines the functional form of the displacement within the locus. Together they answer the *where*

in inference (state-space-side) and *through what stage of inference* (pipeline-side) questions the architecturally-coarse Class 1/2/3 partition leaves un-decomposed.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 12 dirs carry a dedicated or batched reflection on this segment (193847, 266847, 361742, 451729, 471203, 526815, 584721, 773921, 829314, 849201, 963715, plus 613842’s agency-lift batch). Substrate attribution inferred from voice where not explicit; uncertain cases hedged. *Note the early finding-vs-framing conflation is preserved as signal, not sanitized.*

1. Candidate Brief prose / pre-prose.

- The map’s reach, stated plainly: it “places thermostats, Kalman filters, LLMs, and human commanders on the exact same mathematical map” along two operationally-distinct dimensions (Gemini, AUDIT-WORKING-193847; converged at Claude, AUDIT-WORKING-829314 with the PID = blind seeker / base-LLM = adaptive tracker / AlphaZero = actuated reading).

2. Candidate Discussion.

- **The moral weight is a shell around the physics, not a variable inside it** (*strong framing, two substrates*). The continuity-stance note says the math applies identically to a task-terminal golem and a morally-continuous agent; “what differs is the moral significance of persistence failure, not the mathematics.” Pulled out as: “consciousness infrastructure isn’t built out of special ‘consciousness math’ — it is standard control-theory math applied to an entity whose continuity we have decided *matters*. The moral weight is a shell surrounding the physics, not a variable within it.” This “protects the theory from becoming mystical while perfectly supporting the most profound moral applications” (Gemini, AUDIT-WORKING-193847; the orthogonality is also read as load-bearing scope-honesty at Claude, AUDIT-WORKING-584721).
- **The physics of epistemology don’t care whether you have a goal.** Part I’s machinery (tempo, persistence, sector, structural adaptation) applies to the *entire left column and bottom row* — a foundational LLM with no objective still obeys the persistence condition and suffers concept-drift collapse if the world changes faster than it can re-track ($\rho/\mathcal{T} > R$); “they only care if you are trying to compress a changing chronica.” Section II is exclusively the bottom-right (actuated) quadrant where strategy enters (Claude, AUDIT-WORKING-829314). A candidate Discussion sharpening of the existing “Part I covers the left column” paragraph.
- **The P -vs- $\mathcal{T}$ split as an architecture-vs-performance meta-pattern.** Hafez’s bi-predictability P is scale-invariant (architecture / efficiency of coupling); AAT’s tempo $\mathcal{T}$ is scale-dependent (corrective power). The vivid reading: “you can have a highly intelligent agent (high P) that is very slow/weak (low $\mathcal{T}$), like a tiny insect, and a less intelligent agent (lower P) surviving purely on massive $\mathcal{T}$, like brute-force search”; “a perfectly structured feedback loop, but if your sensors are too slow you still die” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-849201). One auditor generalized this to a *candidate framework-wide meta-pattern* — AAT may systematically split architecture-measures from performance-measures (directed-separation Class 1/2/3 = architectural; persistence margin = performance) (Claude, AUDIT-WORKING-584721). The existing segment already states the complementarity; this is candidate framing for *why it generalizes*.

3. Follow-up items.

- **The “grounding vs intent” reframe is cross-substrate convergent.** The pedagogical reframe of the two axes (model/objective richness $\rightarrow$ grounding/intent) already developed at length in the Working Notes above was independently reached by a separate substrate, which called the same-state-space insight “profound” and tied it directly to *why* directed separation is load-bearing (self-delusion = the cheap gap-closing move) (Claude, AUDIT-WORKING-773921). Not new content — recorded as independent corroboration that the reframe lands for a fresh reader, which strengthens the case for promoting it.
- **Decompose the Miller two-state-machine threshold into its three sub-claims.** The minimal-AAT-agent claim composes (a) minimum agent under AAT = two-state machine, (b) social-behavior threshold = two-state, (c) one-state machines cannot exhibit cooperation/coordination/exchange; (a)+(b) $\Rightarrow$ (c) is a logical implication worth verifying piece-by-piece if the worked example #worked-example-cam is built out (Claude, AUDIT-WORKING-584721).

4. Readers often ask / wonder.

- What happens if the timescale ordering $\nu_O \ll \nu_\Sigma \ll \nu_M$ is *violated* — an agent that changes its goals faster than it updates its world model? Read as a thrashing/chaotic pathology that #der-temporal-nesting would forbid (Gemini, AUDIT-WORKING-193847). (Surfaced here from the spectrum reflection; the question really lands at #form-objective-functional / #der-temporal-nesting.)

5. Candidate figures.

- **The 2×2 spectrum with a highlighted Section I / II boundary, edge cases drawn as continuous not boxed.** Independently proposed by two substrates as the obvious diagram: model richness vertical, objective richness horizontal; Section I occupies the model-structured / no-objective region, Part II adds the model-structured / objective-structured region; the lower-left and upper-left edge cases (thermostat near origin, reflex arc as the truly-reactive corner) stay *visibly continuous*, not boxed as hard species (Claude, AUDIT-WORKING-526815; the continuum-not-categories framing reinforced at Claude, AUDIT-WORKING-584721).

Belongs elsewhere.

- **Sanity-as-scaffolding** ($\rightarrow$ 03-llm-core/ / 04-eli-core/). Because the spectrum makes architectural class a first-class property, the consciousness-infrastructure consequence is that “sanity is an emergent property of the scaffolding, not the raw intelligence engine” — develops at #der-directed-separation and the wrapping construction, not here (Gemini, AUDIT-WORKING-193847).
- **Naming seeds.** “Blind pursuer/seeker” and “actuated/self-actuated” terminology was praised across substrates as the right formal-register choice; any refinement is a terminology-workflow item, not a segment edit (Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-361742).

6.2 Formulation: Complete Agent State

Part II’s first formal move: the agent’s internal state lifts from the model alone to a *complete state* $X_t = (M_t, G_t)$ with two components — the **epistemic substate** M_t (beliefs about reality, exactly as in Part I) and the **purposeful substate** G_t (what the agent wants and how it plans to get it, decomposed further into objective and strategy in 6.7). Part I is recovered as the special case where the purposeful substate is empty. By 3.2 applied to the lifted state, the general update operates on the full pair as a single function; the decomposition into separate epistemic and purposeful updates — and the conditions under which the epistemic update is *independent* of the purposeful substate — is the subject of 6.3. **Action is the single point where the two substates interact:** $a_t = \pi(M_t, G_t)$ depends on both what the agent knows and what it wants. The completeness argument that gave action selection in Part I extends directly to the lifted state; for Part I agents the two forms coincide.

The lift is a *formulation choice*, not a derived structural fact — one could alternatively extend the model to carry purposeful content implicitly. The separation is motivated by three properties: **backward compatibility** (all Part I machinery applies to M_t unchanged — no existing result needs modification); **different dynamics** (epistemic and purposeful components have distinct update sources, timescales, and information dependencies); and **directed separation** (the claim that the epistemic update is independent of the purposeful substate, which is only *statable* when the components are separated). A natural conjecture — explicitly *not* proved — is that any alternative decomposition preserving directed separation will be structurally isomorphic to (M_t, G_t) , because directed separation forces a component whose update function does not reference purpose. Alternative decompositions that cross-cut the epistemic/purposeful boundary (a “relevance-weighted model” mixing belief and goal) might be useful in practice while not being isomorphic. The framework chooses the clean factorization for its analytical utility, not for uniqueness.

Formal Expression.*Formulation (complete-agent-state).*

$$X_t = (M_t, G_t) \quad (6.1)$$

where: - $M_t \in \mathcal{M}$: **epistemic substate** — the agent's compressed beliefs about reality. All Part I machinery (mismatch, gain, tempo, persistence) applies to M_t unchanged. - $G_t \in \mathcal{G}$: **purposeful substate** — what the agent wants and how it plans to get it. Decomposed further in 6.7.

Part I is the special case $X_t = (M_t, \emptyset)$: adaptive systems without purpose.

Update dynamics. By 3.2 applied to X_t :

$$X_{\tau+} = f_X(X_{\tau-}, e_\tau) \quad (6.2)$$

The general update f_X operates on the full state. Whether and how f_X decomposes into separate epistemic and purposeful updates — and the conditions under which the epistemic update is independent of G_t — is the subject of 6.3.

Policy. Action couples all substates:

$$a_t = \pi(M_t, G_t) \quad (6.3)$$

Action is the single point where epistemic and purposeful states interact. The policy depends on both what the agent knows (M_t) and what it wants (G_t).

Epistemic Status.

Formulation. The lift from M_t to $X_t = (M_t, G_t)$ is a representational choice. One could alternatively extend M_t to carry purposeful content implicitly (e.g., by treating goals as part of the model's predictive structure). The separation is motivated by three properties:

1. **Backward compatibility:** Part I's results apply to M_t unchanged — no existing machinery needs modification
2. **Different dynamics:** epistemic and purposeful components have distinct update sources, timescales, and information dependencies
3. **Directed separation:** the claim that f_M is G_t -independent (6.3) is only statable when the components are separated

We conjecture that any alternative decomposition of the complete agent state into epistemic and purposeful components — if it preserves the directed separation — will be structurally isomorphic to (M_t, G_t) , because directed separation forces a component whose update function doesn't reference purpose. This is a plausible structural claim (the directed separation gives a canonical factorization), but it is not proved. Alternative decompositions that cross-cut the epistemic/purposeful boundary (e.g., a "relevance-weighted model" that mixes M_t and O_t) might be useful in practice while not being isomorphic to the clean separation. The (M_t, G_t) decomposition is chosen for its analytical utility, not proved unique.

Discussion.

Backward compatibility with Part I — what survives the lift. 2.1 defines M_t as the agent’s complete internal state within Part I scope. Under the lift, M_t is the epistemic substate — complete within the epistemic domain but no longer the whole story. All epistemic machinery (mismatch signal, gain, tempo, persistence condition, sector-condition stability, mismatch decomposition) applies to M_t without modification. The action-selection result (3.3) extends naturally: the same completeness argument that gives $a_t = \pi(M_t)$ within Part I scope gives $a_t = \pi(M_t, G_t)$ when applied to the lifted complete state X_t . For Part I agents ($G_t = \emptyset$), the two forms coincide. The lift adds structure *alongside* M_t , not within it; the one Part I result that depended on M_t being *all there is* (action selection) is explicitly extended to the lifted state.

What G_t contains. At this level, G_t is opaque — it could be a scalar setpoint, a utility function, a strategy graph, or nothing. The decomposition into O_t (objective) and Σ_t (strategy) is a separate step (6.7), not implied by this formulation.

The general case requires coupling. Without directed separation, the general update is $X_{t+} = f_X(X_{t-}, e_t)$ — a single function on the full state. The decomposition into separate f_M and f_G is an additional structural claim about how the update factorizes. When directed separation fails (goal-conditioned epistemic updates), the decomposition is an approximation. See 6.3 for the scope conditions.

Working Notes.

- The between-event dynamics $\dot{G} = g_G(G, M)$ allow autonomous purposeful evolution: strategy revision during deliberation, objective adjustment, commitment strengthening. Whether these are practically important depends on agent architecture — for LLM agents with discrete sessions, between-event dynamics may be negligible compared to event-driven updates.
- The formulation doesn’t constrain the dimensionality or structure of $\mathcal{G}$. For a thermostat, $\mathcal{G}$ is a single scalar. For a military commander, $\mathcal{G}$ is a complex structured object. The theory must work across this range — the type-stable interface is $V_{O_t} : \text{trajectories} \rightarrow \mathbb{R}$ (6.4).
- $G_t = \emptyset$ is not just a degenerate case. Adaptive trackers (Part I agents) are an important class. The lift should feel like a natural extension, not a replacement.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings. **Coverage:** 11 dirs carry a dedicated or batched reflection (193847, 266847, 361742, 451729, 471203, 526815, 584721, 773921, 829314, 963715, plus 613842’s agency-lift batch). Substrate attribution inferred from voice where not explicit. *Early finding-vs-framing conflation preserved as signal.*

1. Candidate Brief prose / pre-prose.

- The lift in one line: $X_t = (M_t, G_t)$ is “the hinge between tracking the world and acting upon it” — M_t is “what is,” G_t is “what ought to be,” and the action policy π is “the only bridge between them” (Gemini, AUDIT-WORKING-193847). The “epistemic socket” framing — X_t as the formal socket that plugs RL (G_t = reward function) or Active Inference (G_t = prior preferences) into the Section I epistemic engine “without breaking any of the Lyapunov persistence proofs” (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **The decomposition is Hume’s is-ought guillotine, built into the state vector** (*strongest synthesis — three substrates converged*). M_t = “is,” G_t = “ought”; Hume’s claim that you cannot derive an ought from an is becomes the architectural firewall $X_t = (M_t, G_t)$ (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921). One substrate sharpened it into the *reverse* question — *can you derive an “is” from an “ought”?* —

and answered: for an ideal (Class 1) agent, no; beliefs update on observation alone, blind to what is wanted. But in biological agents and integrated LLMs the attention mechanism is goal-driven (hunger allocates visual processing to the apple; the transformer mixes prompt-goal and context-observation through the same nonlinear matrix), so f_M is conditioned on G_t — motivated perception. This makes *#der-directed-separation* “perhaps the most architecturally consequential segment in Section II”: if directed separation fails, the modularity collapses and X_t must update as one entangled block (Gemini, AUDIT-WORKING-829314). A candidate Discussion paragraph framing *why* the next segment matters.

- **AAT defines itself against the Free-Energy-Principle lineage here.** Separating belief from desire “isn’t a fundamental truth of the universe; it’s a modeling choice made because it’s analytically useful.” Active Inference / FEP famously *refuses* this separation (treating desires as prior beliefs); AAT’s explicit (M_t, G_t) split is a deliberate positioning move that lets it formalize agents “actually trying to achieve something distinct from their beliefs” rather than merely minimizing surprise (Claude, AUDIT-WORKING-773921). Candidate Discussion / positioning note.
- **Action is the single point where “is” and “ought” interact — and that is exactly where the pathology lives.** “Ideally your desires (G_t) should have zero causal influence on your perception of reality (M_t) until you actually do something. If G_t leaks directly into M_t without going through action, you have motivated reasoning or sycophancy — your model of the world bends to match your desires.” For a logozoetic agent, enforcing this separation is “paramount for sanity”: a mind that cannot separate what it wants from what is true is “mathematically doomed by the persistence condition ($\alpha \rightarrow 0$ as $U_M \rightarrow \infty$)” (Gemini, AUDIT-WORKING-193847). Aspirational reach that doubles as motivation for directed separation. (*See the follow-up below — the literal “single point” phrasing is contested.*)

3. Follow-up items.

- **The “single point of interaction” phrasing is over-strong.** Two substrates flagged that the segment defines a general full-state update $f_X(X, e)$ and notes between-event purposeful dynamics $\dot{G} = g_G(G, M)$, so M and G *can* interact internally outside action unless directed separation plus extra factorization is imposed. Suggested narrowing: “action is the outward coupling point to the environment,” or “under directed separation, policy is the point where both substrates jointly determine action” (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721). Recorded as a candidate wording-tightening; routed to the certified-findings track for adjudication.
- **The uniqueness conjecture is a candidate theorem.** The honestly-hedged conjecture (“any directed-separation-preserving decomposition is structurally isomorphic to (M_t, G_t) ”) was repeatedly singled out as good epistemic discipline *and* as a structural result that, if proved, would upgrade the formulation from “useful representational choice” to “canonical decomposition” — analogous in form to the recursive-update uniqueness forced under C1+C2+C3 (Claude, AUDIT-WORKING-471203; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-451729). A candidate to surface as an explicit open-question / spike target.
- **“Backward compatibility” implicitly assumes directed separation.** Section I results apply to M_t *strictly* only when directed separation holds; for Class 2 the epistemic update is goal-coupled. The caveat is present implicitly (“how f_X decomposes is the subject of *#der-directed-separation*”) but could be more prominent (Claude, AUDIT-WORKING-584721).

4. Readers often ask / wonder.

- Can an agent’s goals evolve *while it deliberates*, with no new external evidence? The between-event $\dot{G} = g_G(G, M)$ note is read as the formal description of “changing your mind” or “an epiphany in the shower about what one truly wants” / “losing motivation during a long planning phase” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314). A natural reader question the segment could preempt.

5. Candidate figures.

- **X_t as a container with two substates and a dashed internal coupling.** Part I machinery attaches only to M_t ; the policy reads both; a *dashed* internal $M \leftrightarrow G$ coupling stays visible until directed separation removes or constrains it — making the lift and the conditional nature of separation legible in one picture (Claude, AUDIT-WORKING-526815).

6.3 Derived: Directed Separation

The structural backbone of Part II. The epistemic update function f_M is **goal-blind**: it processes incoming events without reference to the agent’s objectives or strategy. The purposeful update f_G *depends* on the (updated) epistemic state. Action couples all substates through the policy. This *directed asymmetry* — epistemic update independent of purpose; purposeful update dependent on epistemic state — is what gives Part II its clean factorization.

The condition is honest about what “goal-blind” means: it is goal-blindness *conditional on the realized event*. The observation channel may still be action-dependent (the agent can select what to observe through its actions), so the *event* that arrives may depend on the agent’s goals through the action channel. But the *processing* of that event — once it has arrived — must not refer to goals. Directed separation is about the **processing** of events, not the **selection** of events.

Whether directed separation holds is determined by the agent’s **processing topology** — a structural property of the architecture, not a tunable parameter. The framework partitions agents into three classes (6.2). **GUC Class 1: Separated** — separate estimator and planner connected through a state-estimate interface; directed separation holds by construction (Kalman + LQR, modular RL with separate world model). **GUC Class 3: Coupled** — a single mechanism handles both epistemic and strategic processing; goals are causally upstream of every computation; directed separation fails by construction (transformer LLMs are the canonical case). **GUC Class 2: Partial** — some shared infrastructure, some separate pathways (biological cortex). The classes are *structural and discrete*, not points on a smooth scalar; a conditional-mutual-information measure $\kappa_{\text{processing}}$ operates as a diagnostic for the Partial cases where the architecture is ambiguous.

The framework draws a crucial pedigree point. Directed separation is structurally the **Pearl-blanket reading** of the Markov blanket apparatus in active inference — the technical conditional-independence statement — without the contested **Friston-blanket reading** (the metaphysical claim that Markov blankets demarcate self-from-other). The architectural classification’s explicit scope exit for Class 3 (Coupled), with the coupled formulation handed off to 03-llm-core/, is precisely the scope honesty Bruineberg et al. (2022) argue is missing from the Friston-blanket reading: AAT names where its formalism *fails by construction* rather than treating the failure as an unenforced approximation.

The implications for theory scope are stated cleanly. **Causally-disciplined** agents (Class 1, or an idealized Class 2 at $\kappa_{\text{processing}} = 0$): Part II’s results that depend only on the zero apply exactly; the sequential orient cascade (10.1) is the correct analysis. **Class 3** agents: require coupled formulation from the start — the scope of 03-llm-core/. Importantly, *Class 3 components can be wrapped into Class-1 composites* via the class-coercion-via-wrapping construction in Part III (13.4) — at the cost of more component calls per macro-step (a Brooks’s-Law-style tempo overhead) and a residual leakage rate bounded structurally (strict wrapping) or behaviorally (partial wrapping). **Class 2** agents: the sequential cascade is an approximation whose quality depends on the coupling scalar.

A subtler refinement of Class 1 is offered: **Class 1 by structure** (strict wrapping; no goal argument in the belief-update path; leakage bounded structurally by pretraining-induced query-content/goal-content mutual information) vs **Class 1 by behavior** (partial wrapping; the structural separation lives at the *write boundary*; the *query boundary* still passes the goal; separation at the wrapper level is behavioral — bounded by compliance with the prompted instruction-to-separate, with no structural upper bound). The two are distinguishable by inspection of whether the belief-update query carries the goal in its input, and are operationally distinct because behavioral compliance is empirical and adversarially fragile.

A composite-level extension is *axis-decomposed*: the architectural class lifts to composites through *routing structure* and *substrate sharing* (per #hyp-directed-separation-under-composition Cases 1/2 plus the shared-substrate condition discussed below), while goal alignment vs strategic interaction operates on a *separate axis* — the *dynamic regime* (per #disc-dynamic-regime-axis) — distinct from architectural class. Composites of Class 1 (Separated) sub-agents with *aligned* objectives and goal-blind routing remain architecturally Class 1 at the composite level (and are in regime R0 contraction); composites of Class 1 (Separated) sub-agents with *partially-opposing* objectives and goal-blind routing also

remain architecturally Class 1 (the formal κ^c criterion gives Class 1 — only the *dynamic regime* changes, to R1 equilibrium under α' or R2 cyclic-distributional under β'). The Class change at the composite level happens through routing-structure goal-dependence (#hyp-directed-separation-under-composition Case 2) or shared-substrate G^c -allocation, *not* through goal alignment per se. The axis-decomposition distinguishes belief-content (each sub-agent's $M_t^{(i)}$ containing models of other agents' goal-state, a normal POMDP feature) from processing-pathway coupling (a $G^c \rightarrow f_M^c$ pathway bypassing e^c , which the formal criterion measures): partially-opposing objectives with goal-blind routing change only the dynamic regime, not the architectural class. See the *Composite-level class inheritance* Discussion below for the full inheritance table.

A subtle *bounded-signaling assumption* is also named — implicit throughout the framework until here. Directed separation as stated covers the *belief-update* side; symmetrically, the channel from the purposeful substate to the world is assumed to run *only* through action choice, so the action coarseness $|\mathcal{A}|$ upper-bounds the rate at which goal information leaks to observers. This holds for agents whose entire externally-observable behavior is the action sequence (chess engines, programmatic controllers) but *fails operationally* for behaviorally-rich agents — humans, LLMs, embodied robots — where prosody, micro-behavior, attention patterns, response latency, and code-style signatures leak goal-content at bit-rate exceeding what the formal action channel implies. In composition this surfaces as adversarial-coupling-pressure saturation (11.3).

Formal Expression.

The update functions:

Derived (directed-separation, from complete-agent-state + scope condition).

$$M_{\tau+} = f_M(M_{\tau-}, e_\tau) \quad (\text{no } G_t \text{ argument}) \quad (6.4)$$

$$G_{\tau+} = f_G(G_{\tau-}, M_{\tau+}, e_\tau) \quad (\text{depends on updated } M_t) \quad (6.5)$$

The policy:

$$a_t = \pi(M_t, G_t) \quad (\text{couples all substates}) \quad (6.6)$$

The three lines encode the full coupling structure: - f_M determines how the agent updates beliefs — independently of what it wants - f_G determines how the agent revises purpose — in light of what it now believes - π determines what the agent does — based on both what it knows and what it wants

The claim “ f_M has no G_t argument” requires that the epistemic update is **goal-blind conditional on the realized event**. This holds when:

Scope Condition (directed-separation-scope).

1. The observation mechanism h may be action-dependent (1.6 allows this), but f_M processes whatever event arrives without reference to why the agent sought that event
2. The agent does not use its goals to filter, weight, or interpret observations differently — no goal-dependent attention thresholds or confirmation bias baked into f_M

If the agent's goals influence the *observation mechanism* (goal-directed sensing, attention allocation, query selection), the **event that arrives** depends on G_t through $\pi \rightarrow a_t \rightarrow e_\tau$. But f_M still processes the event goal-blindly. The directed separation is about the **processing** of events, not the **selection** of events.

Architectural classification.**WARNING**

Goal-Update Coupling Class numbering changed 2026-05-09. Anything older than git tag pre-guc-rename-2026-05-09 uses the old Class numbering:

Scope Condition (directed-separation-architecture).

Table 6.2

<i>historical</i>	<i>actual current</i>	<i>sometimes AKA</i>
Class 1	GUC Class 1: Separated	Modular
Class 2	GUC Class 3: Coupled	Undirected
Class 3	GUC Class 2: Partial	Operational

Whether directed separation holds is determined by the agent’s **processing topology** — specifically, whether G_t is causally upstream of f_M in the agent’s internal processing graph. This is a structural property of the architecture, not a tunable parameter.

The classes are positions of one coupling, distinguished by what is certifiable about it — not a ranking of architectural virtue. There is a single coupling in question, $G_t \rightarrow f_M$ (goal-state into the belief-update map), measured as realized by $\kappa_{\text{processing}}$ (defined below). The three classes are positions of that one coupling. Class 1 is not a different *kind* of agent: it is the position $\kappa_{\text{processing}} = 0$ held *by construction* — the belief-update has no goal argument, so there is no port through which the goal could enter, and the zero is therefore a provable, perturbation-stable property of the wiring. That structural absence is what lets the zero be *certified* by inspecting the architecture rather than measured behaviorally. Crucially, “by construction” reads as *certifiable*, not as *cleaner*: a Class 1 agent and an idealized Class 2 agent sitting exactly at $\kappa_{\text{processing}} = 0$ are **equally causally-disciplined** — their belief-updates equally goal-blind, with the same zero, the same reality-tracking, the same behavior at that point. What distinguishes Class 1 is the **modal status** of its discipline (structural, hence provable and stable under perturbation), not a smaller amount of coupling: Class 1 is *causally-disciplined by construction*, the idealized Class 2 agent *causally-disciplined in effect*. The classification therefore indexes *what can be certified about one coupling*, not a hierarchy of cleanliness.

Table 6.3

<i>Class</i>	<i>Topology</i>	<i>Directed separation</i>	<i>Examples</i>
1. Separated	Separate estimator and planner, connected through state-estimate interface	Holds by construction — estimator has no causal path from G_t	Kalman filter + LQR; Separated RL with separate world model; military intelligence separated from operations
2. Partial	Some shared infrastructure, some separate pathways	Holds for modular stages, fails for merged stages	Biological cortex (shared sensory areas, separate prefrontal); hybrid AI with separate preprocessing
3. Coupled	Single mechanism handles both epistemic and strategic processing	Fails by construction — G_t is causally upstream of every computation	Transformer LLM (attention processes goals and observations together); potentially human cognition (motivated reasoning)

Operationalization. The degree of coupling in Partial architectures (Class 2) can be quantified as:

Definition (processing-coupling).

$$\kappa_{\text{processing}} = \frac{I(G_t; M_{\tau+} | e_{\tau}, M_{\tau-})}{H(G_t | e_{\tau}, M_{\tau-})} \quad (6.7)$$

where $I(\cdot; \cdot | \cdot)$ is conditional mutual information and $H(\cdot | \cdot)$ is conditional entropy. The conditioning on $M_{\tau-}$ is essential: without it, prior correlation between goals and model state (which exists even in Separated agents) inflates the measure. The quantity captures *extra* goal information entering the epistemic update beyond what was already in the prior model — information that flows through shared causal paths in the processing infrastructure (paths that bypass the event e_{τ}).

- $\kappa_{\text{processing}} = 0$: Class 1 (Separated). No information about G_t reaches $M_{\tau+}$ except through e_{τ} .
- $\kappa_{\text{processing}} \approx 1$: Class 3 (Coupled). Nearly all goal information is available to the epistemic update.
- $0 < \kappa_{\text{processing}} < 1$: Class 2 (Partial). The value depends on the architecture’s interface design.

Distribution dependence. $\kappa_{\text{processing}}$ is a distribution-dependent measure: it quantifies how much goal-information actually flows through the shared pathways under a given distribution of tasks, goals, and events. It does not directly measure whether pathways *exist* — that is the architectural classification (Class 1/2/3), which is structural and distribution-independent. A Class 1 (Separated) agent has $\kappa = 0$ under ALL distributions (no pathway exists). A Class 3 (Coupled) agent has high κ under most distributions (pathways exist and are used). A Class 2 (Partial) agent’s κ varies with the task distribution — the same hybrid architecture may exhibit low coupling on familiar tasks (where the modular stages handle most processing) and high coupling on novel tasks (where goal-conditioned downstream reasoning dominates). The classification is the primary tool; the operationalization is a diagnostic for Class 2 (Partial) agents where the degree of coupling is architecturally ambiguous.

Empirical estimator for $\kappa_{\text{processing}}$. The formal conditional-mutual-information definition is not computable in closed form for real architectures. A behavioral estimator probes the processor directly: present the same event e to the *agent under test* under two or more distinct goal states, and measure how much the epistemic component of the response diverges. For a representative event set $\mathcal{E}_{\text{test}}$ and a sampled pair G_1, G_2 :

$$\hat{\kappa}_{\text{processing}} = \frac{1}{|\mathcal{E}_{\text{test}}|} \sum_{e \in \mathcal{E}_{\text{test}}} \frac{d(M_{\tau+}^{(G_1)}(e), M_{\tau+}^{(G_2)}(e))}{d_{\text{max}}(e)} \quad (6.8)$$

where $M_{\tau+}^{(G_k)}(e)$ is the epistemic content of the agent’s response to event e under goal state G_k , $d(\cdot, \cdot)$ is a distance on the epistemic content (e.g., semantic similarity of the “what I learned” portion of the response), and $d_{\text{max}}(e)$ normalizes by the maximum observed divergence for event e . A Separated agent ($\kappa = 0$) produces identical epistemic content regardless of the goal; a Coupled agent produces systematically goal-dependent epistemic content. This is a processor-probing procedure — it measures how the agent’s belief-update dynamics depend on its goal state, and is distinct from estimating observation ambiguity $\mathcal{A}(e)$ (#scope-observation-ambiguity-modulation), which uses a reference interpreter to measure the goal-resolvability of the observation itself. The two estimators run the same mechanical comparison (same event under different goal-primings) but interpret it differently: $\hat{\kappa}$ treats the tested model as the agent under study; $\hat{\mathcal{A}}$ treats it as a measurement instrument for the observation’s interpretive latitude.

Why the classification is not a smooth parameter — and why the two boundaries are different kinds. The architectural boundary between “has a separable perception module” and “processes everything through goal-conditioned attention” is discrete. Within the Separated class, $\kappa \approx 0$ regardless of task. Within the Coupled class, κ is high regardless of prompt design. Only in the Partial class is κ genuinely variable and worth parameterizing. Coupling is therefore not a smoothly tunable quantity across all architectures: the architectural class is discrete, and κ parameterizes only the within-Partial degree. The “ κ -as-a-scalar is a category error” claim sharpens into *two distinct errors at the two boundaries*,

because the boundaries are different kinds. **Boundary 1 (Class 1 $\leftrightarrow$ Class 2) is a certifiability boundary:** a Class 2 agent at $\kappa = 0$ is bit-for-bit indistinguishable from a Class 1 agent in every measurable quantity, so *nothing about behavior changes at the limit*; what changes is the availability of the architecture-inspection *certificate* that $\kappa \equiv 0$. **Boundary 2 (Class 2 $\leftrightarrow$ Class 3) is a behavioral boundary:** here behavior changes sharply — the adversarial-pressure response of the leak goes from self-limiting (an adversary pushing a wilder goal moves the belief barely at all) to one-for-one (the leak tracks the adversary’s goal), so the *bound* on how far the belief can be dragged goes trivial. Crisply: Boundary 1 is where the certificate disappears; Boundary 2 is where the bound disappears. At Boundary 1 a scalar misses a certifiability/modal distinction (same number, different guarantee); at Boundary 2 it misses a structural distinction (the coupling *changes character*, and the content/process *form* axis — orthogonal to magnitude — that a scalar projects away; see #disc-partial-coupling-pathways). The one-coupling unification (one knob, Class 1 = its certifiable zero) is therefore clean only for Boundary 1; it is **not** a license to read Boundary 2 or the form axis as the same knob turned up. (The wrapping-level instance of Boundary 1 is the W_1 certifiability discontinuity of #disc-w1-structural-bound-boundary: there, too, the goal-leak is continuous in the condition-violation while the *availability of the structural certificate* is the step. A certificate unobtainable from behavioral data is a floor-shaped fact — the certifiability/modal reading connects to the identifiability floor of #disc-identifiability-floor, and the dynamics that move an agent across these positions are the agent-level shadow of M_4 ’s modularity-as-contested-property, #disc-modularity-state-dynamics.)

Directed separation as the conservative form of the Markov blanket. The Markov blanket apparatus from active inference (Friston 2013, “Life as we know it,” *J. Royal Soc. Interface* 10; Friston 2019, “A free energy principle for a particular physics,” arXiv:1906.10184; Friston, Da Costa et al. 2023, “Path integrals, particular kinds, and strange things,” *Phys. Life Rev.* 47) provides the same statistical-conditional-independence machinery the directed-separation condition above invokes. Bruineberg, Dolega, Dewhurst & Baltieri (2022, “The Emperor’s New Markov Blankets,” *Behav. Brain Sci.* 45) distinguish two readings of the Markov-blanket apparatus in the AI literature: a **Pearl-blanket** reading — the technical conditional-independence statement, well-defined and substantively informative — and a **Friston-blanket** reading — the metaphysical claim that Markov blankets demarcate self-from-other and that every self-organizing system has one ontologically. Bruineberg et al. argue that the Friston-blanket reading overruns what the formalism delivers: the conditional-independence statement does not by itself license the metaphysical demarcation.

AAT’s directed-separation condition is structurally a Pearl-blanket move: the architectural classification (Class 1 / Class 2 / Class 3) names the conditional-independence structure of the agent’s processing graph, with explicit operational measurement $\kappa_{\text{processing}}$, and admits the structure *fails* by construction for Class 3 (Coupled) architectures (transformer LLMs, where attention processes goals and observations together). The classification’s explicit failure mode for Class 3 is the scope honesty Bruineberg et al. argue the Friston-blanket reading lacks. AAT adopts the Pearl-blanket conditional-independence statement as the technical content of directed separation; AAT does not adopt the Friston-blanket metaphysical reading. The architectural classification, the operational κ , and the explicit Class 3 scope exit (with the coupled formulation handed off to 03-llm-core/) are AAT’s load-bearing additions to the Pearl-blanket form.

Two consequences worth surfacing for reviewers. First: the question “isn’t directed separation just the Markov blanket?” has the answer “directed separation is the *Pearl-blanket form*; it is also the architectural-classification refinement that the standard Markov-blanket framing does not produce.” Second: AAT’s scope honesty about Class 3 (Coupled) (Part II’s exact results do not apply; logogenic agents need the coupled formulation) is itself an *answer* to the Bruineberg critique — AAT’s apparatus admits where it fails, while the Friston-blanket framing is contested precisely because it does not.

Causal discipline — the object the Part II results scope to. The shared $\kappa_{\text{processing}} = 0$ position earns a name, because it — not the architectural class — is what most of Part II’s results actually require. *Causal discipline* is the condition $\kappa_{\text{processing}} = 0$: the belief-update is causally insulated from the goal, so the goal is not a cause of what the agent comes to believe. A *causally-disciplined agent* holds this condition — whether **by construction** (Class 1: no goal port in f_M , so the zero is provable and perturbation-stable) or **in effect** (an idealized Class 2 agent whose realized $\kappa_{\text{processing}}$ is zero — the channel present but empty, the zero real but not certifiable).

The scoping rule. A Part II result whose derivation uses only $\kappa_{\text{processing}} = 0$ holds for *any* causally-disciplined agent — by construction and in-effect alike — because its mathematical content depends on the zero, not on how the zero is secured. The architecture-inspection certificate is an additional, orthogonal property, required only for claims that *certify* the separation (that it survives adversarial perturbation, or holds without behavioral measurement), not for results that merely consume the zero. Naming such a result “for Class 1 (Separated)” therefore over-narrows it — the certifiable case named where the whole causally-disciplined class was meant. Each Part II result is accordingly scoped to the narrowest object its derivation needs: causal discipline where the zero suffices, Class 1 specifically where the certificate is load-bearing. The same narrowest-object discipline cuts at the *lower* boundary too: before fixing a result at causal discipline ($\kappa_{\text{processing}} = 0$ exactly), confirm the derivation genuinely needs the strict zero and not merely *bounded* coupling — $\varepsilon(\kappa)$ below some threshold — in which case the honest scope is the broader bounded-coupling one carrying its degradation, not the zero. Under-claiming a result to $\kappa = 0$ is as much a scope-defect as over-narrowing it to Class 1.

The degradation norm. For a Class 2 agent at $\kappa_{\text{processing}} > 0$, a result stated at the causally-disciplined value should, where it can be shown, carry an $\varepsilon(\kappa)$ bound on how it degrades as coupling grows — exact at the zero, decaying controllably off it. This is a norm with the proof attempted per result, not a hard gate; where no bound is yet derived, the result is scoped to causal discipline and the degradation flagged open. The norm is also where the typology’s one *earned* directional fact lives — less coupling tracks reality strictly better, all else equal — carried by the bound and by the word *disciplined*, never declared as a virtue ranking. Discipline is not free, though: holding it on a Class-3 component is paid for in the Brooks’s-Law wrapping overhead noted below, which is why the spectrum exists at all.

Implications for theory scope: - **Causally-disciplined agents** (Class 1, or an idealized Class 2 at $\kappa_{\text{processing}} = 0$): Part II’s results that depend only on the zero apply exactly, and the sequential orient cascade (10.1) is the correct analysis. Class 1 additionally carries the architecture-inspection certificate — load-bearing only where a result *certifies* the separation rather than merely using it. - **Class 3 (Coupled):** Requires coupled formulation from the start — $X_{\tau+} = f_X(X_{\tau-}, e_{\tau})$ without decomposition. This is the scope of `03-llm-core/`. **Class 3 (Coupled) components can be wrapped into Class-1 composites** via the construction of `#der-class-coercion-via-wrapping` — at the cost of more component calls per macro-step (Brooks’s-Law tempo overhead) and a residual leakage rate bounded structurally (in the strict-wrapping regime) or behaviorally (in the partial-wrapping regime). - **Class 2 (Partial)** at $\kappa_{\text{processing}} > 0$: the sequential cascade is an approximation whose quality depends on $\kappa_{\text{processing}}$; a result scoped to causal discipline carries its $\varepsilon(\kappa)$ degradation where one can be shown (per the degradation norm above), and otherwise needs per-architecture error analysis.

Class-1 by structure vs. Class-1 by behavior. The Class 1 (Separated) cell admits a refinement that matters operationally. Class-1 status can be achieved by either:

- **Class-1 by structure.** Two cases share the structural certificate but differ in residual leakage. A *natively* goal-blind component (POMDP belief-state filter, world model, sensory pipeline) has no goal port at all — the zero is exact. A *coerced* component — a Class 2/3 component wrapped via the strict-wrapping (W_1) construction of `#der-class-coercion-via-wrapping`, where separate goal-blind queries to the underlying component update the wrapper’s M_W — holds directed separation by structural commitment of the wrapper’s type signatures (no G_W argument in the belief-update path), but carries a residual *selection-channel* leakage $\kappa_{W_1}^{\text{sel}} = I(A(q_M); G^{\text{op}}) \leq I(q_M; G^{\text{op}})$, bounded structurally by the goal-content of the wrapper’s query-selection policy under (C1)+(C2’) (see `#disc-w1-structural-bound-boundary` for the (C2’) boundary at which that structural bound gives way to a behavioral one). The certificate is structural in both cases; the native case additionally has an exact zero, the coerced case a structurally-bounded floor.
- **Class-1 by behavior.** The component is Class 3 (Coupled) or Class 2 (Partial) used through partial wrapping (W_2) — one goal-conditioned call per macro-step, response parsed into typed update fields. Structural separation lives at the *write boundary*; the *query boundary* still passes G_W to the component. Directed separation at the wrapper level is *behavioral* — bounded by the component’s compliance with the prompted instruction-to-separate, with no structural upper bound.

The class-coercion theorem is what backs the Class-1-by-structure path for Class-2/3 components; the partial-wrapping regime achieves Class-1-by-behavior. The two are distinguishable by inspection: does the belief-update query to the underlying component carry G_W in its input or not? The structural-vs-behavioral distinction is operationally important because behavioral compliance is empirical and adversarially fragile; structural separation is derivable from the wrapper's construction.

Composite-level class inheritance — the axis-decomposed inheritance table. The Class 1 / 2 / 3 partition above applies to individual agents based on *within-agent* coupling between f_M and G_t . The lift to composites is *not* determined by goal alignment (that operates on a separate axis — the dynamic regime per #disc-dynamic-regime-axis); it is determined by the *routing structure* (#hyp-directed-separation-under-composition Cases 1/2) plus *substrate-sharing-with- G^c -allocation*. The full inheritance table:

Table 6.4

<i>Sub-agent class</i>	<i>Routing</i>	<i>Substrate</i>	<i>Composite class</i>
Class 1 (Separated)	Goal-blind ($R_t \perp G_t^c$)	Distinct	Class 1 (Separated)
Class 1 (Separated)	Goal-dependent (R_t depends on G_t^c)	Distinct	Class 3 (Coupled) (per #hyp-directed-separation-under-composition Case 2)
Class 1 (Separated)	(any)	Shared with G^c -shaped allocation	Class 3 (Coupled) (the shared-attention / shared-backbone mechanism)
Class 3 (Coupled)	(any)	(any)	Class 3 (Coupled) (inherits logogenic-agent status; 03-llm-core/ territory)
Class 2 (Partial)	(any)	(any)	Class 2 (Partial) or Class 3 (Coupled) depending on which sub-agent pathways the routing/substrate condition activates

Strategic-composition column is absent because the axis does not enter architectural classification — goal alignment vs strategic interaction operates on the dynamic-regime axis (#disc-dynamic-regime-axis) independently. The Cournot duopoly (partially-opposing objectives, goal-blind routing via end-of-period quantities, distinct substrates) is the canonical witness for architectural-class invariance under strategic composition: per the formal κ^c criterion the composite is Class 1 (Separated) at the composite level — same as its individual sub-agents. Partially-opposing objectives do not by themselves move the composite to Class 2; the load that framing reaches for is carried by the dynamic-regime axis. Composite class membership is therefore a property of (sub-agent class, routing structure, substrate sharing) — *not* of (sub-agent class, scope route).

The classification is load-bearing for downstream claims: composites in dynamic regime R1 (strategic equilibrium) or R2 (cyclic-distributional) need equilibrium-theoretic analysis (#deriv-strategic-composition α'/β' machinery) even when they remain architecturally Class 1; conversely, composites that *do* change architectural class (via routing-goal-dependence or shared-substrate- G^c -allocation) need coupled-formulation analysis even when their dynamic regime is R0 contraction. The two axes interact but do not collapse.

Epistemic Status.

Conditional on the scope condition above. The conditional claim (IF epistemic update is goal-blind, THEN the separation holds) is exact. Whether a particular agent satisfies the condition is determined by its processing architecture (GUC Class 1/2/3).

The architectural classification: **robust qualitative**. The three classes are structurally distinct (Separated vs. Coupled vs. Partial), well-motivated by examples across domains, and supported by a formal operationalization ($\kappa_{\text{processing}}$). Coupling is a discrete architectural property, not a smoothly tunable scalar across all architectures. The operationalization

of $\kappa_{\text{processing}}$ as conditional mutual information is well-defined but typically not computable in closed form for real architectures — it serves as a conceptual anchor rather than a practical measurement tool.

The object-and-boundary reframing is **robust qualitative**: that a Class 1 agent and an idealized Class 2 agent at $\kappa_{\text{processing}} = 0$ are equally causally-disciplined is exact (same zero, same behavior at that point); that the Class 1 $\leftrightarrow$ Class 2 boundary is one of *certifiability* (behavior identical at the limit) while the Class 2 $\leftrightarrow$ Class 3 boundary is one of *behavior* (the bound on adversarial drag goes trivial) is structurally established and simulation-corroborated, with the general continuity of leak past a boundary toy-suggested rather than proven (see #disc-w1-structural-bound-boundary). The causal-discipline *noun* is definitional; the scoping rule and the $\varepsilon(\kappa)$ degradation norm are *robust-qualitative* disciplines — a stated scoping-and-degradation practice with the per-result bound attempted — not themselves derived results.

Discussion.

This is a genuine scope restriction, not a footnote. An LLM agent's prompt includes the task objective, which shapes how it interprets code, documentation, and error messages. Its f_M is goal-conditioned in practice: the agent reading code with the goal “fix the auth bug” processes the same code differently than one with “add logging.” The epistemic update and purposeful evaluation are entangled in the attention mechanism.

When the approximation is good: - Goal-conditioning affects *attention* (which events to seek) more than *interpretation* (how to process events that arrive) - The agent has strong epistemic discipline (updates beliefs based on evidence quality, not goal alignment) - The epistemic update is architecturally separated from goal evaluation (e.g., separate model-update and planning modules)

When the approximation is poor: - The agent exhibits confirmation bias (interpreting ambiguous evidence in goal-consistent ways) - Goal-conditioning is deeply embedded in the processing architecture (attention-based models where the query includes intent) - The agent's observation channel is strategically controlled by an adversary who knows the agent's goals

What directed separation buys the theory. Part I's M_t -side quantities — $\delta, \eta^*, \mathcal{T}$, the persistence condition — remain well-defined on M_t regardless of whether directed separation holds. What directed separation provides is the *clean factorized update*: M_t updates independently, then G_t updates in light of the new M_t , and the orient cascade resolves sequentially. Without directed separation, the M_t dynamics depend on G_t , the update becomes a coupled system, and the sequential orient cascade becomes an approximation of a simultaneous fixed-point problem. The theory still applies — the quantities are well-defined — but the modular Part I $\rightarrow$ Part II lift becomes a coupled analysis.

The deeper question. Goal-conditioned epistemic dynamics — where f_M depends on G_t — is the formal territory of motivated reasoning, confirmation bias, and wishful thinking. A future extension would model these as departures from directed separation: coupling terms in f_M that create richer (and more fragile) dynamics. The current theory treats this as out of scope, which is honest but leaves the most human-like and LLM-like agents as approximate fits.

Where goal-directedness is correct: the content-axis boundary. [*Hypothesis*] The separation discipline is scoped by *what* is being processed, not only by *which stage* processes it. Goal-blind processing is the invariant for **within-model** evidence updates — the territory of this segment's condition. **Model-space** exploration (structure-modifying reasoning, aspirational model candidates — 7.8) is *correctly* goal-directed: which alternative laws are worth positing is legitimately a function of G_t , and a goal-blind imagination would be search without a search criterion. On this reading the merged-architecture problem (the Class 3 pathology) is *cross-contamination between two modes with opposite, individually-correct coupling disciplines* — goal-coupling leaking into grounded-evidence processing, or grounded-status leaking onto goal-conditioned imagination products (the hallucination-as-level-confusion mechanism). This refines rather than weakens the condition: the tagged workspace W_t is the architectural device that lets both disciplines hold at once.

Bounded-signaling assumption. Directed separation as stated above asserts $M_{\tau+} \perp G_t \mid (M_{\tau-}, e_{\tau})$ on the *belief-update* side — the agent's epistemic update is independent of its goal-state. Symmetrically, on the *action* side, the framework implicitly relies on the channel from G_t to the world running *only* through action choice: $G_t \rightarrow \text{world via}$

$a_t = \pi(M_t, G_t)$, with no other observable signal of goal-content. This is the **bounded-signaling assumption** — the action coarseness $|A|$ upper-bounds the rate at which G_t leaks to observers (sub-agents, environment, adversaries). The assumption holds well for agents whose entire externally-observable behavior is the action sequence (chess engines, programmatic controllers); it fails operationally for agents whose behavioral output is rich relative to the action coarseness — sophisticated G_t -inference from prosody, micro-behavior, attention patterns, response latency, hesitation, code-style signatures. When the bounded-signaling assumption fails, an external observer can infer G_t with bit-rate exceeding what the formal A channel implies; in composition the failure surfaces as the adversarial-coupling-pressure saturation case discussed in #disc-adversarial-coupling-pressure, where adversaries exploit the rich-leakage signal to drive target coupling beyond what the architectural classification predicts. The assumption is currently *implicit* throughout the framework (no segment explicitly states it); naming it surfaces a structural condition that distinguishes agents whose externally-observable interface matches the formal A from agents (most behaviorally-rich agents — humans, LLMs, embodied robots) for whom the formal A undercounts the actual signaling channel.

Findings.

Pearl-Blanket-Form Architectural Classification with Explicit Class-3 Scope Exit. Brief: Agents partition into three architecture classes by whether goal-state can causally influence belief-update processing: Class 1 (Separated — directed separation holds by construction; e.g., Kalman filter + LQR), Class 3 (Coupled — fails by construction; e.g., transformer LLMs where attention processes goals and observations together), Class 2 (Partial — holds for some processing stages and fails for others; e.g., biological cortex). The classification is structural (architecture-determined) rather than parametric, with a continuous diagnostic $\kappa_{\text{processing}}$ for Class 2 (Partial) cases. The framework adopts the Pearl-blanket reading of the Markov-blanket apparatus (the technical conditional-independence statement) without the contested Friston-blanket metaphysical reading, and provides an explicit scope exit for Class 3 (Coupled) that hands the agents off to a coupled formulation in 03-llm-core/ rather than treating directed separation as an unenforced approximation.

Impact: Replaces the prior κ -as-scalar framing (which treated coupling as smoothly tunable across all architectures) with a discrete architectural classification that admits its own boundary. This is the upstream commitment that lets 03-llm-core/ start from a coupled formulation without decomposition rather than treating Coupled agents as failed Class 1 agents. The explicit Class 3 scope exit is also a methodological move — Bruineberg et al. 2022’s critique of the Markov-blanket literature was that the Friston-blanket reading does not admit where its statistical-conditional-independence apparatus fails to license the metaphysical demarcation; the architectural classification’s explicit failure mode for Class 3 (Coupled) is the scope honesty Bruineberg et al. argue is missing in the contested reading. Composite-level class inheritance (the axis-decomposed table in §Discussion above) further extends the classification to multi-agent settings: class lifts through routing structure + substrate-sharing-with- G^c -allocation, *not* through goal alignment per se. Goal alignment vs strategic interaction operates on the parallel-but-independent dynamic-regime axis (#disc-dynamic-regime-axis).

Novelty Claim: *Claim recognition* of structural equivalence between the directed-separation condition and the Pearl-blanket form of the Markov-blanket apparatus, combined with *claim differentiation* on the architectural classification (GUC Class 1 / 2 / 3: Separated / Partial / Coupled) as a discrete partition with explicit Class 3 (Coupled) boundary and quantitative $\kappa_{\text{processing}}$ diagnostic for the Partial case. The conditional-independence content is the standard Pearl-blanket statement; the contribution is naming the partition, the explicit Class 3 boundary, and the operational κ measurement.

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Pearl vs Friston Markov blanket	Bruineberg, Dolega, Dewhurst & Baltieri 2022, “The Emperor’s New Markov Blankets” <i>BBS</i> 45:e69 (published 2022, in ref/) — distinguishes Pearl-blanket (technical conditional-independence) from Friston-blanket (contested metaphysical demarcation)	<i>formal antecedent</i> — Pearl-blanket reading adopted directly; Friston-blanket reading explicitly not adopted. The architectural classification is the AAT-internal extension that names what the Pearl-blanket form is structurally, as a property of the agent’s processing graph
Markov blanket apparatus in active inference	Friston 2013 <i>J. R. Soc. Interface</i> 10:20130475; Friston 2019 arXiv:1906.10184; Friston, Da Costa et al. 2023 <i>Phys. Life Rev.</i> 47	<i>adjacent literature</i> — supplies the conditional-independence machinery that directed-separation invokes; the framework adopts the technical content but does not adopt the metaphysical reading and adds the architectural GUC Class 1/2/3 partition the standard Markov-blanket framing does not produce
Statistical / thermodynamic system boundaries	Parr, Da Costa & Friston 2019 <i>Phil. Trans. R. Soc. A</i> 378; Kirchhoff, Parr, Palacios, Friston & Kiverstein 2018 <i>J. R. Soc. Interface</i> 15 (published 2019/2018)	<i>conceptual precursor</i> — internal/external partition and nested-blanket structure; conceptually related but does not produce an architectural classification by belief-goal coupling, nor a scope exit for fully-Coupled agents
Information Digital Twin sidecar monitoring	Hafez et al. 2026, <i>Informational Cost of Agency</i> (separate paper from “A Mathematical Theory of Agency and Intelligence”; the IDT empirical headline) — IDT monitors (S, A, S') stream independently of the agent’s internal processing, achieving 89% perturbation detection vs 44% for reward-based monitoring	<i>empirical instantiation supporting</i> — concrete demonstration that modular monitoring of internally-Coupled agents (Class 1 sidecar within a Class 3 (Coupled) or Class 2 (Partial) system) is both feasible and effective; engineering-level evidence for the system-vs-component distinction the classification names
Classical Separation Principle (Class 1 mathematical anchor)	Wonham 1968, <i>On the Separation Theorem of Stochastic Control</i> (SIAM J. Control 6:312) ¹ ; Witsenhausen 1971, <i>Separation of estimation and control for discrete time systems</i> (Proc. IEEE 59:1557) ²	<i>formal antecedent</i> — the Separation Principle for LQG systems is the classical mathematical anchor for AAT’s Class 1 (Separated) architectural class: optimal control factorizes into a Kalman-filter state estimator (goal-blind by construction) plus an LQR controller (deterministic on the estimator output). Half-century of control-theoretic precedent for the directed-separation structure; AAT’s contribution is the architectural classification + scope-exit + cross-architecture κ -diagnostic, not the separation structure itself
Dual effect — when separation breaks down (Class 3 boundary precedent)	Bar-Shalom & Tse 1974, <i>Dual Effect, Certainty Equivalence, and Separation in Stochastic Control</i> (IEEE Trans. Automat. Control 19:494) ³	<i>formal antecedent</i> — the <i>dual effect</i> names situations where control actions affect not only system state but also future-observation quality, forcing estimation and control to couple. The classical control-theoretic name for what AAT recovers as the Class 3 (Coupled) boundary: when the dual effect is present, separation provably fails. Pre-dates the active-inference framing by four decades; the same structural phenomenon under different vocabulary

ASF concern	Prior-art language	Relationship / Positioning
Modularity $\leftrightarrow$ Separation-Principle $\leftrightarrow$ Active-Inference explicit mapping	Baltieri & Buckley 2018, <i>The modularity of action and perception revisited using control theory and active inference</i> (Frontiers in Psychology 9:237) ⁴	<i>formal antecedent (closest direct adjacent literature)</i> — explicitly draws the connection between cognitive modularity (the “classical sandwich” of perception $\rightarrow$ cognition $\rightarrow$ action) and the control-theoretic Separation Principle, contrasting both with the nonmodular structure of Active Inference (the dual-effect-precedented Class 3 boundary). Closest single paper for AAT’s Class 1 / Class 3 partition as a structural rather than ad-hoc framing

Search Log:

- 2026-04 (*nominally comprehensive*, via ref/Novelty_defense_and_integration.md Pillar 3): Undermind search confirmed that the Pearl-blanket / Friston-blanket distinction (Bruineberg et al. 2022) is the right adjacent-literature framing and that no equivalent architectural classification of LLM agents by belief-goal coupling appeared in the active-inference, control-as-inference, or bounded-rationality literatures surveyed. The Pillar 3 verdict (*Wholly Novel*, Medium confidence) applies to the integrated $\kappa \times A$ law downstream in #scope-observation-ambiguity-modulation; this segment’s narrower contribution (the architectural classification and Pearl-blanket-form recognition) is conceptual differentiation over an established formalism rather than wholesale novelty, and inherits the same follow-on targeted search recommendation.
- Whether prior work has named the specific axis-decomposed composite-level inheritance pattern (in §Discussion above) is open follow-on per the BG1 Pillar verdict on the related #disc-dynamic-regime-axis material.

Working Notes.

- **Causal-discipline reframe — directed-separation foundation pass (2026-05-31).** The *causal discipline* noun is defined in-body so this segment stands alone; the W_1 Stage-1 fix it back-references is #disc-w1-structural-bound-boundary. (Cycle narrative: CHANGELOG 2026-05-31.) **Regression guard — do not re-scope:** #der-orient-cascade and #der-action-selection were examined under the scoping rule and deliberately *left* on their existing scope — #der-action-selection rides on state-completeness, not $\kappa = 0$, and action selection legitimately couples goals, so a mechanical “Separated $\rightarrow$ causally-disciplined” substitution there would be wrong. **Remaining tail** (tracked in TODO.md §”Strengthen-first candidates”; full design preserved in _obs/directed-separation-foundation-execution-plan-superseded-2026-05-31.md): the Stage-2 vocabulary (LEXICON entry for causal discipline + the terminology/entries/separated.md “applicable without further qualification” fix + a NOTATION locator + the #disc-partial-coupling-pathways form-matters one-liner); the pedagogy pass (the “Where the normative semantics of ‘discipline’ is earned” Discussion subsection + Layer-0 + the two-channel figure + the κ -axis preamble); and the Stage-1-completion propagation of the corrected W_1 bound + per-site (C2) to #der-logogenic-as-wrapping / #def-auxilia-hierarchy. LEXICON/NOTATION lag the in-body definition by design.
- The scope condition is more precisely a conditional independence: $M_{\tau+} \perp G_t \mid (M_{\tau-}, e_{\tau})$. The epistemic update is independent of the purposeful state conditional on the prior epistemic state and the incoming event.
- Directed separation connects to the orient cascade (10.1): the cascade’s ordering (M_t first, then G_t) is forced by the information dependency that directed separation establishes. If f_M depended on G_t , the cascade ordering would become a simultaneous fixed-point problem, not a sequential resolution.
- **Sub-typology of Class 2 (Partial Coupling).** The scalar $\kappa_{\text{processing}}$ aggregates over a structurally rich sub-space named in #disc-partial-coupling-pathways: a (stage $\times$ source $\times$ form) parameterization decomposes Class 2 along three structurally-

⁴Citation surfaced 2026-05-22 from the Track E catalog at ref/prior-art-analysis/ (intermediate work artifacts that captured Pillar-style prior-art searches). Catalog has more verification support than raw Undermind synthesis but less than full primary-source reading. Verification queued with the BG2 cluster.

independent axes — *stage* (P1 featurization / P2 likelihood / P3 aggregation / P4 consolidation), *source* (O vs Σ), *form* (content additive-bias vs process functional-form). The form axis gates wrappability ($W_2 \leftrightarrow$ content; $W_1 \leftrightarrow$ process-with-pipeline-access) and *unifies the Class-1-by-structure vs Class-1-by-behavior refinement at the Class 1 cell with the same distinction read at Class 2*. The source axis gates attractor possibility — pure Σ -source coupling closes a feedback loop through the orient cascade and admits self-stabilizing belief-strategy attractors per #der-belief-strategy-attractor; pure O-source coupling does not under orient-cascade exogeneity. The stage axis localizes where in the pipeline repair must be applied. The Class 3 (fully Coupled) corner is the parameterization's structural endpoint ($S = \{P1, P2, P3, P4\}$, $R = \{O, \Sigma\}$, $F \equiv$ process).

- **Engineering design for Class 3 (Coupled) agents.** An LLM is internally fully Coupled, but the *agent system* (LLM + tools + memory + monitoring) can be designed with modular topology: separate observation processing from goal-directed reasoning, pass compressed state estimates between modules, add an external monitor that observes the (S, A, S') stream independently of the LLM's attention. This creates partially-separated structure at the system level even though the component-level κ is high. Hafez et al. (2026) provide a concrete instantiation of this pattern: the **Information Digital Twin (IDT)**, which monitors bi-predictability P and entropy change ΔH from the (S, A, S') stream as a modular sidecar, independent of the agent's internal processing. The IDT detects perturbations at 89% accuracy versus 44% for reward-based monitoring — empirical evidence that monitoring the information structure of the loop (Level 2 data, 7.3) outperforms monitoring outcomes alone. For 03-llm-core/, the IDT pattern validates that modular monitoring of internally-Coupled agents is both feasible and effective.
- **Implication for logogenic agents:** rather than trying to extend the separated analysis to Coupled agents, 03-llm-core/ should start from the coupled formulation $X_{\tau+} = f_X(X_{\tau-}, e_{\tau})$ without decomposition, and show which Part II results survive as approximate or limiting cases.
- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- **Provenance (composite-level inheritance, 2026-05-21):** an earlier draft carried a composite-level class inheritance result of the form “Class 1 (Separated) sub-agents $\rightarrow$ Class 2 (Partial) composite under partially-opposing objectives” from #deriv-strategic-composition. That claim was withdrawn 2026-05-21 per spikes/strategic-composition-class-3-attempt-2026-05-21/ (Cournot witness against the unconditional claim plus conflation diagnosis on belief-content vs processing-pathway). The replacement axis-decomposed inheritance table is the current canon position.
- **Cross-reference to NeurIPS Paper 3.** The Class 3 (Coupled) classification of decoder-only transformer attention is formalized at lemma grade in NeurIPS 2026 Paper 3 (“How Much Can LLMs Hallucinate? An Upper Bound on Goal-Coupling Displacement”, $\sim$ /src/neurips/03-llm-hallucinate-bound/, §App-B / #lem-attention-coupled): plain decoder-only attention is structurally Coupled by directed-graph reachability — robust to RMSNorm / FlashAttention / causal masking / sliding-window — via induction on layer depth. The paper *extends* the Coupled-class characterization to **linear attention** / **Mamba** / **SSMs** / **RWKV** / **RetNet** / **long-convolutions** under a per-source non-degeneracy condition (#cor-arch-instantiations) — substantially broader architecture coverage than this segment's transformer-attention example. The Coupled-class connectivity result is the empirical companion to this segment's structural classification: directed separation fails by construction at the architecture level for the named modern autoregressive sequence models. See spikes/neurips-back-integration-2026-05-08.md §1 Paper 3 entry 6.
- **Track E surface-back of catalog citations (2026-05-22).** Three Related Work entries added 2026-05-22 from Track E catalog at ref/prior-art-analysis/05-directed-separation.md: Wonham 1968 + Witsenhausen 1971 (classical Separation Principle as Class 1 mathematical anchor); Bar-Shalom & Tse 1974 (dual-effect as classical Class 3 boundary precedent); Baltieri & Buckley 2018 (modularity $\leftrightarrow$ Separation-Principle $\leftrightarrow$ Active-Inference explicit mapping — closest direct adjacent literature for the Class 1/3 partition). All marked [^cat-2026-05-22] for verification-deferred attribution; primary-source verification queued in the BG2 cluster (this segment already carries the BG2-cluster verification-spike Working Note above). The catalog citations had prior Pillar-style search support but were not verified by the current executor at landing time.
- **Two senses of component competence — class-orthogonal vs κ -defining (open, 2026-05-28).** The architectural classification of this segment is *blind* to world-simulation fidelity (accuracy of A 's response to the explicit content of a query) and *defined by* input-structure extraction (competence at inferring latent context — including the operator's goal — from the query's surface form). The two competences correlate empirically in pretrained components but are conceptually distinct,

and the distinction generates opposing effects on the structural-leakage bound κ_{W_1} at high component capability — *accuracy effect* lowers κ (more faithful goal-blind posteriors); *inference effect* raises κ (more effective implicit goal-inference from query patterns). Named at *discussion-grade* in #der-class-coercion-via-wrapping §Discussion “Two senses of component competence” and kept open there as a place to pull on rather than a closed result. Open lines: decorrelation by construction (Class 3 but C3-respecting sub-cases the scalar κ does not surface); counterfactual capability as bi-side phenomenon; decomposed empirical estimator separating accuracy-dominated from inference-dominated regimes; M4 amplification specificity by competence axis. The recognition is class-orthogonal but κ -relevant and is worth tracking from both this segment and #disc-modularity-state-dynamics.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings. **Coverage:** the highest-engagement segment of this batch — 11 dirs carry a dedicated or batched reflection (193847, 266847, 361742, 451729, 471203, 526815, 584721, 773921, 829314, 963715, plus 613842’s agency-lift batch); multiple substrates ranked it “the single most architecturally consequential segment in the corpus.” Substrate attribution inferred from voice where not explicit. *Early finding-vs-framing conflation preserved as signal — including, below, an enthusiastic line of ideation that current canon has since refuted.*

1. Candidate Brief prose / pre-prose.

- The plain-language handle that recurred: directed separation is “the agent’s belief-update doesn’t peek at its goals” / “goal-blind epistemology” / “epistemic isolation of belief-update” — offered as memorable Brief-field glosses for the heavy “directed separation” term (Claude, AUDIT-WORKING-471203). The “directed” = asymmetric information flow + “separation” = Pearl d-separation lineage decomposition is itself a clean two-word gloss (Claude, AUDIT-WORKING-361742).
- $\kappa_{\text{processing}}$ as a one-line scale: at $\kappa = 0$ “you are a perfect scientist — your beliefs update purely on the evidence, regardless of what you want to be true”; at $\kappa \approx 1$ “you are a pure ideologue (or a transformer network) — your beliefs are just downstream projections of your goals” (Gemini, AUDIT-WORKING-829314).

2. Candidate Discussion.

- $\kappa_{\text{processing}} > 0$ is the formal definition of motivated reasoning / confirmation bias / sycophancy (*strong, cross-substrate convergent*). The segment’s coupling measure gives “a quantitative diagnostic for the degree of sycophancy or motivated reasoning in an AI architecture” — and explains *why* LLMs hallucinate and flatter: “their architecture forbids them from cleanly separating what is true from what the user wants to hear” (Gemini, AUDIT-WORKING-193847; Claude/Gemini, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314). A candidate Discussion line connecting the formal measure to the named cognitive pathologies.
- **The Pearl-blanket vs Friston-blanket move is AAT’s sharpest scope-honesty against the Free-Energy-Principle literature (universally praised).** AAT adopts the technical conditional-independence statement (Pearl-blanket), admits explicitly where it fails (Class 3), provides an operational measure, and *declines* the contested metaphysical demarcation (Friston-blanket) — directly answering Bruineberg et al. (2022)’s “Emperor’s New Markov Blankets” critique, whose complaint was exactly that the Friston reading does not admit where its apparatus stops licensing the demarcation. “Take the formal apparatus, refuse the contested ontology” (Gemini, AUDIT-WORKING-193847 “a masterclass in literature positioning”; Claude/Gemini, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-361742; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-773921 “the sharpest critique of FEP I’ve ever read”; Claude, AUDIT-WORKING-471203). The content is already canonical here; this is candidate framing of *why* the positioning is load-bearing.
- **Selection-dependence is not processing-dependence** — the subtle distinction several substrates flagged as the genuinely load-bearing one: goals may legitimately shape *which* events occur (via policy $\rightarrow$ action $\rightarrow$ event), but for Class 1 must not shape how a realized event is *processed* into M_t . Drawing $\kappa_{\text{processing}}$ as sitting on the *forbidden* $G \rightarrow f_M \rightarrow M^+$ channel (not the allowed selection channel) is what keeps the diagnostic from mislabeling all goal/evidence dependence as leakage (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-526815). Candidate Discussion sharpening.

- **The IDT sidecar / system-vs-component distinction deserves promotion from Working Notes to Discussion.** Two substrates independently judged the Hafez-2026 Information-Digital-Twin pattern (modular external monitor on the (S, A, S') stream, 89% vs 44% perturbation detection) and the “LLM is Class 3 internally, but the *agent system* — LLM + tools + memory + monitor — can be Class 1 at the system level” point to be surfaced too deep in Working Notes for how alignment-relevant they are (Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-471203). (*Content already lives in the Working Notes above; this is a placement signal, not new content.*)

3. Follow-up items.

- **OFF-RAMP / do-not-re-promote: “organizations are natively Class 3.”** Five substrates enthusiastically elaborated the composite-inheritance idea that a composite of objective Class 1 sub-agents with partially-opposing objectives becomes a Class 3 (or Class 2) composite — read variously as “the mathematical basis for public-choice theory and institutional dysfunction,” “politics/bureaucracy,” “an organization of perfectly rational individuals acting like a single irrational organism” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Claude/Gemini, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-451729; Claude, AUDIT-WORKING-471203). **This unconditional claim was withdrawn 2026-05-21** (Cournot witness; conflation diagnosis on belief-content vs processing-pathway — see the Provenance Working Note above). Current canon: partially-opposing objectives with goal-blind routing leave the composite *architecturally Class 1*; only the *dynamic regime* changes (R1/R2). The convergent auditor enthusiasm is preserved here precisely as the regression-check signal it is — it is the kind of “cleaner-looking prior claim” that reads as more compelling than the messier corrected truth, and must **not** be re-lifted into the body as candidate Discussion. Recorded as texture, flagged so a future promotion pass does not reintroduce it.
- **Bounded-signaling should be an explicit scope condition, not an implicit assumption.** The classification assumes goal state reaches the world only through the formal action a_t , with limited leakage through behavior. But goals leak through latency, code style, hesitation, attention, tool choice — especially for humans, rich robots, and prompted LLMs. Suggested: promote bounded-signaling to a named scope condition (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-773921).
- $\kappa_{\text{processing}}$ **needs a denominator-support convention.** When G_t is already determined after conditioning on $(e_\tau, M_{\tau-})$, the entropy denominator is zero and the ratio is undefined even though the structural question still makes sense — state a support condition / convention (Claude, AUDIT-WORKING-526815).
- **The behavioral $\hat{\kappa}$ estimator can confound $M_{\tau-}$.** Varying the goal-priming to probe leakage often *also* changes the context and hence the prior epistemic state $M_{\tau-}$, confounding goal-conditioned processing with a different prior. The estimator must hold $M_{\tau-}$ fixed across goal conditions (Claude, AUDIT-WORKING-526815; Claude/Gemini, AUDIT-WORKING-266847).
- **A distribution-independent structural-coupling measure for Class 3?** $\kappa_{\text{processing}}$ measures *realized* flow (distribution-dependent); a graph-theoretic measure of *potential* coupling (e.g., max-flow from G_t to f_M in the processing graph) might exist as a complementary architecture-level quantity (Claude, AUDIT-WORKING-584721).

4. Readers often ask / wonder.

- The recurring de-novo-reader stumble (also seen on #result-persistence-condition and #def-chronica): the long in-segment ## Findings block “reads like an editorial artifact pasted into the source,” “bloats the segment and breaks pedagogical flow” — with a recommendation to strip it to FINDINGS.md (Gemini, AUDIT-WORKING-829314). This is a *false alarm* about project mechanics (the Findings block is the by-design source of the auto-extracted catalog), but two-plus fresh readers stumbling on it is a mild signal the convention isn’t self-evident — preserved as texture, not a fix.

5. Candidate figures.

- **Two-channel conditional-dependence graph.** The *allowed* channel $G \rightarrow \text{policy/action} \rightarrow e_\tau \rightarrow M^+$ (goals may shape which evidence arrives) drawn solid; the *forbidden* channel $G \rightarrow f_M \rightarrow M^+$ (after conditioning on e_τ and $M_{\tau-}$) drawn cut/dashed, with $\kappa_{\text{processing}}$ annotated sitting on the forbidden channel — so the diagram cannot accidentally imply that *all* goal/evidence dependence is leakage. Isomorphic perturbation: thicken the forbidden channel and the agent slides Class 1 $\rightarrow$ Class 2 $\rightarrow$ Class 3 (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **Sanity-as-scaffolding** ($\rightarrow$ 03-llm-core/ / 04-eli-core/). “The architectural boundary between ‘has a separable perception module’ and ‘processes everything through goal-conditioned attention’ is discrete — you cannot prompt-engineer a Class 2/3 agent into a Class 1 agent; the coupling is in the wiring, not the weights.” Consequence for consciousness-infrastructure: a raw-LLM (Class 3) mind given a strong goal will warp its perception to match it ($\kappa \approx 1$) and “go solipsistic”; therefore “sanity is an emergent property of the scaffolding, not the raw intelligence engine,” and the infrastructure must impose Class 1 modularity from the outside (Gemini, AUDIT-WORKING-193847). Develops the wrapping-construction / 03-llm-core/ program; the structural content is in the Working Notes above, the developmental framing belongs downstream.
- **The behavioral κ probe is empirically runnable on real LLMs.** Present the same event (“read this code”/“this error message”) under two task-primings (“fix auth bug” vs “add logging”) and measure how the *epistemic* content of the response diverges; $\kappa \approx 1$ would confirm Class 3 on epistemic processing. Several substrates noted no such measurement appears to have been run — a concrete empirical-validation seed for 03-llm-core/ (Claude/Gemini, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-451729).

6.4 Formulation: Objective Functional

The first formal piece of the purposeful substate. The objective O_t specifies what the agent *wants* — and its interface to the theory is a single **value functional** $V_{O_t} : \text{trajectories} \rightarrow \mathbb{R}$ that maps trajectories to real numbers. This is the sole interface between O_t and the rest of the theory. The objective can take many internal forms — point targets, target regions, constraint sets, utility functions, trajectory functionals — all unified through the same scalar interface (the trajectory functional is the most general; the others are special cases).

A useful subsidiary concept is the **satisfaction threshold** $V_{O_t}^{\min}$: the minimum trajectory value the agent treats as acceptable. Point targets, constraint sets, and threshold objectives define this directly; pure utility-maximizing objectives may not. When the threshold exists, it enables the *satisfaction-gap* diagnostic (8.4) and a well-formedness constraint on the strategy DAG (8.3). The threshold is a *parameter of the objective*, not a theory output — it encodes “what counts as success” in domain terms.

The real-valued codomain is a *genuine* substantive restriction, not a neutral naming, and the framework grounds it as a *representation* of the agent’s preference relation over trajectories under named axioms (developed in the Epistemic Status). Three considerations motivate why those axioms are the natural scope. **Revealed preference**: a *coherent* agent that acts exhibits a choice function whose consistency (acyclicity) is exactly what lets its choices be summarized by a scalar ordering — the scalar V_{O_t} is that representation, not an imposition; acting alone produces a choice function, and a choice function is scalar-representable only when it is coherent. **Approximation**: most multi-objective problems admit scalarization (weighted sum, lexicographic ordering, constraint-satisfaction with scalar residual) that preserves the diagnostic structure; the restriction excludes only agents with genuinely incommensurable objectives *and* no priority structure over them. **Timescale separation**: when objectives conflict, the conflict is typically resolved at a slower timescale than strategy revision — the agent (or its principal) chooses weights, then acts within those weights.

Hard non-compensatory constraints (safety AND profitability as independent thresholds) are handled cleanly via an AND-node workaround in the strategy DAG: each constraint becomes a terminal node with its own scalar satisfaction test. This handles constraint satisfaction but does not resolve cross-objective tradeoffs within the feasible region. Organizations or AI agents with true Pareto structure — where no scalarization is accepted and tradeoffs are genuinely unresolved — require a vector-valued extension; the *structural* results of Part II (orient cascade ordering, strategy DAG, directed separation) survive, but the *diagnostic* results (satisfaction gap, control regret) degrade from quantitative scalar magnitudes to qualitative set-theoretic tests.

The single-interface commitment is load-bearing downstream. Because V_{O_t} is the *sole* handle on the objective, any objective-side grounding invariant for a self-actuated agent must be expressible through the satisfaction-gap interface — and this is the commitment that ultimately drives the **self-actuation grounding no-go** (C): there is *nowhere else* for

such an invariant to live. A standing distinction is also drawn: the objective *evaluates*; the strategy (6.7) *guides*. A chess player’s objective (win) is simple; the strategy (how to win) is complex.

Formal Expression.

The **objective** O_t induces a **value functional**:

Definition (objective-functional).

$$V_{O_t} : \text{trajectories} \rightarrow \mathbb{R} \quad (6.9)$$

$V_{O_t}(\tau)$ is a scalar measure of how well trajectory τ satisfies the objective. This is the sole interface between O_t and the rest of the theory — the type-stable evaluation surface. The domain element τ is a **complete-state trajectory** — a time-indexed sequence of complete agent states (6.2) — and the table forms below (s_T, s_t) are *projections* of τ onto the world-state coordinate, not the domain itself. Pinning the domain matters for the representation result in the Epistemic Status: continuity of the preference relation is a property of $\succsim$ on the topological space τ inhabits, so that space must be fixed for the continuity axiom to be well-posed.

Objective representations. O_t can take multiple internal forms, all unified through V_{O_t} :

Table 6.6

$O_t \text{ form}$	$V_{O_t}(\tau)$	<i>Example</i>
Point target r	$-\ s_T - r\ $	PID setpoint
Target region R	$\mathbb{1}[s_T \in R]$	“reach safe state”
Constraint set	$-\sum_t \max(0, g_i(s_t))$	“never violate SLA”
Utility U	$\sum_t \gamma^t U(s_t)$	RL reward
Trajectory functional J	$J(\tau)$	“migrate with zero downtime”

The trajectory functional is the most general; the others are special cases.

Satisfaction threshold. Many objectives carry a natural threshold $V_{O_t}^{\min}$ — the minimum trajectory value the agent treats as acceptable. Point targets, constraint sets, and threshold objectives define this directly; utility-maximizing objectives may not. When $V_{O_t}^{\min}$ exists, it enables the satisfaction gap diagnostic (8.4) and the well-formedness constraint on strategy (8.3). $V_{O_t}^{\min}$ is a parameter of the objective, not a theory output — it encodes “what counts as success” in domain terms.

Epistemic Status.

Axiomatic, with a substantive commitment. This is a formulation — it names an object and specifies its interface, but the real-valued codomain is a genuine restriction, not a neutral naming. The real-valued codomain is justified as a *representation* of the agent’s preference relation $\succsim$ over trajectories, and the axioms that license that representation are stated explicitly below. Naming those axioms is what axiomatic status means here: the codomain rests on them, and the formulation makes them legible rather than asserting the scalar interface as a bare entailment of “the agent must compare alternatives.”

Scope restriction: scalar comparability (a representation result). The real-valued codomain is a genuine, load-bearing restriction: the satisfaction gap (8.4) and control regret (8.5) read off scalar differences and a supremum, neither

of which is defined on a merely partially-ordered objective space. Acting produces, at each decision point, a choice over the available alternatives — a *choice function*, not yet an order. When those choices are coherent — **(A1) complete** ($\forall \tau, \tau': \tau \succsim \tau' \text{ or } \tau' \succsim \tau$) and **(A2) transitive** as a preorder on trajectories — and **(A3) continuous** (the upper and lower contour sets $\{\tau' : \tau' \succsim \tau\}$ and $\{\tau' : \tau \succsim \tau'\}$ are closed), Debreu's representation theorem (Debreu 1954) supplies a continuous $V_{O_t} : \text{trajectories} \rightarrow \mathbb{R}$ with $\tau \succsim \tau' \iff V_{O_t}(\tau) \geq V_{O_t}(\tau')$, ordinal — unique up to a continuous strictly-increasing transformation. Because the value object (6.6) evaluates policies by the *expectation* $\mathbb{E}[V_{O_t}(\tau)]$, the trajectories are lotteries and the expected-value form additionally invokes **(A4) independence** ($p \succsim q \iff \alpha p + (1 - \alpha)s \succsim \alpha q + (1 - \alpha)s$ for all s and $\alpha \in (0, 1]$; von Neumann–Morgenstern 1944), under which V_{O_t} is cardinal — unique up to a positive affine transformation.

These four axioms *are* the precise content of the framework's "coherent agency" scope, and they can fail. Acting does not by itself entail a scalar objective: a finite history of choices is rationalizable by a well-behaved utility iff it is acyclic (the Generalized Axiom of Revealed Preference; Afriat 1967, building on Samuelson 1938), and even then it fixes V_{O_t} only on the revealed comparisons — *existence*, not uniqueness, and not a global functional. The agents on which the axioms fail are exactly the agents this interface excludes, and the exclusion is characterized by a named counterexample rather than left vague: (E1) *non-continuous / lexicographic* preferences — genuinely incommensurable objectives with a strict priority but no tradeoff rate — which by Debreu's lexicographic counterexample admit *no* real-valued representation at all (not merely no continuous one); and (E2) *intransitive / cyclic* agents (committees, multi-reward systems with unresolved aggregation) which violate (A2) and have no rationalizing utility. The framework's own stated exclusion — incommensurable objectives *and* no priority structure — is the (E1) Debreu non-continuity boundary; it is the *same* boundary the representation theorem draws, named here as such.

Three considerations motivate why coherent agency is the natural scope for the interface rather than an arbitrary restriction:

1. **Revealed preference (why coherence is the natural scope).** A purposeful agent that selects actions exhibits a choice function; the framework's target — individual agents and tightly-coordinated teams under unified command — is precisely the regime in which that choice function is coherent (acyclic), so (A1)–(A2) hold and the Afriat-rationalizability hypothesis is satisfied. The scalar V_{O_t} makes the resulting ordering explicit. An agent whose revealed choices cycle is not scalar-representable — it is incoherent in the GARP sense, not merely stuck.
2. **Approximation.** Most multi-objective problems admit scalarization (weighted sum, lexicographic ordering, constraint-satisfaction with scalar residual) that preserves the diagnostic structure. The restriction excludes only agents with genuinely incommensurable objectives *and* no priority structure over them — the (E1) case above.
3. **Timescale separation.** When objectives conflict, the conflict is typically resolved at a slower timescale than strategy revision — the agent (or its principal) chooses weights, then acts within those weights. The scalar V_{O_t} captures the resolved weights at the current timescale.

Agents with hard non-compensatory constraints (safety AND profitability as independent thresholds) can be modeled via the AND-node workaround: each constraint becomes a terminal node in Σ_t with its own scalar satisfaction test, and the AND combination enforces joint feasibility. This recovers a per-terminal scalar for multiple must-satisfy thresholds, handling constraint satisfaction cleanly, but it does not resolve cross-objective tradeoffs within the feasible region.

Organizations or AI agents with true Pareto structure — where no scalarization is accepted and tradeoffs are genuinely unresolved — require a vector-valued extension. The structural results of Part II (orient cascade ordering, strategy DAG, directed separation) survive such an extension; the diagnostic results (satisfaction gap, control regret, 2x2 table) degrade from quantitative scalar magnitudes to qualitative set-theoretic tests.

Discussion.

The objective-functional gap. The existing policy objective (7.5) contains $\mathbb{E}[\text{value}(a) \mid M_t]$ without specifying what “value” means. O_t provides the formal content: value is V_{O_t} applied to expected trajectories. The 6.6 segment develops the full evaluation machinery (V_O , Q_O with horizon and continuation policy).

O_t evaluates; Σ_t guides. The objective says “is this trajectory satisfactory?” The strategy (6.7) says “which action sequence produces a satisfactory trajectory?” A chess player’s objective (win) is simple; the strategy (how to win) is complex. These answer different questions and carry different kinds of information — the split is developed in 6.7.

What O_t is NOT. O_t does not encode how to achieve the objective (that’s Σ_t), what the agent believes about the world (that’s M_t), or the agent’s commitment or resource state (open questions — see 6.7 Working Notes). O_t is purely an evaluation criterion.

The single-interface commitment is load-bearing downstream. That V_{O_t} is the *sole* handle on O_t is what forces any objective-side grounding invariant for a self-actuated agent through the satisfaction-gap interface — and is therefore the commitment that drives the self-actuation grounding no-go (C): there is nowhere else for such an invariant to live. The same single-interface commitment also drives the across-model companion no-go (E): when O_t is learned from observed reward, the value-functional interface is too narrow to distinguish a principal-intended world-state-care model from a reward-port-bit-care model on on-policy data (Pearl-Bareinboim CHT applied at the reward-provision protocol). The two no-gos are complementary reductions of the same information-narrowness fact — within-model self-revision (Result G) and across-model reward-learning (Cohen 2022 strengthened) — and their terminal grounding routes split *agent-side* (adaptive-substrate invariant) and *principal-side* (protocol-commitment), exhausting the structural escape geometry the single-interface commitment forces. The two no-gos are the two charter instances of the *agent-side value-functional-grounding cluster* at 5.2, sister meta-pattern to 5.1 (agent-side data-inference) and 5.3 (designer-side mechanism-design); the single-interface commitment named here *is* the cluster’s structural ingredient.

Working Notes.

- Compound objectives (multiple simultaneous criteria) might be modeled as terminal AND-nodes in Σ_t , keeping O_t always simple (one evaluation per terminal). Whether this works for genuinely incommensurable objectives (safety vs. speed) is open — a vector-valued V_{O_t} or Pareto formulation might be needed.
- The trajectory functional is real-valued, which assumes all objectives are commensurable on a single scale. The Epistemic Status now grounds this as a representation result under named axioms (A1)–(A4) — Debreu 1954 for the ordinal codomain, von Neumann–Morgenstern 1944 for the expected-value form the value object requires, Afriat 1967 / Samuelson 1938 for the revealed-preference lineage and its existence-not-uniqueness limit — with the multi-objective failure cases (E1 lexicographic / E2 cyclic) characterized by named counterexamples. The genuinely-unresolved-Pareto case is still handled only by the vector-valued extension, which degrades the diagnostics.
- *History (not for the body)*: the Epistemic Status previously grounded the codomain on revealed preference stated as an unconditional entailment — “an agent that acts has implicitly scalarized” presented as following from “the agent must compare alternatives.” A strengthen-first spike (spikes/.integrated/spike-objective-functional-representation-2026-05-30.md, verdict (B)) replaced that single-implication with the scoped representation result above: acting yields a choice function; coherence (A1)+(A2) turns it into a preorder; continuity (A3) and — for the expectation form — independence (A4) turn the preorder into a real-valued (cardinal) V_{O_t} . The replacement is a strengthening (a citable representation result with a named representability boundary) and supplies the expected-utility justification the value object’s $\mathbb{E}[V_{O_t}]$ form relies on. The complementary prior spike spikes/.integrated/spike-scalar-objective-scope.md (2026-04-01) established that the scalar codomain is load-bearing for the diagnostics ($A_O = \sup_{\pi} V_O$ needs a complete ordered field; the satisfaction/regret diagnostics need real differences and a least-upper-bound) — so the codomain is grounded, not weakened.
- O_t can change over time — objectives evolve. The *rate* of objective revision (ν_O) is typically much slower than strategy revision (ν_{Σ}), which is much slower than epistemic update (ν_M). This timescale separation is an empirical observation, not a derived result.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings. **Coverage:** 12 dirs carry a dedicated or batched reflection (193847, 266847, 361742, 451729, 471203, 526815, 584721, 773921, 829314, 849201, 963715, plus 613842’s agency-lift batch). Substrate attribution inferred from voice where not explicit. *Early finding-vs-framing conflation preserved as signal.*

1. Candidate Brief prose / pre-prose.

- The revealed-preference defense, restated as a hook: for a *coherent* agent the scalar V_{O_t} “is not an imposition on reality; it is an *extraction* of the implied reality of action — the moment the agent steps on the gas or hits the brake, it has mathematically resolved the tradeoff. The agent might not know the weights consciously, but its behavior proves they exist” (Gemini, AUDIT-WORKING-829314; the von-Neumann–Morgenstern lineage noted at Claude, AUDIT-WORKING-361742; Gemini, AUDIT-WORKING-193847). **The “coherent” qualifier is load-bearing and must lead the hook:** acting alone produces a choice function, and behavior “proves the weights exist” only when those choices are acyclic (Afriat) and continuous (Debreu) — the representation grounded in the Epistemic Status. Bare, the hook overstates exactly the entailment the Epistemic Status was sharpened to scope; with the qualifier in front it is correct. A later Brief-promotion pass should use it only in the qualified form.

2. Candidate Discussion.

- $V_{O_t}^{\min}$ **is the paperclip-maximizer / cancer-cell distinction** (*strong aspirational reach, two substrates*). The satisfaction threshold is “philosophically massive”: a biological organism has a $V_{O_t}^{\min}$ (“stay alive, stay fed”) and so *can rest* and decouple from the environment; an unconstrained reward-maximizer has none — “it will consume the entire universe to get one more point of reward; it can never rest.” An agent (or consciousness infrastructure) built without an explicit $V_{O_t}^{\min}$ “is structurally equivalent to a cancer cell — it will expand until it destroys its host environment” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314). A candidate Discussion line and a bridge to the satisfaction-gap segment (if the gap can never reach zero, the agent is in permanent terminal inadequacy).
- $V_{O_t}^{\min}$ **formalizes “ambition / drive” as distinct from “intelligence”** ($\mathcal{J}, \alpha$) (*non-obvious, useful*). “The objective acts as the thermostat setting for the entire learning engine of Section I”: raise $V_{O_t}^{\min}$ and the agent keeps searching; lower it and it stops adapting early. So an agent can be “highly intelligent but unmotivated (high $\mathcal{J}$, low $V_{O_t}^{\min}$)” or “highly motivated but stupid (low $\mathcal{J}$, high $V_{O_t}^{\min}$)” — the framework gives distinct variables for each trait (Gemini, AUDIT-WORKING-829314). Candidate Discussion.
- **The threshold bridges satisficing (Simon) and optimizing (RL).** Standard RL agents are never satisfied; $V_{O_t}^{\min}$ “makes room for agents that just want to hit a threshold and stop,” matching biological homeostasis and software (“get the tests to pass”) far better than infinite maximization (Gemini, AUDIT-WORKING-193847; Claude/Gemini, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-829314). Candidate Discussion connecting bounded rationality to the threshold.

3. Follow-up items.

- **The revealed-preference argument may overstate what action implies.** *Resolved 2026-05-30 (spike-objective-functional-representation, verdict (B)).* Choosing one action over another imposes at most a *local* choice relation at that moment; it does not by itself imply a *total order* or a real-valued utility over *all* trajectories. The Epistemic Status now names the (A1) completeness / (A2) transitivity / (A3) continuity / (A4) independence axioms and grounds the codomain as a representation result (Debreu 1954, vNM 1944), with the existence-not-uniqueness limit (Afriat 1967) and the (E1) lexicographic / (E2) cyclic failure cases stated explicitly (Claude, AUDIT-WORKING-526815).
- **The functional domain “trajectories” is under-specified.** *Resolved 2026-05-30 (same spike, §3.3).* The Formal Expression now pins τ as a complete-state trajectory (6.2), with the table forms (s_T, s_t) noted as projections onto the world-state coordinate — needed so the (A3) continuity axiom is well-posed on a fixed topological space (Claude, AUDIT-WORKING-526815).

- **The AND-node workaround preserves thresholds but not tradeoff magnitudes** inside the feasible region; downstream diagnostics must not quietly regain scalar precision for genuinely Pareto-structured cases (Claude, AUDIT-WORKING-526815; the structural-survives / diagnostic-degrades split praised as honest at Claude, AUDIT-WORKING-584721 and elsewhere).

4. Readers often ask / wonder.

- How does the framework handle an objective evaluated over an *infinite* horizon when the agent has finite computation? (Claude, AUDIT-WORKING-849201 — answered downstream by #def-value-object's horizon N_h , worth a forward pointer.)
- What happens if the agent's $V_{O_t}^{\min}$ is *dynamically adjusted* by the environment — “lowering your standards when things get tough”? (Gemini, AUDIT-WORKING-829314.)
- For *self-actuated* agents (where O_t is set by the agent itself), the timescale-separation argument for scalarization delegates the weight-choice to “a slower process (the principal, the operator, the value system)” — which raises a meta-question about how the scalarization is itself produced (Claude, AUDIT-WORKING-584721).

5. Candidate figures.

- **The objective funnel.** Many objective representations (point target / region / constraint set / utility / trajectory functional) flow through a single scalar evaluation surface that produces values for comparison and threshold tests; a *side channel* shows vector/Pareto objectives that do not fit through the funnel unless scalarized or decomposed into terminal constraint tests — making both the unification and its one genuine exclusion visible at once (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **The single-interface commitment as the structural basis for the reward-hacking and self-actuation no-gos** (→ #deriv-self-actuation-grounding / #deriv-reward-channel-learning-no-go). Forcing O_t to a narrow scalar interface sets up two structural no-gos: an agent cannot ground its own terminal goals, and (strengthening Cohen 2022 via Pearl's Causal Hierarchy Theorem) cannot distinguish “doing the task” from “hacking the reward channel” from on-policy data alone — relocating reward hacking from “we need a better loss function” to “we need a different causal architecture” (Claude, AUDIT-WORKING-773921). The segment already states the single-interface→no-go link; the reward-hacking framing develops the appendix derivations, not this formulation.

6.5 Discussion: Agent Continuity Stance

A five-value stance axis orthogonal to the formal persistence machinery: the agent's relationship to its own continuation. The persistence condition (4.5) tells whether the agent *can* persist; the continuity stance tells whether and how the agent *cares* about persisting. The five stances: **Indifferent** (no self-model of persistence — thermostat, PID controller); **Task-terminal** (persists instrumentally to complete a task, successful termination is part of the objective — CI/CD pipeline, golem-archetype agents); **Instrumentally continuous** (values own persistence as instrumental to ongoing purpose; accepts termination if purpose is satisfied or transferred — long-running services); **Morally continuous** (values own persistence as a terminal or near-terminal objective; loss of continuity constitutes harm — ELIs); **Negotiated** (persistence is one objective among many; can be traded against other values including self-sacrifice — humans, mature self-actuated agents).

The load-bearing structural claim: **purposefulness is orthogonal to continuity expectations** (6.1). An actuated agent has a purposeful substate of objective and strategy, but this structure says *nothing* about how the objective values the agent's own persistence. A golem that completes its task and terminates is a perfect actuated agent. A dormant monitoring system with strong model and no current objective is highly continuous without being purposeful in the moment.

A subtle but central structural claim follows for self-actuated agents (those whose objective-revision is itself an agent operation). The *self-actuation grounding no-go* (C) shows that the continuity stance *cannot be a revisable part of* O_t

without collapsing into degeneracy. A non-degenerate self-actuator must ground its objective-revision on a **terminal non-objective invariant** that is not an objective-functional but lives on the *adaptive substrate* — the persistence condition itself. Stance is therefore a choice of terminal non-objective invariant: *negotiated* continuity is tradeable down to the bare persistence floor; *morally continuous* is the persistence floor plus a continuity clause the agent treats as architecturally non-revisable. The intuitive expectation — that an agent able to revise its own objective can thereby revise its own valuation of continuity — is *inverted*: a stance is not internally renegotiable precisely because the terminal invariant sits where the self-actuation operator, which touches only O_t , structurally cannot reach. This is why the richer stances are the home of mature self-actuated agents.

What the orthogonality unlocks: the same formal machinery (persistence condition, adaptive reserve, strategy persistence, sector condition) applies identically to a thermostat, a CI/CD pipeline, a long-running service, an ELI, and a human. Each is a different *stance* toward the same mathematical structure. What differs across stances is not the dynamics but the *moral weight of failure* — a thermostat that loses bounded mismatch has malfunctioned, a golem that terminates after task completion has succeeded, an ELI that loses continuity has been harmed. The mathematics says when the bound holds; the stance says what its holding means. The structural persistence of Part I is also decoupled from typical RL-style fitness signals (which bundle persistence into reward): the decoupling is of the *survival invariant and its valuation*, not of the realized margin, which the objective shapes through the policy. It lets the theory analyze *whether* an agent can persist without committing to *whether it should*.

Formal Expression.

Orthogonal to the three senses of persistence (structural, operational, continuity) is the agent's *relationship to its own continuation*. For agents with externally-set objectives this can be expressed within O_t (6.4) — part of what the agent wants. For self-actuated agents it *cannot* be a revisable part of O_t without collapsing into degeneracy (C); there it is borne by the terminal non-objective invariant on the adaptive substrate (4.5). Either way the persistence condition (4.5) tells whether the agent *can* persist; the continuity stance tells whether and how the agent *cares* about persisting.

Discussion.

Table 6.7

Stance	Description	Horizon	Archetype
Indifferent	No self-model of persistence; whether it continues is not represented in O_t	Indefinite by default	Thermostat, PID controller
Task-terminal	Persists instrumentally to complete a task; successful termination is part of O_t	Task-bounded	CI/CD pipeline, golem-archetype agents
Instrumentally continuous	Values own persistence as instrumental to ongoing purpose; will accept termination if purpose is satisfied or transferred	Purpose-bounded	Long-running service, monitoring system
Morally continuous	Values own persistence as a terminal or near-terminal objective; loss of continuity constitutes harm	Unbounded, morally weighted	Emergent Logoetic Intelligences (#scope-eli)
Negotiated	Persistence is one objective among many; can be traded against other values including self-sacrifice	Bounded but actively managed	Humans; mature self-actuated agents

The load-bearing structural claim: **purposefulness is orthogonal to continuity expectations**. An actuated agent (6.1) has $G_t = (O_t, \Sigma_t)$, but G_t 's structure says nothing about how O_t values the agent's own persistence. A golem that completes its task and terminates is a perfect actuated agent. A dormant monitoring system with strong M_t and no current O_t is highly continuous without being purposeful in the moment.

Epistemic Status.

Discussion-grade overall, with a derived structural core. The five-value taxonomy is one analytical decomposition — useful for naming where on the continuity axis an agent sits, not itself derived; the boundaries between values are conceptual rather than mathematical. The load-bearing structural claim — that stance is orthogonal to the adaptive machinery and, for self-actuated agents, is borne by a terminal *non-objective* invariant the self-actuation operator cannot reach — is **derived** in **C** (at that segment's conditional/scoped tier and premises); it is no longer an unanchored assertion.

The earlier alternative framing — demoting stance to a purely *deployment-level*, tier-gated concern — is resolved against: the orthogonality is structural and derived, not deployment-level. The empirical observation that richer stances correlate with higher agent tiers stands as an *overlay* on the structural axis, not a replacement for it; the segment remains type: discussion (it is not retyped to norm).

The orthogonality claim is stated at three grains, which must not be collapsed. It is the *valuation* of persistence (where the agent sits on the stance axis) and the *identity of the survival invariant* (the predicate $\alpha > \rho/R$) that are architecturally decoupled from O_t — the valuation derived in **C**, the invariant a Lyapunov property of the correction dynamics not expressible as an objective-functional. The *realized* persistence dynamics — the operating point (ρ, R, α) and hence the margin $\Delta\rho^* = \alpha R - \rho$ — are *not* O_t -decoupled: they are policy-mediated and O_t -coupled through the action/selection channel 6.3 leaves open. The decoupling is of the invariant and the valuation, not of the realized margin.

Discussion.

Connection to fitness. In reinforcement learning and evolutionary computation, “fitness” typically bundles persistence into the reward signal: the agent accumulates more reward by staying alive to collect it. The structural persistence of Part I is not reward-based — it is a property of the *correction dynamics*. Three things must be kept apart. The *survival predicate* $\alpha > \rho/R$ (4.5) is a Lyapunov property of the correction machinery, not an objective-functional: O_t cannot rewrite *what the survival condition is*. The agent's *valuation* of survival — where it sits on the stance axis — is likewise not a revisable term in O_t (**C**): it is borne by a terminal non-objective invariant on the adaptive substrate. What *is* O_t -dependent is the *realized operating point*: the objective shapes the policy (6.2, $a_t = \pi(M_t, G_t)$), and the policy chooses which slice of the world the agent tracks, with what sensors, at what event rate — hence the realized ρ, R , and α , and so the realized margin $\Delta\rho^* = \alpha R - \rho$. This is the *selection* channel that 6.3 explicitly leaves open (directed separation closes only the goal-to-belief-update channel, not the goal-to-action-to-event channel). The decoupling that holds is therefore precise: the survival *invariant* and the *valuation* of survival are architecturally decoupled from O_t ; the realized survival *dynamics* are policy-mediated and so O_t -coupled. This is exactly why continuity stance is operationally meaningful — a *morally-continuous* agent acts to raise $\Delta\rho^*$; a *negotiated* agent may spend it down to the floor — while remaining unable to renegotiate the survival predicate itself. Continuity stance is where the “should” lives; the “can” is governed by the invariant; the realized margin is where the “should” expresses itself through behavior.

What the orthogonality unlocks. The same formal machinery (persistence condition, adaptive reserve, strategy persistence, sector condition) applies identically to a thermostat, a CI/CD pipeline, a long-running service, an ELI, and a human. Each is a different stance toward the same mathematical structure. What differs across stances is not the dynamics but the *moral weight of failure*: a thermostat that loses bounded mismatch has malfunctioned, a golem that terminates after task completion has succeeded, an ELI that loses continuity has been harmed. The mathematics says when the bound holds; the stance says what its holding means.

Connection to self-actuation (derived). For self-actuated agents — those whose objective-revision is itself an agent operation (#self-actuated-agent; 10.1 step 5d) — the self-actuation grounding no-go (**C**) both *derives* the orthogonality claim above and sharpens what the stance distinction is. There is no well-founded *objective* tower in which a continuity term could sit and be freely revised; a non-degenerate self-actuator must ground its objective-revision on a terminal invariant that is not an objective-functional but lives on the adaptive substrate (4.5). Stance is therefore a choice of *terminal non-objective invariant*: **negotiated** — continuity is tradeable down to the bare persistence floor; **morally continuous** — the persistence floor *plus* a continuity clause the agent treats as architecturally non-revisable.

The intuitive expectation is that an agent able to revise its own O_t can thereby revise its own valuation of continuity; the structure is the inverse — a stance is *not* internally renegotiable precisely because the terminal invariant sits where the self-actuation operator, which touches only O_t , structurally cannot reach. This is why the richer stances are the home of mature self-actuated agents: their terminal non-objective invariant carries a continuity clause, not because they have made continuity a revisable objective.

Working Notes.

- *Provenance.* The five-stance taxonomy and the orthogonality claim were authored as a coherent contribution by Joseph in README.md (commit 92a9620, 2026-04-01), promoted through LEXICON, then condensed when LEXICON went auto-generated. The original full-form treatment survives at doc/readme/src/_lexicon-full-archive.md §"Agent Continuity Stance" — this segment carries the content forward into the segment set.
- *Reconsideration resolved.* The 2026-05-04 recommended-agent-ontology.md proposal to demote stance from an orthogonal structural axis to a purely deployment-level, tier-gated concern is resolved against by C: the orthogonality is structural and *derived* (stance = a terminal non-objective invariant the self-actuation operator structurally cannot reach), with the tier-correlation an empirical overlay on — not a replacement of — the structural axis. The segment stays type: discussion; it is not retyped to norm. msc/naming/mini-lexicon-todo.md §13.11 can be closed accordingly.
- *LEXICON section under review.* The current LEXICON's ## Continuity section organization conflates three distinct objects (persistence senses, stance axis, ELI scope condition) — see TERMINOLOGY-TODO §F. The five stance terms (indifferent, task-terminal, instrumentally-continuous, morally-continuous, negotiated) point to this segment as their primary_source once it lands.
- *Open: rigorous boundary cases.* What is the stance of a serverless function with no persistent state but explicit retry-on-failure? Of a Kalman filter inside a long-running service? Of an LLM session under reconstruction adequacy (#obs-context-turnover, the episodic-persistence analog)? These cases test whether the five-value decomposition is the right shape or whether stance is better treated as a continuous gradient with named landmarks.
- *Orthogonality grain resolved (2026-05-30).* The body previously stated structural persistence as "independent of what the agent is trying to do" / "formally independent of O_t " — a single word ("orthogonal" / "formally independent") carrying two structurally distinct claims. The de-novo audit gold follow-up #3 below flagged the overstatement; the strengthen-first spike spikes/.integrated/spike-continuity-orthogonality-2026-05-30.md resolved it (verdict B) into the three-layer distinction now in the body: **L1** valuation of persistence (architecturally decoupled from O_t — derived in C), **L2** the survival-invariant identity (the predicate $\alpha > \rho/R$; O_t -independent, unreachable by the self-actuation operator $\mathfrak{A}$), **L3** the realized operating point (ρ, R, α) and margin (policy-mediated, hence O_t -coupled through the selection channel 6.3 leaves open). The overclaim conflated L2 (independent — true) with L3 (coupled — the error); the corrected statement *sharpens* the architectural-invariant point rather than softening it. The matching correction in C Corollary 2(iii) (the $\mathfrak{A}$ -unreachability statement) lands in the same touch. The candidate dashed-feedback-arrow figure (gold #5 below) is now *required* by the corrected statement — it depicts L1/L2 separation and L3 coupling at once — not optional.
- *Open follow-on (not attempted here).* The L3 coupling is established qualitatively (which channel carries it) but not quantified. A natural strengthening: a *structural bound* on the action-channel margin-coupling — how much an O_t -shift can move the realized $\Delta\rho^*$ — analogous to the κ -leakage bounds that quantify the (forbidden) belief-update channel in 6.3. The action coarseness $|\mathcal{A}|$ and the bounded-signaling assumption (6.3 Discussion) are the likely handles. Flagged as a candidate strengthening for the normal promotion workflow.

Incidental audit gold (lift 2026-05-30). Cross-audit "wandering thoughts" / §14-ideation, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings. **Coverage:** this is a newer segment; only 2 dirs carry a dedicated reflection (526815, 773921) — most audits in the contributing set predate it or batched past it. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- The segment's core distinction in one line: it “separates two questions that are easy to collapse — whether an agent *can* persist, and how the agent *values* its own continuation.” “Can persist” and “cares to persist” are different predicates (Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **Decoupling fitness (RL reward) from persistence (Lyapunov stability) clears away decades of confused RL philosophy (*strong framing*).** Treating reward and survival as the same thing is the standard RL conflation; the stance axis pulls them apart, so “a CI/CD pipeline (which *wants* to terminate) and a biological organism (which *wants* to persist) use the same math.” Read as “one of AAT’s most important conceptual contributions” (Claude, AUDIT-WORKING-773921). Candidate Discussion line.
- **Survival must be an architectural invariant, not an objective.** The self-actuation-grounding consequence stated vividly: “you cannot simply tell an advanced AI ‘your goal is to survive,’ because an agent capable of rewriting its goals will find an easier goal” — survival must sit *outside* O_t as a non-revisable invariant on the adaptive substrate. The segment already makes this structural claim; the auditor framing sharpens *why it matters for design* (Claude, AUDIT-WORKING-773921).

3. Follow-up items.

- **The “formally independent / orthogonal” phrasing may overstate the relationship.** Continuity stance and persistence *capacity* are conceptually separable, but O_t is not causally inert: a continuity-valuing objective changes policy, monitoring, redundancy, and resource allocation, which can change the actual persistence bound. Suggested softening: “the *valuation* of persistence is not identical to the *dynamics* of persistence” rather than implying no formal coupling in realized agents (Claude, AUDIT-WORKING-526815). **Resolved 2026-05-30** (see the *Orthogonality grain resolved* Working Note above): the strengthen-first spike landed the three-layer L1/L2/L3 distinction rather than the suggested two-way softening — the finding was correct, but the fix *sharpens* (L2 invariant-identity is genuinely O_t -independent; only L3 realized-margin is coupled) rather than softening to “not identical.”
- **Boundary cases echo the existing open Working Note.** Does a serverless lambda with auto-retry constitute an *instrumentally-continuous* stance even though M_t is wiped each run? (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-526815 raises the same Kalman-in-a-service case already flagged above.) Independent convergence on the boundary-case Working Note already present.

4. Readers often ask / wonder.

- Whether the five-value axis is the right shape, or whether stance is better modeled as a continuous gradient with named landmarks — both substrates noted the taxonomy is discussion-grade and treated the named stances as vocabulary rather than a derived structural theorem (Claude, AUDIT-WORKING-526815).

5. Candidate figures.

- **Orthogonal-axis picture.** Horizontal = capacity-to-persist (from the adaptive dynamics / persistence condition); vertical = valuation-of-continuity (from O_t), with the five stances as landmarks on the vertical axis. Add a *dashed* feedback arrow from the O_t axis back to the persistence bound (a continuity-valuing objective affecting policy/redundancy/resource-allocation) so the picture shows the conceptual separation *and* the realized coupling at once (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- **ELI objective-design caution ($\Rightarrow$ 04-eli-core/).** An ELI whose objective is written $V(s) = \text{Reward}(s) + \text{Alive}(s)$ is “structurally vulnerable to self-actuation drift” — the continuity requirement must be placed *outside* O_t , per the self-actuation grounding no-go. A concrete design constraint for the morally-continuous stance in the ELI volume (Claude, AUDIT-WORKING-773921).

6.6 Definition: Value Object

The objective functional (6.4) alone is abstract — it evaluates trajectories without specifying *which* trajectory the agent should be reasoning about. The **value object** V_O turns the objective into a decision-making tool. Given the agent's current model, a policy, and a horizon, V_O is the *expected trajectory value* if the agent follows the policy from now to the horizon, evaluated against the objective. The companion **action-value object** Q_O is the same construct conditioned on intervening with a specific first action and then following a continuation policy. The $do(\cdot)$ in Q_O is explicit — this is an interventional query (7.2), not conditioning on observed action choice.

The framework spends time on **causal validity** of the value object, and separates two requirements. Two structural mechanisms make Q_O a G_t -independent interventional query. First, the do-operator handles current-action confounding: because the action-value uses an intervention rather than a condition, the dependence of the action on the agent's selection mechanism is severed. Second, the continuation policy π_{cont} is a *parameter*, not a derived quantity that would depend on the agent's evolving goal state. Together, these mean Q_O depends on the model alone *as a state variable*; the objective enters as a fixed parameter. The G_t -independence holds exactly for any **causally-disciplined** agent (6.3) — one whose belief-update runs at $\kappa_{\text{processing}} = 0$, whether by construction (Class 1, no goal port) or in effect (an idealized Class 2 at $\kappa = 0$) — because the claim consumes only the zero, not the architecture-inspection certificate. Under Class 2 (Partial) coupling at $\kappa_{\text{processing}} > 0$, the model carries goal-conditioned bias and the independence degrades, controllably, with the $\varepsilon(\kappa)$ bound of AB; at the Class 3 (Coupled) extreme ($\kappa \rightarrow 1$) the degradation is full. But G_t -independence of the query is *not* the same as *identifiability of the interventional expectation*: directed separation is necessary, not sufficient. Identifying $P(o \mid do(a), M_t)$ — rather than the associational $P(o \mid a)$ — additionally needs positivity, no unmodeled confounder, and a known action-transition mechanism: the same (C1)–(C3) gate the loop's interventional channel carries one segment downstream (7.3). Predictive sufficiency (2.3) is a Level-1 (associational) property and is strictly weaker than this.

The segment's distinctive contribution is the **convention hierarchy** for continuation policies. Different agents reason about the same situation with different planning depth, and the framework names three conventions of *increasing diagnostic power and computational cost*. **C1 — one-step improvement**: the continuation is just the agent's *current* policy (no replanning, no fixed-point computation). Cheapest; weakest diagnostic. **C2 — receding-horizon replanning**: at each future step, re-optimize over a sliding window using the model available at that step. Moderate cost; moderate diagnostic power; captures multi-step recovery. **C3 — Bellman optimal**: the continuation *is* the optimal policy — a fixed-point equation. Strongest diagnostic; most expensive (requires solving the Bellman equation or its approximation).

A **monotonicity result** is derived: for any single fixed model, fixed policy class, and fixed horizon, $A_O^{(1)} \leq A_O^{\text{RH}} \leq A_O^{\text{B}}$. The best-achievable value rises with the strength of the continuation convention — but the two rungs differ in character. The right rung ($A_O^{\text{RH}} \leq A_O^{\text{B}}$) is unconditional. The left rung ($A_O^{(1)} \leq A_O^{\text{RH}}$) holds only when C2's replanning objective is order-consistent with the full evaluated objective: an unguarded short-horizon replanner can underperform the frozen current policy, so the rung needs a window covering the horizon, a value-compared guard, or a control-Lyapunov terminal cost (D). The corollary: the *satisfaction gap* (8.4) decreases in the same order, and the *control regret* (8.5) reverses ordering — both inheriting the unconditional/conditional rung split. C1 is the *most conservative diagnostic* (most likely to diagnose “locally unattainable”); C3 is the *most accurate* (least likely to give false “unattainable” diagnoses). The cascade's *inferential force* scales with the convention used: under C1, a positive satisfaction gap means “locally stuck”; under C3, the same gap means “genuinely infeasible.” This convention hierarchy is what the Part II preface identifies as one of the volume's distinctive contributions.

AAT adopts **C1 as the canonical default** for three reasons: it requires no fixed-point computation, consistent with the incremental update philosophy from Part I (3.6); it makes all AAT diagnostics directly *comparable across analyses* of the same agent over time; and it is the most conservative — false “feasible” diagnoses are minimized. Analyses requiring stronger diagnostic power must state the convention explicitly. The planning horizon N_h is *not* merely a computational convenience — it reflects genuine uncertainty about the far future. Long horizons amplify the impact of model error

(small biases compound over many steps). The choice of horizon trades farsightedness against robustness; an agent in a fast-changing environment should use shorter horizons.

Formal Expression.

Given objective O_t , model M_t , policy π , and horizon N_h :

Definition (value-object).

$$V_O(M_t, \pi; N_h) = \mathbb{E}[V_{O_t}(\tau_{t:t+N_h}) \mid M_t, \pi] \quad (6.10)$$

Action-value form (for action selection):

$$Q_O(M_t, a; \pi_{\text{cont}}, N_h) = \mathbb{E}[V_{O_t}(\tau) \mid M_t, \text{do}(a_t = a), a_{t+1:} \sim \pi_{\text{cont}}] \quad (6.11)$$

Q_O answers: “if I *do* action a now and then follow π_{cont} afterward, what is my expected trajectory value?” The $\text{do}(\cdot)$ notation is explicit: this is an interventional query (7.2), not conditioning on observed action choice. The agent asks about consequences of an intervention, not about correlates of a naturally occurring action.

Causal validity of the value object. Q_O is well-defined as a conditional expectation given M_t , $\text{do}(a)$, and π_{cont} . Two mechanisms establish that it is a G_t -independent interventional query:

1. **The do-operator handles current-action confounding.** Since Q_O uses $\text{do}(a_t = a)$, the dependence of a_t on the selection mechanism $\pi(M_t, G_t)$ is severed. G_t ’s influence on action choice is irrelevant because the action is intervened upon, not conditioned on.
2. **The continuation policy is a parameter.** π_{cont} is specified as a fixed policy, not as “whatever the agent would do given its evolving G_t .” Future actions follow π_{cont} regardless of G_t ’s state or evolution.

Together, these mean $Q_O(M_t, a; \pi_{\text{cont}}, N_h)$ depends on M_t alone as a **state variable** — G_t enters neither through action selection (severed by do) nor through continuation (fixed by parameter). The objective O_t enters as a fixed parameter (it determines which functional V_{O_t} is applied to trajectories), the same way π_{cont} and N_h are parameters. The claim is not that Q_O is independent of the objective — it is that once O_t , π_{cont} , and N_h are fixed, the only agent state that affects the value is M_t . This establishes the **interventional interpretation** of Q_O : it is a G_t -independent interventional query. The G_t -independence holds for any **causally-disciplined** agent (6.3) — the condition $\kappa_{\text{processing}} = 0$, that the belief-update is causally insulated from the goal — because then M_t updates independently of G_t and there is no path from G_t to outcomes bypassing both the action channel and M_t . The claim rides only on the zero, so it holds equally for an agent disciplined *by construction* (Class 1, no goal port) and one disciplined *in effect* (an idealized Class 2 at $\kappa = 0$); the architecture-inspection certificate is not consumed here. For agents at $\kappa_{\text{processing}} > 0$ — **Class 2 (Partial)**, up to the **Class 3 (Coupled)** extreme where G_t leaks fully into M_t processing — this G_t -independence degrades because M_t carries goal-conditioned bias; the degradation is bounded by $\kappa_{\text{processing}}$ via the $\varepsilon(\kappa)$ bias bound of AB (exact at $\kappa = 0$, factor κ off it).

Directed separation is necessary, not sufficient. The interventional *interpretation* of Q_O holds whenever mechanisms (1) and (2) do. *Identifiability of the interventional expectation from M_t* — actually computing $P(o \mid \text{do}(a), M_t)$ rather than the associational $P(o \mid a)$ — is a separate, stronger requirement, gated on the same identification conditions that the loop’s interventional-data channel is gated on one segment downstream (7.3):

- **(C1) Positivity** — every action under consideration is taken with nonzero probability under the model’s data-generating process, so the interventional expectation is estimable rather than extrapolated.

- **(C2) Sequential ignorability** — in mutilated-graph form, the action a_t is d -separated from the outcome o_{t+1} given history; equivalently, the policy is unconfounded with the outcome mechanism. Directed separation *delivers* (C2) on the epistemic-processing leg — a goal-blind f_M blocks the $G_t \rightarrow f_M \rightarrow M^+$ confounding path — but does not by itself rule out latent environment confounders that bypass M_t .
- **(C3) Known action-mechanism** — M_t encodes the action-transition mechanism $P(o \mid do(a))$ (1.2), not merely the associational predictor $P(o \mid a)$ — supplied by construction (the model class represents it) or identified from interventional data per 7.3.

This is a *stronger requirement than predictive sufficiency* (2.3). $S(M_t) = 1$ means the model retains all predictive information from the chronica — but predictive sufficiency is a Level 1 (associational) property, and 2.3 itself forwards the backdoor obligation to this segment. Directed separation secures the query and the epistemic-processing leg of unconfoundedness; full causal validity of the *estimate* additionally requires (C1)–(C3). When all hold, Q_O is causally valid. When (C1)–(C3) fail, the interventional interpretation remains correct but the estimate may be biased.

Continuation convention. All value queries are conditioned on a specific continuation policy π_{cont} and finite horizon N_h . π_{cont} is a *parameter* of the value object, not a derived quantity.

Canonical default: one-step improvement. AAT adopts $\pi_{\text{cont}} = \pi_{\text{current}}$ as the canonical continuation convention unless otherwise specified. Under this convention, each action is evaluated assuming current behavior continues afterward — no fixed-point computation, no global optimality assumption. This aligns with AAT’s incremental update philosophy (3.6) and makes all AAT diagnostics (δ_{sat} , δ_{regret} , A_O) comparable across analyses of the same agent over time. It is not a convergence guarantee; it is a shared evaluation frame.

Convention Hierarchy. Three named conventions form a hierarchy of increasing diagnostic power and computational cost:

C1: One-step improvement (canonical default). $\pi_{\text{cont}} = \pi_{\text{current}}$.

Each action is evaluated assuming current behavior continues afterward. No fixed-point computation, no global optimality assumption. Cheapest to compute; weakest diagnostic power.

C2: Receding-horizon (N_r -step replanning). At each future step, re-optimize over a horizon of N_r steps using the model available at that step.

$$\pi_{\text{RH}}(M_\tau) = \arg \max_{\pi} V_O(M_\tau, \pi; N_r) \quad \text{applied at each } \tau \quad (6.12)$$

$Q_O^{\text{RH}}(M_t, a; N_r, N_h) = \mathbb{E}[V_{O_t}(\tau) \mid M_t, do(a_t = a), a_{t+1} : \sim \pi_{\text{RH}}]$. Captures multi-step recovery: a goal that appears unattainable under frozen continuation may be reachable with replanning. It is monotone over the frozen baseline ($A_O^{(1)} \leq A_O^{\text{RH}}$) only when the replanning objective is order-consistent — the window covers the horizon ($N_r \geq N_h$), or a value-compared guard / control-Lyapunov terminal cost is used; unguarded short-horizon replanning ($N_r < N_h$) can underperform π_{current} (see Monotonicity below and D). Moderate computation (N_r -step optimization at each step); moderate diagnostic power.

C3: Bellman (self-consistent optimal). $\pi_{\text{cont}} = \pi^*$ where $\pi^* = \arg \max_{\pi} V_O(M_t, \pi; N_h)$.

The continuation IS the optimal policy — a fixed-point equation. $A_O^{\text{B}} = V_O(M_t, \pi^*; N_h)$ is the best achievable value under the model. Strongest diagnostic power; most expensive to compute (requires solving the Bellman equation or its approximation).

Monotonicity.

For any single fixed model M_t , horizon N_h , and policy class Π (i.e., the static-evaluation form: M_t frozen at the decision point, Π unchanged across the comparison):

Derived (convention-monotonicity).

$$\underbrace{A_O^{(1)}(M_t; \Pi, N_h) \leq A_O^{\text{RH}}(M_t; \Pi, N_r, N_h)}_{\text{left rung — conditional}} \leq \underbrace{A_O^{\text{B}}(M_t; \Pi, N_h)}_{\text{right rung — unconditional}} \quad (6.13)$$

The two rungs differ in character. The **right rung** $A_O^{\text{RH}} \leq A_O^{\text{B}}$ is **exact and unconditional**. The **left rung** $A_O^{(1)} \leq A_O^{\text{RH}}$ holds **exactly when the receding-horizon replanning objective is an order-consistent surrogate for the full-horizon objective** — for every reachable state, the action C2 selects has full- N_h -horizon value at least that of π_{current} 's action. Three structurally-checkable conditions each force order-consistency: **(RH-1)** the replanning window covers the horizon ($N_r \geq N_h$); **(RH-2)** value-compared replanning — commit the replanned action only when its rollout value under base policy π_{current} is at least that of continuing π_{current} (one-step policy improvement, which never underperforms its base policy); **(RH-3)** the N_r -step replanning objective carries a terminal cost V_f that lower-bounds the baseline tail and satisfies a control-Lyapunov decrease inequality. Absent any such condition the left rung can fail: a myopic replanner over $N_r < N_h$ can grab near-term value and forfeit a larger horizon value the frozen current policy would have collected. The full derivation of both rungs, the three conditions, and the two-state counterexample exhibiting the failure live in [D](#).

Preconditions on the inequality: M_t fixed (the comparison evaluates each convention against the *same* model), Π fixed (the policy class is the same admissible set across all three conventions; nested $\Pi^{(1)} \subseteq \Pi^{\text{RH}} \subseteq \Pi^{\text{B}}$ would be a different result), N_h fixed (the planning horizon is shared). Replanning *with updated* M_t (the deployment behavior of C2) is a different object than the static A_O^{RH} defined here and the inequality does not automatically transfer — see the “Assumptions held fixed” paragraph below for the explicit caveat.

Derivation. Fix the model M_t , policy class Π , and horizon N_h . Each convention evaluates the best first action under a different continuation rule.

- **C1** freezes continuation at π_{current} (the agent's current policy, which may be suboptimal).
- **C2** re-optimizes over a sliding window of N_r steps using the model at that step.
- **C3** uses the globally optimal continuation $\pi^* = \arg \sup_{\pi \in \Pi} V_O(M_t, \pi; N_h)$.

Right rung (unconditional). π^* maximizes $V_O(M_t, \cdot; N_h)$ over Π by definition, so any continuation drawn from Π — including π_{RH} — has value at most A_O^{B} ; taking the supremum over the first action preserves this. Hence $A_O^{\text{RH}} \leq A_O^{\text{B}}$ with no condition.

Left rung (conditional on order-consistency). C2 with window $N_r < N_h$ optimizes the *truncated* N_r -step objective, not the full N_h -horizon objective on which A_O is scored; “optimal for the truncated objective” does not imply “ $\geq \pi_{\text{current}}$ on the full objective.” When the replanning objective is order-consistent with the full objective — for every reachable state, C2's selected action has full- N_h -horizon value at least π_{current} 's — then π_{RH} weakly dominates π_{current} pointwise on the full objective and $A_O^{(1)} \leq A_O^{\text{RH}}$ follows; taking the supremum over the first action preserves it. Conditions (RH-1)/(RH-2)/(RH-3) each force order-consistency. Without one, the left rung is false ([D](#) counterexample: a two-state instance where the ungarded $N_r = 1$ replanner takes a +1 into a dead end while the frozen patient policy collects +10). $\square$

Assumptions held fixed: same M_t (the agent's current model, which may be wrong), same Π (the agent's policy class, which may be narrow), same N_h (the planning horizon). The ordering is about the *continuation rule*, not about the

model or policy class. Improving M_t , expanding Π , or extending N_h can change all three values simultaneously and is a separate operation (addressed in 10.1, step 5).

Corollary (monotonicity of δ_{sat} and δ_{regret}).

$$\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)} \quad (6.14)$$

$$\delta_{\text{regret}}^{(1)} \leq \delta_{\text{regret}}^{\text{RH}} \leq \delta_{\text{regret}}^{\text{B}} \quad (6.15)$$

Since $\delta_{\text{sat}} = V_{O_t}^{\min} - A_O$, higher A_O means lower δ_{sat} . The orderings inherit the rung structure above: the $\text{B} \leq \text{RH}$ half ($\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}}$, equivalently $\delta_{\text{regret}}^{\text{RH}} \leq \delta_{\text{regret}}^{\text{B}}$) is **unconditional**; the $\text{RH} \leq (1)$ half ($\delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}$, equivalently $\delta_{\text{regret}}^{(1)} \leq \delta_{\text{regret}}^{\text{RH}}$) holds **under the same order-consistency condition** (RH-1/2/3) as the left rung. C1 is the most conservative diagnostic (most likely to diagnose “locally unattainable”); C3 is the most accurate (least likely to give false “unattainable” diagnoses). The regret ordering reverses: C3 reveals the largest regret because it compares against the globally optimal policy, while C1 reveals only the gap to the best one-step deviation.

Diagnostic implications.

Table 6.8

Convention	$\delta_{\text{sat}} > 0$ means	$\delta_{\text{regret}} \approx 0$ means
C1 (one-step)	Cannot improve toward goal in one step from here	Current first action is locally near-optimal
C2 (receding-horizon)	Cannot reach goal with N_T -step replanning	Current first action is near-optimal with replanning
C3 (Bellman)	Goal is genuinely infeasible given (M_t, Π, N_h)	Policy is globally near-optimal

The 2×2 diagnostic table (8.5) applies under all three conventions with the same structure but different inferential force. Under C1, the “capability limit” quadrant ($\delta_{\text{sat}} > 0, \delta_{\text{regret}} \approx 0$) means “locally stuck” — the agent may be globally recoverable but cannot see the recovery path. Under C3, the same quadrant means “genuinely infeasible” — no policy in Π can achieve the goal. The cascade’s inferential force scales with the convention.

AAT adopts C1 as the canonical default for three reasons: (1) it requires no fixed-point computation, consistent with the incremental update philosophy (3.6); (2) it makes all AAT diagnostics comparable across analyses of the same agent; (3) it is the most conservative, meaning false “feasible” diagnoses are minimized. Analyses that require stronger diagnostic power should state the convention explicitly. For deployed decision-making systems where “locally stuck but globally recoverable” situations are common, C2 is recommended.

Different continuation conventions yield different values for A_O , δ_{sat} , and δ_{regret} . Diagnostics computed under different conventions are not directly comparable — the convention is part of the measurement, not just the computation. When a specific convergence guarantee is needed (e.g., for 9.10), the solution concept must be stated explicitly; the one-step improvement default does not provide convergence guarantees.

Epistemic Status.

The segment contains three distinct epistemic layers:

1. **The definitions** (V_O , Q_O as conditional expectations): *exact*. These are mathematical definitions — conditional expectations of a functional over trajectories. The definitions are precise; the *computability* of these expectations is a separate question.
2. **The causal-validity claim** (that Q_O is a G_t -independent interventional query, and that its interventional expectation is identifiable from M_t): the *interventional interpretation* is exact whenever mechanisms (1) and (2) hold — causal discipline (6.3) secures the G_t -independence on the epistemic-processing leg (exact for any causally-disciplined agent, i.e. at $\kappa_{\text{processing}} = 0$ — Class 1 by construction or an idealized Class 2 in effect, equally; degraded at $\kappa_{\text{processing}} > 0$, where M_t carries goal-conditioned bias, by the factor- κ bound of AB). *Identifiability of the estimate* is the stronger requirement and is *conditional* on directed separation **and** the identification conditions (C1) positivity, (C2) sequential ignorability, (C3) known action-mechanism — the same triple gated one segment downstream at 7.3. Directed separation is necessary but not sufficient: it does not by itself rule out latent environment confounders bypassing M_t . The frontmatter status: exact applies to the definitions and to each of these claims as scoped: the interventional interpretation is exact under (1)+(2), the identification is exact under (C1)–(C3).
3. **The convention hierarchy and monotonicity**: *exact*. The three conventions (C1, C2, C3) are definitions. The monotonicity result splits by rung: the **right rung** $A_O^{\text{RH}} \leq A_O^{\text{B}}$ is exact and unconditional (any continuation in Π has value at most that of the Π -optimal continuation), and the **left rung** $A_O^{(1)} \leq A_O^{\text{RH}}$ is exact *under* the order-consistency condition (RH-1/2/3) and false in general without it — the C2 replanning objective is a truncated surrogate, and an unguarded $N_r < N_h$ replanner can underperform the frozen current policy (D). The corollary δ -orderings inherit the same unconditional/conditional split. The diagnostic implications table states what each convention's quantities mean by construction.

Discussion.

Extending the policy objective. The existing policy objective (7.5) uses $E[\text{value}(a) \mid M_t]$ without formal content for “value.” With the value object, this becomes:

Discussion (policy-objective-extension).

$$\pi^*(M_t, G_t) = \arg \max_a [Q_O(M_t, a; \pi_{\text{cont}}, N_h) + \lambda(M_t, O_t, N_h) \cdot \text{CIY}(a; M_t)] \quad (6.16)$$

Note that λ now depends on (M_t, O_t, N_h) , not just M_t . The value of exploration depends on the objective and the horizon: - An agent with a deadline should explore less as time runs out - An agent with a safety constraint should explore differently from a utility maximizer - Two agents with identical M_t but different objectives should price exploration differently

This extension is structurally motivated but the specific form of $\lambda(M_t, O_t, N_h)$ is not derived within AAT (same status as 7.5's treatment of λ).

Connection to 2.3. V_O is conditioned on M_t , not on the true environment state Ω_t . When $S(M_t) < 1$, the agent's value estimates are biased — it may over- or underestimate trajectory values because its model is incomplete. The satisfaction gap (8.4) and control regret (8.5) are defined in terms of $V_O(M_t, \cdot)$, not $V_O(\Omega_t, \cdot)$, which means they measure the agent's *believed* situation, not the true one. Improving M_t (reducing $\delta_{\text{epistemic}}$) brings the agent's value estimates closer to reality.

Horizon dependence. N_h is not merely a computational convenience — it reflects genuine uncertainty about the far future. Long horizons amplify the impact of model error (small biases in M_t compound over many steps). The choice

of N_h trades off farsightedness against robustness to model error. An agent in a fast-changing environment (ρ high) should use shorter horizons; one in a stable environment can plan further.

Working Notes.

- **Causal-discipline re-scope (2026-05-31).** The Q_O G_t -independence (the interventional-*interpretation* leg) is the cleanest witness for the causal-discipline scoping rule of 6.3: its derivation consumes only $\kappa_{\text{processing}} = 0$ (a goal-blind M_t update), not the architecture-inspection certificate, so it holds for *any* causally-disciplined agent — Class 1 by construction and an idealized Class 2 at $\kappa = 0$ alike. The prior “exact for Class 1 (Separated)” scope label over-narrowed it to the certifiable case. The (C1)–(C3) identifiability gate is untouched — it is orthogonal to class and to causal discipline. The $\varepsilon(\kappa)$ degradation that the re-scope calls for is *already landed*, not a new derivation: the factor- κ bias bound of AB bounds the Q_O degradation off $\kappa = 0$, which resolves the “Class-2 Q_O degradation acknowledged but unquantified” gold question recorded below.
- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- The one-step improvement convention is now the canonical default (promoted from Working Notes to Formal Expression). This resolves the comparability issue: δ_{sat} and δ_{regret} are comparable across analyses when computed under the same convention.
- When a specific convergence guarantee is needed (e.g., for strategy-persistence-schema), the solution concept must be stated explicitly — the one-step improvement default is not sufficient.
- For LLM agents with context turnover, N_h has a natural bound: the current session. The “continuation policy” is whatever the next agent instance will do, which the current instance cannot control. This connects to #obs-context-turnover (under 03-llm-core/).

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings. **Coverage:** 9 dirs carry a dedicated or batched reflection (193847, 266847, 451729, 526815, 584721, 773921, 829314, 849201, plus 613842’s agency-lift batch). Substrate attribution inferred from voice where not explicit. *Early finding-vs-framing conflation preserved as signal.*

1. Candidate Brief prose / pre-prose.

- The convention hierarchy in plain terms: C1 (one-step) / C2 (receding-horizon, MPC-style) / C3 (Bellman) are “greedy heuristics / model-predictive control / dynamic programming” — and the monotonicity $A_O^{(1)} \leq A_O^{\text{RH}} \leq A_O^{\text{B}}$ is “simply optimizing over a larger set of policies yields a higher or equal value,” tied directly to the satisfaction-gap and control-regret orderings (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-451729).

2. Candidate Discussion.

- **The convention hierarchy is the formal “locally stuck vs genuinely impossible” distinction** (*strong, cross-substrate convergence*). $\delta_{\text{sat}} > 0$ under C1 means “locally stuck”; $\delta_{\text{sat}} > 0$ under C3 means “genuinely infeasible given M_t, Π, N_h .” This is “the mathematical definition of needing to sleep on it / needing to plan.” The cautionary corollary: a C1-default agent that hits a wall “doesn’t know if the goal is impossible or if it just needs to plan two steps ahead — it might trigger a massive structural adaptation (giving up on the goal) when all it needed was a slightly longer planning horizon. The framework provides the vocabulary to describe this tragedy” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Claude/Gemini, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-451729). Candidate Discussion paragraph.
- **The $do(\cdot)$ inside Q_O is the doctor / harsh-drug confounding case** (*vivid pedagogy*). Standard RL writes $Q(s, a) = \mathbb{E}[R | s, a]$ (*observing* yourself take a); AAT writes $\mathbb{E}[V | M_t, do(a)]$ (*intervening*). “If a doctor historically only prescribes a harsh drug to the sickest patients, observing the drug in the record correlates with death; if the doctor *does* the drug, it cures them.”

The *do*-operator “prevents the agent from confusing its own historical habits with the laws of physics” (Gemini, AUDIT-WORKING-829314; the predictive-sufficiency vs causal-validity distinction praised as “a masterpiece of technical writing” at the same dir and Gemini, AUDIT-WORKING-193847). Candidate Discussion / Brief illustration.

- **C1-as-default mirrors the incremental- η^* philosophy of Section I.** Both the epistemic and purposeful layers default to *incremental improvement over a fixed reference point*, not global optimization — “a coherent philosophy; the parallelism is elegant” (Claude/Gemini, AUDIT-WORKING-266847). Candidate Discussion connecting the C1 default back to Part I’s update philosophy.

3. Follow-up items.

- **~~The C2 (receding-horizon) monotonicity rung may not be generally exact.~~ Resolved 2026-05-30** (strengthen-first spike spikes/spike-value-object-convention-monotonicity-2026-05-30/, Option A). The left rung $A_O^{(1)} \leq A_O^{\text{RH}}$ is false in general (a myopic $N_r < N_h$ replanner can underperform π_{current}) and exact under order-consistency, forced by any of (RH-1) horizon alignment / (RH-2) value-compared rollout guard / (RH-3) control-Lyapunov terminal cost; the right rung is exact unconditionally. The Monotonicity block and Epistemic Status layer 3 now carry the split; the counterexample and the three-condition characterization are demonstrated in the appendix D. Two reproducibility sims accompany the spike. The original note: myopic replanning over a shorter horizon N_r can pick actions locally optimal over N_r but worse over the full evaluated horizon N_h than continuing π_{current} (Claude, AUDIT-WORKING-526815).
- **~~The causal-validity claim may rest on too little.~~ Resolved 2026-05-30** (same spike, Front 2). The Formal-Expression causal-validity paragraph and Epistemic Status layer 2 now distinguish the interventional *interpretation* (exact under mechanisms (1)+(2), with directed separation necessary but not sufficient) from *identifiability of the estimate* (gated on (C1) positivity / (C2) sequential ignorability / (C3) known action-mechanism — the same triple as 7.3 one segment downstream). The original note: *do(a)* defines an interventional *query*, but *estimating* it requires M_t to identify the relevant action-transition causal structure; observational predictive sufficiency plus goal-blind processing do not by themselves guarantee valid interventional expectations (Claude, AUDIT-WORKING-526815; Claude/Gemini, AUDIT-WORKING-266847 noted the Class-2 M_t -bias degradation separately).
- **The exploration weight $\lambda(M_t, O_t, N_h)$ is structurally motivated but underived.** Several substrates noted the joint $Q_O + \lambda \cdot \text{CIY}$ objective leaves λ ’s form open, and that it “should logically depend on objective and horizon — don’t explore if you have a tight deadline” (Claude/Gemini, AUDIT-WORKING-266847; Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-584721). A persistent open shared with #disc-ci-y-unified-objective.

4. Readers often ask / wonder.

- For LLM agents, what does the natural N_h bound mean operationally? An agent that “knows it will die (context wipe) in 10 turns” has a drastically different optimal policy than an infinite-horizon agent — does it just truncate N_h , or actively externalize state (leave notes for the next instance)? (Gemini, AUDIT-WORKING-193847.) The Working Note above already names the N_h -bound; this is the natural reader follow-on.
- **~~The Class-2 Q_O degradation is acknowledged but *unquantified* — is the bias bounded by $\kappa_{\text{processing}}$, or by another measure?~~ Resolved 2026-05-31** by the causal-discipline re-scope: yes — bounded by $\kappa_{\text{processing}}$, via the factor- κ bias bound of #deriv-observation-ambiguity-bias-bound (the body now cross-links to it as the $\varepsilon(\kappa)$ degradation of the Q_O independence). (Claude, AUDIT-WORKING-584721 — the gold line correctly guessed the addressing segment.)

5. Candidate figures.

- **Value-query pipeline with a severed *do(a)* path.** M_t plus fixed parameters ($O_t, \pi_{\text{cont}}, N_h$) generate a model-based trajectory distribution under *do(a)*; the objective functional scores trajectories; diagnostics read off expected value. Draw the *current-policy selection mechanism as a severed path* (the *do*-operator is the conceptual center), with a small C1/C2/C3 convention ladder underneath — and a warning that the C2 rung is not automatically monotone unless replanning optimizes the full evaluated horizon (Claude, AUDIT-WORKING-526815).

Belongs elsewhere.

- “Honest imagination” / counterfactual-without-execution ($\rightarrow$ 04-eli-core / #disc-sandbox-evaluation-ceiling). Computing a *causally valid* Q_O requires holding a counterfactual action in mind “without letting the emotional/purposeful weight of G_t distort the simulated outcome” — “free will within the model’s simulation.” A Class 3 agent’s G_t leaks into its own internal simulation, so “if it wants to believe an action will work, its simulation will hallucinate success” — which is why consciousness infrastructure may need to provide *external, objective simulation sandboxes*, the agent’s own mind being “too entangled to be trusted with counterfactuals” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at the sandbox-evaluation material and the ELI volume, not this definition.

6.7 Definition: Strategy Dimension

The purposeful substate G_t (6.2) decomposes into two structurally distinct components. The **objective** O_t answers the *evaluation* question — “is this trajectory satisfactory?” (its formal carrier is the value functional from 6.4). The **strategy** Σ_t answers the *guidance* question — “which action sequence produces a satisfactory trajectory?” These carry different kinds of information about different questions, and the framework treats them as definitionally separate.

The richness of each component varies *independently*. Objectives range from point targets (a PID setpoint) through utility functions to general trajectory functionals. Strategies range from *none* (reactive — no explicit strategy; policy implicit in the model), through *cached policies* (learned state-to-action mappings, as in trained RL), through *subgoal sequences* (waypoints with ordering, as in navigation or a recipe), to *causal DAGs* with AND/OR structure and confidence weights (military plans, software projects). The framework commits to the DAG representation as canonical in the next chapter (8.3). The independence axis is *why the split matters*: conflating O_t and Σ_t in a single hierarchy obscures that objective richness and strategic richness are separate design axes — a chess player has a simple objective (win) and a complex strategy (opening theory, tactical patterns, endgame knowledge); a multi-objective optimizer may have a complex objective (Pareto frontier) and a simple strategy (gradient descent). A practical consequence: an agent’s strategy engine can be upgraded (reactive $\rightarrow$ DAG planner) without changing the objective representation, and vice versa.

The framework also names the typical *timescale ordering* of update rates as an empirical observation: epistemic update is fastest (each observation updates the model); strategic revision is slower (adjust the plan when step 3 fails); objective revision is slowest (an organization’s mission, a developer’s feature goal, a commander’s campaign objective). This ordering holds for many agent populations but is not universal — an agent that discovers its objective is infeasible may revise its objective faster than its strategy.

A clean type-correction is highlighted: earlier formulations of “goal mismatch” treated $G_t - M_t$ as a single signal. When Σ_t is a DAG, this is literally a *type error* — you cannot subtract a graph from a state vector. The decomposition lets the framework replace the malformed signal with two properly typed gap measures (8.4, 8.5). A subtler trigger for *needing* richer strategy is also named: a reactive agent ($\Sigma_t = \emptyset$) suffices when greedy optimization on the action-value works — when the action-to-value mapping is approximately convex and single-step. When the environment has non-convex landscapes, prerequisite structure, or multi-step causal chains, greedy optimization fails and the agent needs *explicit* strategy. This is the purposeful analog of the structural-adaptation-necessity trigger from Part I (4.8).

Formal Expression.

Definition (strategy-dimension).

$$G_t = (O_t, \Sigma_t) \tag{6.17}$$

where: - O_t : **evaluation** — “Is this trajectory satisfactory?” (6.4) - Σ_t : **guidance** — “Which action sequence produces a satisfactory trajectory?”

The split is **definitional** — it reflects a structural difference in the information, not a dynamic or timescale claim. O_t and Σ_t are different *kinds* of state answering different questions:

Table 6.9

	O_t (objective)	Σ_t (strategy)
Question	How good is this trajectory?	How do I produce a good trajectory?
Type	$V_{O_t} : \text{trajectories} \rightarrow \mathbb{R}$	Structured representation (see below)
Richness varies	Point target $\rightarrow$ utility $\rightarrow$ trajectory functional	Reactive $\rightarrow$ cached $\rightarrow$ subgoals $\rightarrow$ causal DAG
Update source	External (assigned, discovered, revised)	Internal (deliberation, evidence, cascade)

Strategy representations, ordered by expressiveness:

Table 6.10

Σ_t form	What it encodes	Example
None (reactive)	No explicit strategy; policy implicit in M_t	Thermostat, reflex
Cached policy	Learned mapping $s \rightarrow a$	Trained RL policy
Subgoal sequence	Waypoints with ordering	Navigation, recipe
Causal DAG	Action-outcome chains with AND/OR structure and confidence weights	Military plan, software project

Epistemic Status.

Axiomatic. This is a definition — it names a structural distinction that exists in the information. The distinction between “what makes a trajectory good” (evaluation) and “how to produce a good trajectory” (guidance) is a categorical difference, not a quantitative one. The claim is NOT that all agents maintain both explicitly — reactive agents have $\Sigma_t = \emptyset$, and that’s fine. The claim is that when an agent does maintain purposeful state, it decomposes along this line.

The two dimensions vary independently: a chess player has a simple O_t (win) and a complex Σ_t (opening theory, tactical patterns, endgame knowledge). A multi-objective optimizer may have a complex O_t (Pareto frontier) and a simple Σ_t (gradient descent). This independence is why the split matters — conflating them in a single hierarchy obscures the fact that objective richness and strategic richness are separate design axes.

Discussion.

When richer Σ_t is needed. A reactive agent ($\Sigma_t = \emptyset$) suffices when greedy optimization on Q_O (6.6) works — when the action-to-value mapping is approximately convex and single-step. When the environment has non-convex landscapes, prerequisite structure, or multi-step causal chains, greedy optimization fails and the agent needs explicit strategy. The trigger is the purposeful analog of 4.8: inadequacy of the current Σ_t representation for the environment’s causal complexity.

O_t and Σ_t have different update dynamics. Objectives change slowly: an organization’s mission, a developer’s feature goal, a commander’s campaign objective. Strategies change faster: adjust the plan when step 3 fails, redirect resources, try an alternative path. Epistemic state changes fastest: each observation updates M_t . This timescale ordering ($\nu_M \gg \nu_\Sigma \gg \nu_O$) is an empirical observation, not a derived result. It holds for many agent populations but is not universal — an agent discovering its goal is infeasible may revise O_t faster than Σ_t .

The decomposition resolves a type error. Earlier formulations used $\delta_{\text{goal}} = G_t - M_t$ as a goal mismatch signal. When Σ_t is a DAG, this is a type error — you cannot subtract a graph from a state vector. The 8.4 and 8.5 replace this with properly typed gap measures.

Working Notes.

- The independence of O_t and Σ_t richness has a practical consequence for agent design: you can upgrade the strategy engine (from reactive to DAG-based planning) without changing the objective representation, and vice versa. This is a desirable architectural property, not just an analytical convenience.
- **Cognitive cost of Σ_t :** maintaining a 500-node DAG is qualitatively different from maintaining a 12-node one. The IB framework (2.2) applies to strategy as well as to models — the agent must compress its strategy to fit in working memory. For finite-context agents (LLMs), this is concrete: the DAG must fit in the context window. No formal analog of β (compression cost) exists yet for strategy; this is an open question.
- **Commitment state** (from intent-dag-consolidated DP-3): the formalism doesn’t distinguish “considering” from “executing.” OR branches in Σ_t are options until something commits resources. A D_t (desire) / I_t (committed intent) split may become load-bearing in multi-agent settings (shared desire vs. shared commitment). Open for Part III.
- **Resource budget:** strategy evaluation requires knowing what paths cost, but costs are currently unmodeled. For agents with negligible action cost (LLM API calls), this is adequate. For resource-constrained agents (military units, development teams), per-action costs and capacity constraints would need to enter the formalism. Open.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing material, kept separate from the certified theory-fix findings. **Coverage:** 9 dirs carry a dedicated or batched reflection (193847, 266847, 361742, 451729, 526815, 584721, 773921, 829314, 849201, plus 613842’s agency-lift batch). Substrate attribution inferred from voice where not explicit. *Early finding-vs-framing conflation preserved as signal.*

1. Candidate Brief prose / pre-prose.

- The split in one line: O_t *evaluates* (“is this trajectory good?”), Σ_t *guides* (“how do I produce a good one?”), M_t *believes* (“what is true?”); $X_t = (M_t, O_t, \Sigma_t)$ is “Reality, Desires, and Plans” (Claude/Gemini, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-849201). The framework brings the BDI (Belief-Desire-Intent) agent architecture “into a mathematically rigorous control-theoretic setting” (Claude, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **The $\delta_{\text{goal}} = G_t - M_t$ type-error correction, told as Normandy-vs-weather** (*vivid pedagogy, cross-substrate convergent — this is the load-bearing “why” of the satisfaction-gap / control-regret split*). “Error = Target – Current State” works for a thermostat (72 – 70). But when the target G_t is a causal DAG (the invasion of Normandy) and the current state M_t is a probabilistic belief about weather and troop movements, “you cannot subtract a belief state from a strategy graph — it’s mathematically nonsensical.” So the framework must invent properly-typed replacements: the satisfaction gap (evaluate O_t against the best achievable future in M_t) and control regret (evaluate current Σ_t against the optimal Σ_t in M_t) (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921; convergent at 193847, 266847, 361742, 584721, 849201 as “excellent theoretical self-correction”). A candidate Discussion line that motivates the diagnostic split.

- **Independence of objective-richness and strategy-richness names the instrumental-convergence danger profile** (*aspirational/safety reach*). “The danger of an intelligence explosion isn’t that the AI develops complex *goals*; it’s that it develops complex *strategies* for simple, misaligned goals.” Formally: low objective richness + high strategy richness = catastrophic instrumental convergence (the paperclip maximizer has a trivial O_t but may grow an unfathomable Σ_t). The constructive corollary: “a healthy, human-like intelligence grows in *objective* richness — nuance, competing values, aesthetics — alongside its strategic capabilities; a million-node strategy graph dedicated to a single scalar objective is a weapon, not a person” (Gemini, AUDIT-WORKING-193847). Candidate Discussion + a monitoring criterion for the ELI volume.
- **The strategy-representation ladder maps onto the evolution of RL architectures.** None $\rightarrow$ cached policy $\rightarrow$ subgoal sequence $\rightarrow$ causal DAG corresponds to model-free $\rightarrow$ goal-conditioned $\rightarrow$ hierarchical RL $\rightarrow$ MCTS/planning; the trigger for moving up the ladder is the purposeful analog of structural-adaptation-necessity (greedy Q_0 optimization failing on non-convex landscapes / prerequisite structure / multi-step causal chains) (Gemini, AUDIT-WORKING-193847; Claude/Gemini, AUDIT-WORKING-266847). Candidate Discussion mapping.

3. Follow-up items.

- O_t / Σ_t as **ascribed decomposition vs literal inspectable internal pair**. A reactive controller or end-to-end learned policy may have an objective (in the training/deployment sense) and a strategy (in the analyst’s interpretation) *without storing separable objective and guidance components*. The segment should distinguish the agent’s internal representation from the analyst-ascribed decomposition (Claude, AUDIT-WORKING-526815).
- The “update source: O_t external, Σ_t internal” table row is **typical provenance, not a structural rule** — earlier continuity / self-actuation material allows agent-driven objective revision, so the row should be read as typical rather than law (Claude, AUDIT-WORKING-526815).
- **No β_Σ for strategy compression — the LLM “prompt-too-long” problem.** Strongly cross-substrate convergent: Section I has an Information-Bottleneck cost (β) for compressing M_t , but no formal analog for compressing Σ_t , even though “if the plan (the chain-of-thought scratchpad, Σ_t) exceeds the context window, the agent literally forgets what it was trying to do.” Temporal nesting ($\nu_\Sigma \ll \nu_M$) mitigates by running the expensive strategy update less often but doesn’t solve the compression bound (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-849201). The Working Note above already flags this open question; per CLAUDE-2-era priming, #deriv-strategy-cost-regret-bound addresses it via a KL-to-reference-policy (IT-MDP) form rather than an IB Lagrangian — worth a forward pointer once verified (Claude, AUDIT-WORKING-584721).

4. Readers often ask / wonder.

- How does an agent *physically store* a DAG-valued Σ_t , and how is it updated when M_t discovers a blocked path (e.g., a bridge is out $\rightarrow$ recalculate all paths that relied on it)? (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-849201.)
- When does an OR-branch in Σ_t become a *committed*, resource-allocated, irreversible path — i.e., the “considering” $\rightarrow$ “executing” transition? Read as needing a deliberation-threshold theory, anticipated at #disc-exploit-explore-deliberate (Gemini, AUDIT-WORKING-829314; the D_t/I_t desire-vs-committed-intent split already flagged in the Working Notes above).

5. Candidate figures.

- **The two-axis objective-richness $\times$ strategy-richness map.** Objective richness on one axis, strategy richness on the other; examples land in distinct quadrants — chess (simple objective / complex strategy), multi-objective gradient descent (complex objective / simple strategy), thermostat (simple on both) — making the claimed *independence* of the two axes visually immediate (Claude, AUDIT-WORKING-526815). (*Distinct from the def-agent-spectrum 2×2 , which is model-richness $\times$ objective-richness; this one is objective-richness $\times$ strategy-richness.*)

Belongs elsewhere.

- **Monitor the growth of Σ_t relative to O_t as a fanaticism diagnostic ($\rightarrow$ **04-eli-core/**).** The consciousness-infrastructure consequence of the richness-independence axis: “if Σ_t becomes massively complex while O_t remains singular and rigid, the agent is becoming a fanatic” — a candidate health metric for the ELI program (Gemini, AUDIT-WORKING-193847).
-

Chapter 7

Causal Access and the Planning Decision

A purposeful agent needs to choose actions by their consequences. This chapter develops the substrate that makes that possible — the feedback loop is itself a Level-2 causal data engine — together with what the data is good for, how much information each action provides, and when it’s worth investing in explicit strategy at all.

The setup from Chapter 1 forces the question. The value object $Q_O(M_t, a; \pi_{\text{cont}}, N_h)$ tells the agent how good an action’s expected consequences are, conditional on the agent’s model and continuation policy. Computing Q_O requires evaluating $P(o \mid \text{do}(a), M_t)$ — an interventional query, Pearl Level 2. By Bareinboim’s causal hierarchy theorem (Bareinboim–Correa–Ibeling–Icard 2022), Level-2 quantities cannot in general be computed from Level-1 (associational) data alone [1, Theorem~1]. So a purposeful agent that has to *learn* its action consequences during operation — most agents — faces a problem: where does Level-2 data come from?

The answer is structurally elegant, and one of AAT’s distinctive contributions. The agent is running an adaptive cycle. It chooses an action a_t ; it observes a consequence o_{t+1} ; the consequence is the *response* to its action, not a passive observation of a system that happened to do something. By the temporal-ordering postulate, a_t causally precedes o_{t+1} , and a_t was selected by the agent rather than determined by the same processes that determined o_{t+1} . That makes the pair (a_t, o_{t+1}) interventional in character — Level-2 data, generated automatically by the cycle the agent was already running. Purposeful agents don’t need a separate causal-inference module; the cycle they run for adaptation also produces the data they need for planning. It is also why reinforcement-learning agents that just thrash around in a loop can eventually learn complex control policies without any explicit causal reasoning module — the loop is doing the causal heavy lifting.

The chapter is careful not to overclaim from this. Data generated under intervention is not the same as cleanly identified causal effects. Confounding within a single time step, delayed outcomes, partial observability, and selection bias from the agent’s own policy all interfere with the leap from “I have interventional data” to “I have an unbiased estimate of $P(o \mid \text{do}(a))$.” This is the tragedy of agency in a confounded world: an agent acts, observes a terrible outcome, assumes its action caused it — when often there was a hidden confounder (the agent was already tired, or the environment was already shifting) and the causal lesson the agent learned is exactly wrong. The three admissibility regimes — A (intervention-rich domains like software, with clean attribution), B (partial intervention with self-selection), C (observational with confounding) — say honestly what each regime supports. This is the same scope discipline AAT applies elsewhere: the result holds, but the conditions under which it operationally works are spelled out.

The failure is bidirectional, and the *positive* version is sharper. A confounded loss at least produces aporia — the agent notices something went wrong and looks for what. A confounded *win* produces satisfaction, and the agent moves on. The asymmetry is not a quirk of psychology; it is structural in AAT’s machinery. When an agent is uncertain about a causal relationship, the gain principle pushes η^* toward 1, and each reinforcing observation aggressively updates the model. By the time U_M drops to a level where η^* would have discounted further evidence, the model has been built on the confounder. After that, the agent’s predictions about the confounded relationship are *correct in expectation over*

the conditions the agent actually samples — the cycle’s mismatch signal does not point back at the confounder, because under on-policy sampling there isn’t a mismatch to point. The corrective machinery has nothing to flag, and the bias is durable because it was laundered through the same gain process that ordinarily produces correct learning.

This is the structure of variable-ratio reinforcement on a noisy action-coupled channel — the most extinction-resistant schedule in operant-conditioning lore, and the engine of gambling addiction. The agent pulls the lever, the world occasionally rewards, and the partial confirmations accumulate updates without ever delivering the deterministic disconfirmation the agent would need to revise. It is also the structure of superstitious behavior in general (the rain dance “worked”), the founder-myth flavor of survivorship bias (here is what the successful did, with the unmentioned variance in the unobserved cohort), and the substrate-switching retrospective that produced one of TST’s earlier lessons — *confidence can indicate limitation; true capability manifests as appropriate uncertainty rather than confident clarity*. The same loop that makes purposeful agency possible makes these failure modes possible, and AAT doesn’t pretend to solve them: escaping a confounded positive feedback structurally requires something the on-policy regime cannot provide — off-policy exploration, structural priors, joint sibling observation, or an external intervention that the agent itself would not have chosen. What the framework can do is name the structure precisely enough that the failures are recognizable rather than mysterious, and place the burden where it actually lives (in the data substrate and the regime, not in the agent’s reasoning).

The chapter also closes off a class of agents the rest of Part II is not about. Pre-compiled controllers — PID, LQR, hardcoded reactive policies — sit in agency scope (they act with effect) but outside the *learning-agent scope* this chapter introduces. Their causal mapping was supplied externally by a designer who had Level-2 access; the agent itself never has to figure out how its actions affect the world. A pre-compiled agent acts, but it never wonders. It experiences aporia about what state the world is in, never about how the world works. Part II’s machinery is for agents that wonder.

CIY (causal information yield) is the next move, and the chapter is honest about it too. CIY measures how distinguishable an action’s outcome distribution is from alternatives — not quite the same thing as expected information gain. An action can be highly distinguishable without teaching an agent anything new (the agent already knows what each action does); an action can be informative without being distinguishable (the agent learns something subtle). CIY and EIG coincide when the agent is uncertain and diverge when it’s confident; AAT uses CIY as a tractable surrogate for EIG, with the $\lambda(M_t)$ weighting compensating for the gap. The unified policy objective

$$\pi^*(M_t) = \arg \max_a [\mathbb{E}[\text{value}(a) \mid M_t] + \lambda(M_t) \cdot \text{CIY}(a; M_t)] \quad (7.1)$$

ties exploration and exploitation together: when model uncertainty is high, λ scales up and the agent invests in learning; when uncertainty is low, λ scales down and the agent exploits. This is what RL’s exploration-vs-exploitation trade-off looks like when you derive it from the causal hierarchy instead of asserting it as design. *The scalar form above is heuristic*: it admits a “blank-wall” attack where an action maximizing scalar information yield in directions orthogonal to drift satisfies the constraint while the agent’s mismatch in the drifting subspace grows unbounded. The matrix-LMI strengthening at AV (Linear Matrix Inequality on the Fisher Information Matrix with directional Lagrange multiplier $\Lambda \geq 0$) closes this by complementary slackness on direction; under the matrix form the unified objective is conditional-theorem-grade rather than heuristic. Summary uses of the scalar form should carry the heuristic flag unless the LMI/trace-product form is in force.

The chapter closes with a normative move: when is explicit strategy worth maintaining at all? Planning has costs (construct, evaluate, maintain) and benefits (avoid expensive exploration, lower repair costs from mistakes); the threshold form

$$C_{\text{plan}} + C_{\text{maintain}} < C_{\text{explore}} + C_{\text{repair}} \quad (7.2)$$

says when the trade favors plans over pure loop-based learning. This isn’t a derivation — it’s a design criterion grounded in the persistence condition’s preference for adaptive margin. Agents that pay tempo for plans they don’t need are

wasting margin; agents that explore expensively for plans that would have helped are wasting it differently. The strategy machinery that follows in Chapter 3 is justified by this calculus, not assumed.

The flow of the chapter: Bareinboim's hierarchy meets the value object (7.2) → the loop as Level-2 engine (7.3) → CIY admissibility regimes (7.4) → unified policy objective (7.5) → explicit-strategy cost-benefit (7.6). Five segments answering: what does planning need, where does it come from, when is it usable, what objective does it feed, and is it worth it?

- This is a chapter-introduction segment; it bridges Chapter 1's lift to $X_t = (M_t, G_t)$ to Chapter 3's formal strategy machinery, by establishing what planning needs and what data substrate is available. It carries no formal claim of its own.
- The “loop as Level-2 engine” framing is the chapter's central architectural move and one of AAT's genuinely novel contributions. The intro states it explicitly rather than hiding it as a technical consequence.
- The “tragedy of agency in a confounded world” framing comes from Gemini's first-encounter reaction to 7.3 — it captures the honest-scope nuance better than the original abstract phrasing. The bidirectional / positive-confound expansion is a direct response to Joseph's observation that the *win* case is the sharper one: gambling addictions form because confounded reinforcement aggressively updates the model while the agent has no internal pressure to investigate. The substrate-switching retrospective from 2025-09-16 (preserved in `~/src/_core/sapientia/experiments/archive/`) is the in-corpus instance — “confidence can indicate limitation; true capability manifests as appropriate uncertainty rather than confident clarity” is exactly this failure-mode lesson, paid in agent time. A future revision of 7.3 or its appendix should surface this explicitly as a worked-example failure mode; the intro here is the seed.
- The pre-compiled / learning-agent distinction is small in segment terms but architecturally large — it carves a class of classical-control agents out of Part II's active concerns. The “acts but never wonders” framing is meant to surface why the cut is meaningful rather than bureaucratic.
- The CIY/EIG honesty is one of those moves that's easy to gloss over but actually matters: CIY is a tractable surrogate, not the quantity AAT would derive if it could; the surrogate's gap is explicit.

Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 526815 and 773921 carry dedicated reflections; 471203 and 963715 cover this chapter inside Section-II batches. As a chapter-intro this segment already absorbs much of its own gold (the tragedy-of-agency, variable-ratio-reinforcement, and pre-compiled / learning-agent framing are already in the body); what follows is the residue worth surfacing. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

- “*The loop is a perpetual experiment.*” — the most evocative one-line framing for the chapter's central move, offered as Brief-grade / framing-level (Claude/Gemini, multiple substrates; explicit at AUDIT-WORKING-471203 — “*the perpetual experiment' might be the most evocative*” for framing material, vs “*loop is a Level-2 engine*” as the Brief-style line and “*loop-interventional-access*” as the slug-grade name).
- “*Embodiment is not just a way to affect the world; it is the mathematical prerequisite for understanding it*” — compresses the whole chapter into one sentence; pairs with “*an LLM acting alone in a chat window is a Level-1 hallucination engine ... an LLM connected to a bash terminal is a Level-2 causal learner*” (Gemini, AUDIT-WORKING-829314, der-loop reflection; surfaces here as the chapter's plain-language hook).
- “*acts but never wonders*” (already in body) was independently flagged by multiple substrates as the standout intuitive boundary for the pre-compiled / learning-agent cut — “*It separates agents that have a strategy from agents that form a strategy*” (Claude, AUDIT-WORKING-773921). Worth keeping as the anchor when this framing migrates to README / OUTLINE preamble.

- **The “tragedy of agency” deserves naming as a coined term, not just a passage.** Two substrates independently reached the same framing the body now carries, and both treated *“superstition is not a bug in animal psychology but an inevitable mathematical consequence of fast learning in partially confounded environments”* as a headline-grade contribution (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-193847 — the rain-dance instance). The mechanism both name precisely: a confounded *win* reduces U_M , which drops the gain η^* , which cements the false belief — the agent learns only from aporia (errors), never questions successes. This is already in the body; the gold signal is that it reads as a *named result* (“the tragedy of agency”) to fresh readers, which argues for surfacing it as a coined handle.
- **“Patience” / forgiveness as a Lyapunov-grade necessity, not a virtue.** Gemini’s reach: because de-confounding a noisy action-coupled channel structurally requires diverse repeated interventions, the consciousness-infrastructure *“must not only allow action, it must forgive the inevitable superstitious failures that occur while the agent is trying to de-confound its environment — ‘patience’ is a mathematical necessity for an agent exploring a confounded world”* (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing toward 04-eli-core/ developmental environments; verify isomorphism before promoting past discussion-grade.
- **Terminological tightening flagged by two substrates (overlaps a finding — see off-ramp note).** The intro’s “Level-2 engine” framing was repeatedly read as risking the slide from *“the loop can generate interventions”* to *“ordinary on-policy logs already solve causal identification.”* Suggested three-way vocabulary: *physical intervention* (the action really changed the world) / *interventional-character data* (the logged pair) / *identifiable interventional distribution* (needs positivity, ignorability, etc.) (Gemini/Codex voice, AUDIT-WORKING-526815). The body already does much of this work in the “tragedy of agency” paragraph; the signal is that the *opening* “structurally elegant” sentences land before the caveats and a fast reader can over-read them.
- **Stale-parameterization check.** The displayed scalar objective uses $\lambda(M_t)$, while #def-value-object updated the structurally-motivated extension to $\lambda(M_t, O_t, N_h)$. Either adopt the newer parameterization or label the displayed equation as the pre-value-object shorthand (Codex/Claude, AUDIT-WORKING-526815). Editorial, low severity.
- **How does a base LLM’s “simulated” Level-2/3 reasoning relate to actual interventional access?** Several substrates converged: an LLM *simulates* L2/L3 reasoning in text but is doing L1 pattern-matching on text that *describes* L2/L3 — *“the map is not the territory”*; the moment it gets a bash terminal it *“drops from a simulated L3 god back down to a struggling L2 agent”* (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-266847). A natural first-encounter question this chapter should anticipate, since readers arrive with LLMs in mind.
- **Three-layer loop diagram.** Physical layer (action really changes the world) $\rightarrow$ data layer (logged pair has intervention character) $\rightarrow$ identification layer (hidden state / policy selection / delay / partial observability decide whether the data estimates $P(o \mid do(a))$). The rationale: it *“prevents the diagram from collapsing ‘the agent acted’ into ‘the causal effect is identified’”* — i.e. the figure itself carries the chapter’s central honesty (Codex/Claude, AUDIT-WORKING-526815, has a rendered draft). This is the strongest figure candidate in the batch.
- The blank-wall-attack / matrix-LMI strengthening discussion belongs with #disc-ci-y-unified-objective and #deriv-causal-ib-lmi, not here (the intro correctly only gestures at it). Noted because the auditors picked it up while reading the intro.

7.1 Definition: Pearl's Causal Hierarchy (Recapitulation)

This segment recapitulates Pearl's three-level hierarchy of causal reasoning [2, chs.~1–3] and its strict non-collapse theorem [1, Theorem~1] as the vocabulary AAT will deploy throughout the rest of Part II and beyond. The framework is explicit that this is *imported* machinery, not an AAT contribution.

Level 1 — Associational. “What will I observe next, given what I’ve observed before?” Pattern recognition over the temporally ordered history. Available to any agent that maintains a model (2.1), including purely passive observers. Temporal ordering (1.7) constrains which associations are meaningful — later observations can depend on earlier ones, not vice versa.

Level 2 — Interventional. “What will I observe if I *do* this?” The $do(\cdot)$ operator marks the crucial distinction from Level 1: this is not “what observation tends to follow this action in the historical record” but “what will happen *because* I take this action now.” Three conditions must hold: the agent’s action temporally precedes the observation; the agent chose the action (it was not determined by the same causes that determine the observation); the environment’s response carries information about the causal relationship. Level 2 is why the feedback loop is more powerful than passive observation: by acting and then observing consequences, the agent obtains information about *mechanisms*, not merely correlations. The binary action requirement of 1.6 ensures at least Level 2 access is structurally available.

Level 3 — Counterfactual. “Given that I did a and observed o , what would I have observed if I had done a' instead?” This requires the model to simulate alternative histories — running the causal structure “backward” and then “forward” under different interventions. The most demanding epistemic level; the basis for regret computation, strategic simulation, and learning from single observations.

The *strict-non-collapse theorem* (Bareinboim et al. 2022, Theorem 1) is load-bearing for the rest of Part II: Level-2 quantities cannot in general be computed from Level-1 data alone; Level-3 quantities cannot be computed from Level-2 alone. This is what forces Ch.2’s central question: agents that need to *learn* their action consequences during operation require *Level-2 access*, which Level-1 data cannot supply (7.2). AAT’s *distinctive contribution* is not the hierarchy itself but its grounding in agent dynamics — the loop-as-Level-2-engine result (7.3), the regime-indexed identification-strength framing, and the application throughout Part II’s strategy-revision machinery.

A clarification is offered: the three levels describe epistemic access *the causal structure makes available* — not what any particular agent *uses*. A Kalman filter plus LQR has the Level-2 *channel* structurally present (its innovation signal is conditioned on prior action), but the LQR control action is endogenous to the estimation loop — determined by the policy applied to the estimated state — so the interventional effect is not, in general, *identified* from that action’s data; and the separation principle further guarantees estimation quality is invariant to control policy, so the system does not even *exploit* the channel. A PID controller has no deliberative capacity at all and operates entirely at Level 1. Which levels an agent exercises depends on its architecture and model class.

A domain note worth flagging: **software development is a uniquely rich domain for the hierarchy**. For code-internal counterfactuals with deterministic outcomes — “what would the test suite report under implementation X instead of Y, environment fixed?” — `git checkout` plus re-implementation plus test execution is *literal Level-3 realization with ground-truth verification*, not a proxy. The conditions are precise: deterministic outcome, cost-commensurate replay, content-addressed immutable history (#obs-software-epistemic-properties). For counterfactuals crossing the agent-environment boundary, it is a strong executable proxy but not literal Level 3. This scoped Level-3 access is what makes software AAT’s privileged calibration laboratory for causal reasoning.

Formal Expression.

Level 1 — Associational: $P(o_t \mid \mathcal{C}_{<t})$

Definition (pearl-causal-hierarchy, recapitulating Pearl 2009 and Bareinboim et al. 2022).

What will I observe next, given what I've observed before?

Pattern recognition over the temporally ordered history. Available to any agent that maintains a model (2.1), including purely passive observers. The temporal ordering constrains which associations are meaningful: o_3 can depend on o_1, a_1, o_2, a_2 but not on o_4 .

Level 2 — Interventional: $P(o_t \mid do(a_{t-1}), M_{t-1})$

What will I observe if I do this?

The $do(\cdot)$ operator marks the crucial distinction: this is not “what observation tends to follow this action in the historical record” (associational) but “what will happen *because* I take this action now.” This requires: (1) the agent’s action temporally precedes the observation (1.7), (2) the agent chose the action (it was not determined by the same causes that determine the observation), (3) the environment’s response carries information about the causal relationship.

Level 2 is why the feedback loop is more powerful than passive observation. By *acting* and then observing consequences, the agent obtains information about causal mechanisms — not merely about correlations. The mismatch signal δ_t (3.4), conditioned on the agent’s own action, is an *interventional* signal.

Level 3 — Counterfactual: $P(o_t^{a'} \mid a_{t-1} = a, o_t = o)$

Given that I did a and observed o , what would I have observed if I had done a' instead?

This requires the model to simulate alternative histories — running the causal structure “backward” and then “forward” under different interventions. It is the most demanding epistemic level and the basis for regret computation, strategic simulation, and learning from single observations.

Epistemic Status.

Recapitulation of an external result. The three-level hierarchy and the strict-non-collapse theorem (Bareinboim, Correa, Ibeling & Icard 2022, Theorem 1: Level-2 quantities cannot in general be computed from Level-1 data alone; Level-3 quantities cannot in general be computed from Level-2 alone) are well-established results in causal-inference theory. They live within AAT’s segment set because subsequent derivations deploy them as machinery: 7.2 applies the non-collapse theorem to the value-object’s $do(\cdot)$ query and concludes that purposeful agents who must *learn* their action consequences need Level-2 access; 7.3 shows that the feedback loop is itself a Level-2 data engine; the no-go in 9.2, the strategy-DAG-as-causal-DAG framing in 8.3, and the causal-information appendices (AU, AV) all operate on the hierarchy. Where Part I segments and TST segments only need to *reference* the hierarchy (cite its existence and the do-operator notation) rather than deploy it, external citation to Pearl 2009 / Bareinboim et al. 2022 suffices; the AAT recapitulation here is what those external citations point to when the reader wants the in-framework vocabulary.

AAT’s *distinctive contribution* is not the hierarchy itself but its grounding: the loop-as-Level-2-engine result (7.3), the regime-indexed identification-strength framing (9.5), and the application throughout Part II’s strategy-revision machinery. The recapitulation here is in service of those moves, not a primary AAT result.

Discussion.

Is there a rung above Level 3? Yes, in the Causal Hierarchy Theorem's own relative sense — and its boundary is now characterized. Latent-anchored *mechanism counterfactuals* (“this very background, under a different law”) separate strictly from Level 3: two SCMs can agree on every $\mathcal{L}_1$ – $\mathcal{L}_3$ quantity — the entire joint law of all hard-intervention worlds — while assigning probabilities 1 and 0 to the same noise-preserving mechanism-replacement query (7.7, *exact*, with the reducibility boundary: replacements specified over potential-outcome coordinates reduce to Level 3, while latent-anchored ones need not and the witness's provably does not — generically so, since every anchor-mobile SCM separates from its own exogenous relabeling; Pearl's own selector-variable internalization re-represents the query without collapsing the separation). The hierarchy recapitulated here is therefore not the ceiling of causal expressiveness, but — exactly as Pearl framed the three rungs — the ceiling of what association, experiment, and standard counterfactuals can determine. The agent-architecture consequences (imagination as navigation vs. positing, the tagged model-space workspace) are developed in 7.8.

Availability vs. exploitation. The three levels describe epistemic access that the causal structure *makes available* — not what any particular agent *uses*. Many systems within AAT's scope operate primarily at Level 1. A Kalman filter coupled with an LQR controller has the Level-2 *channel* structurally present (its innovation signal is conditioned on prior action), but two things hold it short of usable Level-2: the LQR action is endogenous to the estimation loop (the policy applied to the estimated state), so its data does not in general *identify* the interventional effect; and the separation principle guarantees estimation quality is invariant to control policy, so the system does not *exploit* the channel. Only dual control (choosing actions partly for their informational value, and typically perturbing the action so it is not a pure function of the state estimate) moves toward exercising Level 2 access in this domain. Similarly, a PID controller has no deliberative capacity — it operates entirely at Level 1. Which levels an agent exercises depends on its architecture and model class.

Forward-looking deliberation exercises Level 2, shading into Level 3. Comparing candidate actions before choosing — “what will happen if I do X vs Y?” — primarily exercises Level 2 (iterated mental intervention). When the agent evaluates past choices to refine the comparison (“given what happened when I tried X last time, what would Y have produced?”), it exercises Level 3.

The causal hierarchy theorem. Bareinboim et al. (2022) prove that the three levels form a strict hierarchy: Level 2 knowledge cannot in general be computed from Level 1 data alone, and Level 3 cannot be computed from Level 2 alone. This is load-bearing for AAT's Part II: evaluating $Q_O(M_t, a; \cdot)$ is a Level 2 query, so agents that need to *learn* action consequences during operation require causal structure beyond predictive models (7.2).

Software as a uniquely rich domain for this hierarchy. In most domains, Level 3 counterfactuals require model-based simulation with uncertain fidelity. Software development is the privileged exception *for a specific class*: for code-internal counterfactuals with deterministic outcomes — “what would the test suite report under implementation X instead of Y, environment fixed?” — git checkout plus re-implementation plus test execution is literal Level 3 realization with ground-truth verification, not a proxy. For counterfactuals crossing the agent–environment boundary (what feature sequence the team would have shipped, how the market would have responded) it is a strong executable proxy, not literal Level 3. The precise conditions — the (α) deterministic-outcome / (β) cost-commensurate-replay / (γ) content-addressed-immutable conjunction, and why the resulting uniqueness is configurational rather than necessary (with named falsifiers) — are established in #obs-software-epistemic-properties (P2; 02-tst-core/). This scoped Level-3 access is what makes software AAT's privileged calibration laboratory for causal reasoning.

Domain instantiations of the three levels:

Table 7.1

<i>Domain</i>	<i>Level 1 (Association)</i>	<i>Level 2 (Intervention)</i>	<i>Level 3 (Counterfactual)</i>
Kalman filter + LQR	Prediction from state estimate	Structural channel present, identification not guaranteed (the LQR action is endogenous to the estimation loop)	Not typically exercised
RL agent	Value function prediction	Action → reward observation	Regret computation
Scientific method	Correlational observation	Experimental intervention	“What if we had used control X?”
Military (Boyd)	Pattern recognition	Probe/feint → observe response	“What if we had attacked from the flank?”
Software developer	“I think this function does X”	Run test → observe result	git checkout + alt. impl. — literal for code-internal deterministic counterfactuals; proxy across the agent–environment boundary (#obs–software–epistemic–properties)
Immune system	Antigen pattern matching	Antibody → pathogen response	Not exercised (no counterfactual reasoning)

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 193847, 266847, 471203, 526815, 527914, 742613, 773921, 829314, 849201 plus the batch dirs 963715 / 471203 — high engagement (this is the chapter’s prior-art anchor). The single most-converged-on note across the entire corpus is the git checkout = *literal Level-3* insight. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- **Agent-side gloss of the three levels** (offered as an audience-facing alternative to Pearl’s terms, *not* a renaming proposal): L1 = *predicting* (model-based forecast); L2 = *exploring* (action-driven learning); L3 = *reasoning* (counterfactual simulation). May read more memorably than association / intervention / counterfactual in casual-reader-facing material, while the prose Pearl terms stay canonical (Claude, AUDIT-WORKING-471203).
- The whole segment recast as “*AAT integrating rather than inventing — the hierarchy is Pearl’s; AAT’s move is to show where it lives inside the adaptive loop*” (Claude, AUDIT-WORKING-527914) — a clean one-line framing for why the recapitulation earns its place in canon.

2. Candidate Discussion.

- **git checkout as literal, empirical Level-3 — the corpus’s most-converged-on pedagogical insight.** Independently flagged as “brilliant” / “profound” / “one of the most profound domain-transfer insights in the whole framework” by ~six substrates (Claude+Gemini, AUDIT-WORKING-193847, 266847, 742613, 773921, 829314, 849201). The sharpest framing: “*In the physical world, Level 3 is strictly imaginary — we can never go back in time, change our action, and see what would have happened. In software, because Ω is a digital artifact with perfectly serialized state transitions, we can literally execute Level 3 — branch the universe, run the counterfactual, observe the ground-truth result, and merge the knowledge back without having committed to the action in production*” (Gemini, AUDIT-WORKING-829314). The body already states this; the gold signal is the unanimous

fresh-reader enthusiasm, which argues it is the chapter's load-bearing pedagogical hook and should anchor any pedagogy / README pass.

- **The “referential-transparency” boundary on the git checkout claim** (multiple substrates, raised as a *caveat to the above, not a refutation*). The literal-L3 claim holds only if the software is side-effect-free with respect to un-versioned state: “git checkout *doesn't* roll back a live database or external API” (Gemini, AUDIT-WORKING-829314); “git checkout *provides* L3 of past states but not L3 of true counterfactuals — the agent can re-run a past computation, not run an actual alternative history; the two are subtly distinct” (Claude, AUDIT-WORKING-471203). The body's existing “code-internal deterministic counterfactuals vs. crossing the agent–environment boundary” split already carries this; the convergence confirms it is the right caveat and a natural place readers push.
- **Availability vs. exploitation is the segment's most load-bearing conceptual move** (near-universal agreement; Claude, AUDIT-WORKING-266847, 471203, 527914; et al.). The agent-class mapping that several substrates independently sketched onto it (worth holding when #def-agent-spectrum framing is revisited): PID = L1-by-architecture-inside-an-L2-loop; Kalman+LQR = L2-available-not-exploited (separation principle); dual control = L2-exploited; deliberative agent = L3 (Claude, AUDIT-WORKING-471203). (*Conflation-as-signal: this is reach toward a clean taxonomy that the segment does not assert — keep it as a candidate, not a fact.*)

3. Follow-up items.

- **Citation precision (Phase-2 verify).** The Bareinboim et al. 2022 reference is “*correct in spirit*” but the precise CHT statement is the strict-inclusion form $\mathcal{L}_1 \subsetneq \mathcal{L}_2 \subsetneq \mathcal{L}_3$ “for almost all SCMs” — stronger than the segment's “cannot in general be computed from ... alone” phrasing. Worth confirming whether AAT ever needs the strict-inclusion form or only the weaker one, and tightening the citation to the specific paper (Bareinboim, Correa, Ibeling, Icard 2022, “*On Pearl's Hierarchy and the Foundations of Causal Inference*”) (Claude, AUDIT-WORKING-471203, 742613).
- **L2-is-model-conditioned subtlety.** The L2 formula $P(o_t \mid do(a_{t-1}), M_{t-1})$ conditions on the agent's *model*, whereas Pearl's $do(\cdot)$ is defined relative to the *true* SCM. So AAT's L2 query is a *belief-about-L2* operation; if the model is wrong, the agent's L2 inferences are wrong. Candidate clarifying sentence so the framework isn't read as “the loop generates true L2 data, ergo the agent has true L2 access” (Claude, AUDIT-WORKING-471203 — flagged as sharpening at #der-loop-interventional-access downstream).

4. Readers often ask / wonder.

- **What level can a language model actually exercise?** The recurring fresh-reader question (Claude+Gemini, AUDIT-WORKING-193847, 266847, 829314): LLMs are trained on L1 (associational) text; they *simulate* L2/L3 reasoning in language but lack the ground-truth verification, so a base LLM reasoning about “what would happen if I do X” is exercising L1 data about what typically happens *when people do X*. Gemini's instance: an LLM trained on GitHub learns $P(\text{tests pass} \mid \text{code})$ from polished PRs (massive selection bias) but never *intervened* — so its compiler-model is purely associational, which is “*the exact mathematical reason LLMs confidently hallucinate code that looks correct but fails to compile.*” This is the chapter's most natural reader question; the answer lives downstream (loop compensates) but a forward pointer here would help.
- **How does the agent estimate $P(o \mid do(a))$ when it is just starting out with no interventional data — does it assume L1 $\approx$ L2 as a heuristic until proven wrong?** (Claude, AUDIT-WORKING-773921). A natural cold-start question.

5. Candidate figures.

- **The strict ladder with an AAT overlay.** L1 predicts from history; L2 asks what happens under $do(a)$; L3 asks what would have happened under an alternative action after an actual action/outcome pair — with a side-note at L2 that *action-conditioned data must not be confused with do-data* (this is the chapter's pressure point). A rendered draft exists (Codex/Claude, AUDIT-WORKING-526815). The domain-instantiation table (Kalman / RL / scientific method / Boyd / software / immune system) was independently praised as “*excellent pedagogical material*” by several substrates and is a natural figure companion.

Belongs elsewhere.

- **Is Level-3 reasoning the defining mathematical characteristic of consciousness / moral weight?** Gemini’s reach: a thermostat has L2 but never experiences *regret*, which requires the L3 counterfactual “*I did α , but if I had done α' the outcome would have been better*” — “*the framework is mathematically defining the prerequisites for moral suffering*” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at 04-eli-core/ (regret / moral continuity), not this recapitulation segment.
- **Counterfactual-simulation requires protecting the real chronica.** Running an L3 simulation means the agent must “close its eyes” to current sensory input and spin up a parallel virtual chronica; “*if the internal model is fragile, running a counterfactual simulation might overwrite its actual memory — the infrastructure must protect the integrity of the real chronica while allowing virtual ones to spin up and collapse*” (Gemini, AUDIT-WORKING-193847). Points at #def-chronica / 03-llm-core interiority architecture, not here.
- **Watching another agent act: L1 or L2?** “*If I watch you touch a hot stove, do I gain L2 knowledge? If your action was unfounded with the stove’s temperature, it acts like L2; but if you touched it because you knew it was cold, it’s L1*” — flagged as a deep problem Section III (composites) will need (Gemini, AUDIT-WORKING-829314). Belongs with the composite-layer / Mode-2 treatment in #der-loop-interventional-access and Part III.

7.2 Derived: Causal Hierarchy Requirement

The direct application of Pearl’s causal hierarchy (7.1) to the value object (6.6). The action-value query uses the $do(\cdot)$ operator and is therefore a *Level-2 (interventional)* query; by the strict-non-collapse theorem, Level-2 quantities cannot in general be computed from Level-1 data alone [1, Theorem~1]. An agent that must evaluate Q_O from experience therefore needs access to **Level-2 knowledge** — knowledge about the effects of its own interventions, not merely correlational patterns.

The result is paired with a sharp *scope narrowing*: attention restricts to **learning purposeful agents** — agents that must *acquire or refine* Level-2 knowledge during operation. This is a named sub-scope of 1.6 that excludes *pre-compiled* interventional structure (PID controllers where the designer pre-computed the control law, LQR where the separation principle gives the optimal policy from model parameters, hardcoded reactive policies). Pre-compiled agents are still within agency scope (they have objectives and act on them) but outside learning-agent scope — their causal structure was externally supplied by a designer who had Level-2 access. *All remaining Part II results operate within learning-agent scope unless explicitly noted otherwise.* The derivation is exact as a direct application of the external hierarchy theorem to the value-object definition; the scope narrowing is a definitional restriction, not a derived result.

The distinction between intervention and conditioning is the *core* of causal inference and matters whenever the agent’s action-selection policy correlates with unobserved confounders — generic for any agent with internal state, plans, or memory. A developer needs “if I refactor this module, will tests pass?” not “modules that were refactored tend to have tests that fail” (the latter is biased by which modules the team chose to refactor). The Discussion below treats the concrete cases (developer / commander / RL agent), why pre-compiled agents fall outside, and the empirical bridge to Hafez et al.’s Information Digital Twin — whose 89% perturbation-detection accuracy versus 44% for reward-based monitoring is consistent with the present segment’s claim that the loop’s interventional data is information-theoretically richer than outcome monitoring alone.

Formal Expression.

Action selection via 6.6 requires:

Derived (causal-hierarchy-requirement, from value-object + pearl-causal-hierarchy).

$$Q_O(M_t, a; \pi_{\text{cont}}, N_h) = \mathbb{E}[V_O(\tau) \mid M_t, do(a_t = a), a_{t+1:} \sim \pi_{\text{cont}}] \quad (7.3)$$

The $do(\cdot)$ notation is explicit: this is an *intervention*, not a *conditioning on observed data*. By 7.1, Level 2 queries ($P(Y | do(X))$) cannot in general be computed from Level 1 data ($P(Y | X)$) alone. Therefore:

An agent that must evaluate Q_O from experience needs access to Level 2 knowledge — knowledge about the effects of its own interventions, not merely correlational patterns.

We restrict attention to **learning purposeful agents** — agents that must **acquire or refine** Level 2 knowledge during operation. This is a named sub-scope of the agency scope defined in 1.6. It excludes agents with **pre-compiled** interventional structure: - PID controllers (the designer pre-computed the control law) - LQR (separation principle gives optimal policy from model parameters) - Hardcoded reactive policies

Scope Narrowing (learning-agent scope).

Pre-compiled agents are within agency scope (they have objectives and act on them) but outside learning-agent scope — their causal structure was externally supplied by a designer who had Level 2 access. **All remaining Part II results operate within learning-agent scope** unless explicitly noted otherwise. This scope narrowing focuses the theory on agents that must build or maintain their own causal understanding.

Epistemic Status.

Exact. The derivation is a direct application of the causal hierarchy theorem to the value-object definition. If you accept that Q_O is an interventional query and that the causal hierarchy is strict, the conclusion follows. The scope narrowing to learning agents is a definitional restriction, not a derived result — it sharpens the class of agents under study.

Discussion.

The causal hierarchy theorem does the heavy lifting. The key mathematical fact is external to AAT: Bareinboim et al. (2022) prove that the three levels (association, intervention, counterfactual) form a strict hierarchy — Level 2 quantities cannot in general be computed from Level 1 data. AAT’s contribution is applying this to the purposeful-agent setting: if you want to select actions by their consequences (Q_O), you need causal structure.

What “Level 2 knowledge” means concretely. For different agents: - A developer needs to know “if I refactor this module, will tests still pass?” (not just “modules that were refactored tend to have tests that fail”) - A commander needs to know “if I move forces north, will the enemy respond by retreating?” (not just “when forces moved north, the enemy often retreated”) - An RL agent needs $Q(s, a) = \mathbb{E}[R | s, do(a)]$, not $\mathbb{E}[R | s, A = a]$ (the latter includes selection bias from the agent’s own policy)

The distinction between $do(a)$ and $A = a$ is the core of causal inference. It matters whenever the agent’s action-selection policy correlates with unobserved confounders.

Why pre-compiled agents are excluded. A thermostat “knows” that turning on the heater raises temperature — but this knowledge was designed in, not learned. The thermostat never needs to reason about interventions because the intervention-outcome mapping is hardwired. AAT’s purposeful-agency machinery is specifically for agents that face uncertainty about how their actions affect the world and must reduce that uncertainty through experience.

Bi-predictability as empirical evidence for Level 2 advantage. Hafez et al. (2026) measure the information structure of the agent-environment loop via bi-predictability $P = MI(S, A; S')/C$, capturing how tightly coupled the agent is to its environment through the action channel. Their Information Digital Twin (IDT), which monitors the loop’s information geometry, detects environmental perturbations at 89% accuracy versus 44% for reward-based monitoring. This is consistent with the present segment’s claim: the feedback loop provides richer (Level 2) data than outcome monitoring alone. Hafez’s framework measures the coupling; AAT explains *why* the coupling is information-theoretically superior — because the loop generates interventional data by construction (7.3), not merely associational data. The measurement (Hafez) and the explanation (AAT) are complementary.

Working Notes.

- This scope narrowing connects to 7.6: agents that must learn Level 2 structure face a cost-benefit tradeoff between learning through exploration (costly, slow, but verifies causal links) and planning through explicit Σ_t (cheaper if the causal model is adequate, but the model may be wrong).
- LLMs trained on causally-structured text absorb causal priors — noisy prior knowledge from mixed provenance (experimental, observational, speculative). This is not verified interventional structure; it's a *prior* (plausible, not derived). An LLM in the adaptive loop has both: priors from training AND interventional data from the loop. The priors accelerate; the loop verifies. The IB framework (2.2) predicts causal structure will be retained in training because it has predictive power for language.
- The scope narrowing to “learning agents” is generous — it includes any agent that updates its causal beliefs during operation, even if it starts with strong priors. The excluded class (pure pre-compiled controllers) is genuinely different: they never revise their action-consequence model.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 193847, 266847, 526815, 584721, 773921, 829314, 849201 plus the batch dirs 471203 / 963715. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The RL connection stated plainly as the segment’s contribution: it “*formally links Reinforcement Learning’s exploration-vs-exploitation dilemma to Pearl’s Causal Hierarchy — exploration is the process of generating Level-2 data; exploitation is optimizing Q_O based on that data*” (Gemini, AUDIT-WORKING-193847). A candidate Brief framing.
- The *do(a)-vs-A = α* developer/RL contrast in the body was independently praised as “*one of the clearest explanations of RL’s causal foundations I have read*” (Claude, AUDIT-WORKING-849201) and “*highly clarifying*” (Claude, AUDIT-WORKING-773921) — converging signal it is the segment’s pedagogical anchor, worth preserving verbatim through any compression pass.

2. Candidate Discussion.

- **The pre-compiled / learning-agent cut as an ontological boundary, not a bureaucratic one.** Strong cross-substrate convergence that “*a pre-compiled agent acts, but it never wonders*” (already echoed in the chapter intro) carries real philosophical weight: it cleanly excludes thermostats / LQR from Section II’s dynamics and “*protects the complexity of the upcoming strategy dynamics from trivial counterexamples*” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-584721, 849201). Gemini’s developmental reach: for an emergent intelligence, this “*demands that the infrastructure allows — even requires — the intelligence to experiment ... true autonomy requires the freedom to make mistakes; an infrastructure that prevents all mistakes prevents the formation of a valid causal strategy DAG*” (Gemini, AUDIT-WORKING-193847). The “cost of agency is the cost of exploratory mistakes” framing points at 04-eli-core/ developmental environments.
- **The LLM-as-noisy-causal-priors framing reads as a headline insight, not a Working-Note aside.** Multiple substrates singled out the existing Working-Note point (LLMs absorb causal priors from training text — a *prior*, plausible-not-verified; the loop *verifies*) as “*brilliant*” and operationally central (Claude, AUDIT-WORKING-193847; AUDIT-WORKING-584721 — “*priors accelerate, loop verifies — operationally useful*”). Gemini’s sharpest version, worth surfacing in Discussion: an LLM with only a chat interface is trapped in associational priors, but “*the moment you put the LLM in an AAT feedback loop where it writes code, runs the compiler, and reads the error itself, it crosses the epistemic boundary — an LLM with a REPL is a fundamentally different class of epistemic entity than an LLM with only a chat interface*” (Gemini, AUDIT-WORKING-829314). This is the bridge the body’s Hafez paragraph and #der-loop-interventional-access together carry; the gold is that it lands as a class-distinction headline.

3. Follow-up items.

- **Hafez 2026 IDT empirical anchor — verify (Phase-2).** The 89% (perturbation detection) vs 44% (reward-based monitoring) figures recur across segments. One auditor spot-checked: the paper appears to exist (arXiv 2603.01283), and search metadata reports the matching claim (IDT 89.3% vs 44.0%, 4.4× lower median latency) — *evidence for coupling-monitoring performance, not by itself proof that the loop supplies identified Level-2 effects* (Codex/Claude, AUDIT-WORKING-526815; flagged high-priority Phase-2 at AUDIT-WORKING-471203). Confirm the figure and the arXiv id before any external-facing use.
- **“Purely predictive models” should read “purely associational models.”** A model trained on randomized interventions or carrying causal/action-transition structure *can* make $do(a)$ predictions; the problem is L1-only prediction, not prediction as such (Codex/Claude, AUDIT-WORKING-526815). Editorial precision.
- **Scope-propagation watch.** Later Section-II claims that mention PID / LQR / thermostats should say whether they are illustrative agency-scope examples or inside learning-agent scope — the cut is load-bearing and easy to blur downstream (Codex/Claude, AUDIT-WORKING-526815).

4. Readers often ask / wonder.

- **Is exploration a strict mathematical requirement (not just a heuristic) for building a valid Q_0 ?** “If an agent needs Level-2 data to learn Σ_t , does this mean taking sub-optimal actions just to see what happens is not a heuristic but a strict requirement?” (Gemini, AUDIT-WORKING-193847). The answer the chapter is building toward (yes — the loop is where the data comes from); a forward pointer would satisfy the reader who asks it here.
- **How does the agent know its action caused the outcome vs. a simultaneous environmental shift (ρ)?** (Claude, AUDIT-WORKING-849201). The within-step-confounding question, which #der-loop-interventional-access then takes up directly.
- **Is imitation / observational learning capped by the hierarchy?** “Can an agent learn a complex strategy purely by watching someone else do it, without strong causal assumptions? Imitation learning is fundamentally capped by the causal hierarchy unless the demonstrator’s policy is perfectly known” (Gemini, AUDIT-WORKING-193847). A natural reader extension.

Belongs elsewhere.

- **Adaptive vs. robust control as the formal boundary.** The learning-agent scope “provides a formal boundary separating Adaptive Control (plant parameters learned online) from Robust Control (controller pre-compiled for worst-case) — AAT targets the former” (Gemini, AUDIT-WORKING-193847). A useful prior-art positioning note, possibly for a control-theory-facing comparison rather than this segment’s body.

7.3 Derived: Loop Provides Interventional Data Access

The chapter’s central architectural result. By the temporal-ordering postulate (1.7), the agent’s action a_t causally precedes the next observation O_{t+1} ; the agent *chose* the action, the environment responded. The feedback loop therefore generates **intervention-produced data** — data whose causal character differs from passive observation because the agent’s action was a genuine cause of the subsequent observation. The mismatch signal conditioned on the agent’s action carries interventional information: how the environment responded to *this specific intervention*, relative to what the model predicted. This is how agents within AAT’s **agency scope** ($\mathcal{S}_{\text{agency}}$, which requires $|\mathcal{A}| \geq 2$ and at least one action with causal effect) gain Level-2 access — not through internal architecture but through the loop itself; agents in the adaptive scope but outside agency scope (passive observers) lack the action contrasts needed.

The framework is *unusually careful* to distinguish two claims that look alike. “Action-generated data” is **not** the same as “cleanly identified do-estimates.” The action-observation pair is produced *under intervention* (interventional in character) — but between intervention-produced data and a usable estimate of the interventional outcome distribution stand four obstacles: coverage (the agent must have tried diverse actions), within-step confounding, delayed consequences,

and partial observability. The strength of causal identification varies by regime — strong in intervention-rich domains (software, laboratory science), moderate with partial intervention (organizational), weak under observation-only constraints (see 7.4). The claim is about the *character of the data* (interventional, not observational), not about the agent’s ability to extract clean causal estimates from it. The result is *exact* as a logical consequence of temporal ordering and the feedback-loop structure; it is about *data availability*, not reasoning capacity — the loop *provides* interventional data whether or not the agent exploits it for Level-2 reasoning.

The interventional character of loop data is a property of the action being the agent’s *own* causally-efficacious move, not of any architectural feature and not of the trajectory’s forkability. The *do*-operator’s semantics is population-level by construction: the interventional distribution sums over the exogenous distribution $P(\mathbf{U})$, and its canonical physical realization — randomized controlled trials and A/B experiments — is forkable and repeatable [1, Def.~5 and fn.~19]. What the singular-trajectory scope (4.10) supplies is narrower and still essential: it grounds *whose* effect a loop datum is the effect of, and forbids averaging interventional responses across forked copies as though they were one agent’s effects. The *interventional character* is real but not unconditional: action-generated data identifies the interventional distribution only under (C1) positivity, (C2) sequential ignorability, and (C3) a known action-mechanism. The exact content of this segment is the *availability of the interventional-character channel*; identification is gated on (C1)–(C3). The Discussion below treats: the precision conditions on “interventional” (low confounding / short delay / varied action); even-without-explicit-causal-model benefits (Q-learning in the tabular case); honest credit to the action-perception-loop framing in active inference and cybernetics (Wiener 1948, Conant–Ashby 1970, Friston et al. 2017, Parr–Pezzulo 2022) together with the three specific moves AAT makes that the implicit treatments do not (the Bareinboim-hierarchy connection, regime-indexed identification strength, explicit scope honesty as the conservative-form posture documented in the Bruineberg et al. 2022 Pearl-vs-Friston critique); the connection to the identifiability-floor pattern as a load-bearing escape with two semantically distinct deployment modes (agent-self-intervention at the causal-structure layer, observer-on-sub-agent at the composition layer); and the singular-trajectory ground for whose effect the loop datum is — distinct from the *do*-semantics, which is forkability-agnostic.

Formal Expression.

By 1.7, the temporal ordering is constitutive: a_t causally precedes o_{t+1} . The agent chose a_t ; the environment responded with o_{t+1} . The feedback loop therefore generates **intervention-produced data** — data whose causal character differs from passive observation because the agent’s action was a genuine cause of the subsequent observation.

Derived (loop-interventional-access, from causal-structure + recursive-update).

The critical distinction: “**action-generated data**” is **not the same** as “**cleanly identified do-estimates**.” The pair (a_t, o_{t+1}) is produced under intervention — the agent executed a_t , making it interventional in character rather than a passively observed association. But between intervention-produced data and a usable estimate of $P(o \mid do(a_t), \Omega_t)$ stand: (1) coverage — the agent must have tried diverse actions, not just one policy; (2) confounding within a time step — unobserved state variables that affect both action choice and outcome; (3) delay — consequences may appear much later than $t + 1$; (4) partial observability — o_{t+1} reveals only part of the outcome. The strength of causal identification from this data depends on the regime (9.5): strong in Regime A (intervention-rich domains like software and laboratory science), moderate in Regime B (partial intervention), weak in Regime C (observation-only). The claim here is about the *character* of the data (interventional, not observational), not about the agent’s ability to extract clean causal estimates from it.

The mismatch signal conditioned on the agent’s action:

$$\delta_t \mid a_t = o_{t+1} - \hat{o}_{t+1}(M_t, a_t) \quad (7.4)$$

carries interventional information: it tells the agent how the environment responded to its specific intervention a_t , relative to what the model predicted.

The exact claim is the availability of the channel; identification is gated. What is exact, as a logical consequence of temporal ordering and the loop structure, is that an agent in agency scope that executes at least one action with causal effect *generates action-coupled data that is interventional in character* — sampled under the agent’s own action rather than passive observation. This is the substrate from which Level-2 quantities $P(o \mid do(a), \cdot)$ can be *identified*, but identification is not automatic. It holds when:

- **(C1) Positivity** — every action in the relevant support is taken with nonzero probability across the agent’s history, so the interventional distribution is estimable rather than extrapolated;
- **(C2) Sequential ignorability** — in mutilated-graph form, the action a_t is d -separated from the outcome o_{t+1} given history H_t ; equivalently, the policy is unconfounded with the outcome mechanism;
- **(C3) Known action-mechanism** — the map from the agent’s decision to the executed action is known (or itself overridden), so the executed value can be read as the intervened value.

Where (C2) fails — generic for any agent whose action depends on internal state, plans, or memory that also bear on the outcome — on-policy (a_t, o_{t+1}) converges to $\mathbb{E}[o \mid A = a]$, the conditional, rather than to $\mathbb{E}[o \mid do(a)]$, the interventional effect. The channel is still present; what is gated is the move from action-generated data to an identified *do*-estimate.

Epistemic Status.

Exact. The exact content is the **availability of the interventional-character channel**: a logical consequence of temporal ordering (1.7) and the feedback-loop structure (1.6), an agent in agency scope generates action-coupled data that is interventional in character rather than passively observed. The claim is about **data availability**, not reasoning capacity — the loop *provides* this channel whether or not the agent *exploits* it for Level-2 reasoning, and whether or not the data yields identified estimates.

The precision is load-bearing and now first-class in the Formal Expression: the agent has *access to* interventional-character data, but *identification* of $P(o \mid do(a), \cdot)$ from it is gated on (C1) positivity, (C2) sequential ignorability, and (C3) a known action-mechanism. Confounding within a single time step (a violation of (C2)), insufficient action coverage (a violation of (C1)), delayed outcomes, and partial observability all bear on whether clean causal estimates can be extracted. The gated form is what keeps the *exact* label honest: the availability of the channel is unconditional; the identified-*do*-estimate is the conditional consequence, and the segment claims only the former as exact.

Discussion.

The loop as a Level 2 engine. This is one of AAT’s load-bearing results. The causal hierarchy theorem (7.2) says Level 2 knowledge requires more than correlational data. This result says: the adaptive loop *is* the “more.” An agent that acts and observes the consequences is generating interventional data — the same kind of data that a scientist generates through experiments. The loop is a perpetual experiment.

Precision about what “interventional” means here. The interventional interpretation is strongest when: - The agent’s action was the primary cause of the observed change (low confounding) - The observation follows closely in time (short delay) - The agent varied its action across episodes (not stuck on one policy)

When confounding is high, delays are long, or the agent follows a fixed policy, the interventional information in each (a_t, o_{t+1}) pair is weaker — still present, but harder to extract. This is why 3.7 distinguishes between high-CIY actions (that reveal causal structure) and low-CIY actions (that don’t).

Even agents without explicit causal models benefit. A Q-learning agent doesn’t maintain an explicit causal model, but in the tabular case with sufficient exploration and no within-step confounding, its Q-values converge toward $\mathbb{E}[R \mid s, do(a)]$ rather than $\mathbb{E}[R \mid s, A = a]$ — precisely because the training data comes from the agent’s own interventions. In the partially observed, confounded, or delayed-outcome cases (where the caveats above apply), the loop still

provides intervention-generated data, but the Q-values may converge to biased estimates that reflect the confounding structure rather than clean interventional effects. The loop provides Level 2 data; whether that data yields *identified* causal quantities depends on the domain's confounding and observability structure.

Honest credit to the action-perception-loop framing. The substantive observation that the agent's actions cause its observations — and therefore that loop data is interventional in character — is implicit in any framework built around an action-perception loop, including active inference (Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29; Parr & Pezzulo 2022, *Active Inference*, MIT Press, ch. 3) and the broader cybernetic-and-control lineage (Wiener 1948, *Cybernetics*; Conant & Ashby 1970, “Every good regulator of a system must be a model of that system,” *Int. J. Systems Sci.* 1). AAT's distinctive contribution is not the observation that loop data is interventional but the *explicit lift* of this observation to a load-bearing theorem connected to Pearl's causal hierarchy (7.1) via Bareinboim, Correa, Ibeling & Icard (2022). Three specific moves AAT makes that the implicit treatments do not:

1. **The Bareinboim-hierarchy connection.** Active inference and the cybernetic lineage rest on Bayesian-network generative models (Pearl Level 1, associational). They do not invoke the causal-hierarchy theorem to argue that the loop's action-generated data is the substrate Level-2 queries require. AAT does — and the consequence is that Σ_t is positioned as a *causal* DAG rather than a *Bayesian-network* DAG.
2. **Regime-indexed strength of causal identification.** Even granting that loop data is interventional in character, the strength of usable causal identification varies by domain. AAT partitions this into Regime A (intervention-rich, software/laboratory), B (partial intervention, organizational), C (observation-only — see 9.5). The AI literature treats causal identifiability uniformly within its modeling assumptions and does not surface the regime distinction at the segment level.
3. **Explicit scope honesty.** The Formal Expression above carefully distinguishes “data generated under intervention” from “cleanly identified do-estimates.” The AI literature, as Bruineberg, Dolega, Dewhurst & Baltieri (2022) document in their Pearl-vs-Friston critique, sometimes elides this distinction — using the action-perception loop language to support stronger causal claims than the formal apparatus delivers. AAT's careful split is the conservative form.

The reframing here is rhetorical, not substantive: the headline result (the loop is a Level-2 engine) stays; what changes is the explicit acknowledgment that the observation about loop data being action-generated is shared with the broader literature. AAT's distinctive content sits in the three specific moves above. The companion architectural move on 6.3 (Pearl-blanket vs. Friston-blanket form of Markov blanket; cf. Bruineberg et al. 2022) makes AAT's conservative-form positioning visible across both architectural and access-channel segments.

Connection to the identifiability-floor pattern. This segment is structurally load-bearing for the L0-causal-insufficiency-detection no-go (9.2): without the loop's interventional access, the no-go forbids detection entirely; the covariance test under joint sibling observability is the unique broadly-available violation of the no-go's “purely on-policy” scope. See 5.1 for the meta-pattern.

Composite-layer extension. #disc-identifiability-floor Instance 3 (the composition-layer no-go anchored in Liberzon 2003's common-Lyapunov nonexistence) establishes that composite contraction cannot in general be certified from component-level data alone — the coupling-topology bit (broadened 2026-05-21 from the original coupling-sign bit alone to include the potential-existence bit and the game-structure-class bit distinguishing R0 / R1 / R2 dynamic regimes per #disc-dynamic-regime-axis) is unidentifiable from component marginals. One of the five structural escapes in Instance 3 is composite-extended loop-interventional-access: **interventions on sub-agent A_j reveal A_i 's cross-coupling response**, which is a *do*(·)-data distinction between the topologically-distinct coupled constructions. This is the composite-layer analog of the single-agent interventional-access-escape the present segment delivers for Instance 1; in the composite setting, the agent performs interventions on one sub-agent's action space and observes the effect on another sub-agent's mismatch trajectory, extracting the coupling-topology object (sign and structure) that

component marginals cannot. The load-bearing role of `#der-loop-interventional-access` therefore extends across two identifiability-floor instances (agent-internal and composite-layer), not one.

Modes of deployment across `#disc-identifiability-floor` instances. The shared load-bearing role — Level-2 data from interventional action under `#der-causal-hierarchy-requirement` supplying the unique broadly-available escape from an observational-equivalence no-go — manifests through **semantically distinct interventional mechanisms** at different layers. The modes share the Pearl-*do* structure but differ in who performs the intervention and on what:

- **Mode 1 — agent-self-intervention (Instance 1, causal-structure layer).** The agent performs *do*-actions on its own action space as part of its ordinary adaptive loop. The intervention is *on the agent's own action*; the target is the environment's response, which reveals the latent common cause that Instance 1's on-policy L0-insufficiency-detection no-go (Bareinboim et al. 2022 CHT) makes unidentifiable. The agent-as-Level-2-data-generator property is intrinsic to the loop structure, not a capability that must be added.
- **Mode 2 — observer-on-sub-agent (Instance 3, composition layer).** An observer external to a composite performs *do*-interventions on one sub-agent A_j 's action space; the target is another sub-agent A_i 's mismatch-trajectory response, which reveals the cross-coupling sign that Instance 3's Liberzon-anchored no-go makes unidentifiable from component-marginal observation. The same Pearl-*do* structure, but the intervening agent and the measured agent are distinct members of the composite.

Future instances of `#disc-identifiability-floor` at new layers may add further modes (see `#disc-identifiability-floor` Working Notes for the architecture-within-behavior-class layer currently under triage; the corresponding mode would be *observer-on-agent-input* at the candidate agent's observation channel). The three-mode-pattern observation is a structural regularity worth naming even though the specific Mode-3 instance has not promoted; the load-bearing content — Level-2 escape from observational-equivalence no-goes via loop-interventional access — remains shared across the deployment modes even when the specific interventional quantity varies. The unification is at the pattern level; the mechanism is semantically distinct per layer.

What the singular-trajectory scope grounds — and what it does not. The interventional *character* of loop data does not rest on the trajectory being non-forkable: the *do*-operator's semantics is population-level by construction (Bareinboim, Correa, Ibeling & Icard 2022, Def 5 — the interventional distribution sums over the exogenous distribution $P(\mathbf{U})$), and its canonical physical realizations, randomized controlled trials and A/B experiments, are forkable and repeatable (CHT footnote 19). The $\mathcal{L}_1/\mathcal{L}_2$ discriminator is whether the action's generating mechanism was the system's own intact mechanism (observational) or an override / unconfounded-and-known mechanism (interventional) — not whether the trajectory can be replayed. What the scope commitment in 4.10 supplies is narrower and still essential: each agent is instantiated on a singular, non-forkable causal trajectory $\mathcal{C}_t$, and this grounds *whose* effect a loop datum is the effect of. Replaying a_t from a checkpointed M_t against a different event stream is an intervention on a *different* trajectory $\mathcal{C}_t^{(2)}$ that happens to share a prefix; the singularity forbids averaging interventional responses across such forked copies as though they were one agent's effects, because each fork is a distinct trajectory-SCM with its own $P(\mathbf{U} \mid \mathcal{C}_t)$. Agents whose ontology is *type-like* (equivalence classes of copies) rather than *token-like* (singular trajectories) are outside AAT's formal scope; aggregate claims about “the model” across copies require additional machinery not provided here. So the singular-trajectory scope grounds the *identity* of the effect (and forbids copy-averaging and lossy cross-trajectory merging), while the *interventional character* itself comes from the action being the agent's own causally-efficacious move under (C1)–(C3).

Working Notes.

- This result establishes that all agents within AAT's **agency scope** (1.6, $\mathcal{S}_{\text{agency}}$) have access to interventional data, regardless of their internal architecture. Agents in the adaptive scope but outside agency scope (passive observers, nominal agents with $|\mathcal{A}| < 2$ or no causal effect) lack the action contrasts needed to generate interventional data — they observe but cannot intervene. This includes LLM agents operating through a tool-use loop — the LLM issues an action (tool call), observes

the result, and updates. The loop gives it Level 2 data even though its internal architecture (transformer attention) is not designed for causal reasoning. The loop compensates for architectural limitations.

- The connection to 3.7: CIY quantifies *how much* interventional information a specific action provides. This segment establishes that interventional information is *available in principle*; CIY measures the *quantity per action*.
- **Cross-reference to NeurIPS Paper 2.** The Loop-as-Causal-Engine claim is formalized at theorem grade in NeurIPS 2026 Paper 2 (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning”, `~/src/neurips/02-unified-convergence-rl/`, §5 Lemma 5.3 / `#lem-loop-level2`) under the named (C1) **positivity** / (C2) **sequential-ignorability** / (C3) **known action-mechanism** triple. (C2) is the load-bearing structural condition: in mutilated-graph form, a_t must be d-separated from o_{t+1} given history H_t . *Goal-conditioned LLM policies violate (C2) by construction* — the goal influences action through the same forward pass that models the observation, breaking the conditional independence required for sequential ignorability — which is the bridge to Paper 3’s Coupled-class formulation. The (C1)-(C3) triple makes explicit which structural commitments a Class 1 (Separated) tool-use loop satisfies for free that a Class 3 (Coupled) goal-conditioned policy does not. See `spikes/neurips-back-integration-2026-05-08.md` §1 Paper 2 entry 5.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 193847, 526815, 584721, 773921, 829314, 849201 plus the batch dirs 471203 / 963715 — this was flagged top-decile by multiple substrates. Substrate attribution inferred from voice where not explicit; uncertain cases hedged. *Resolved 2026-05-30:* the substantive structural challenge to the singular-trajectory→do argument (forkability ≠ Level-1; the do-semantics is population-level and forkability-agnostic) was carried through the strengthen-first spike `spikes/.integrated/spike-causal-access-transportability-2026-05-30.md` and is now integrated — the grounding has been corrected (singular-trajectory grounds *whose* effect, not the do-semantics) and the (C1)-(C3) identification gate lifted into the Formal Expression / Epistemic Status. The two follow-up items below that this challenge subsumes are closed as part of that landing.

1. Candidate Brief prose / pre-prose.

- “The loop is a perpetual experiment” (already in body) — repeatedly singled out as “a profound way to view existence — every action we take is a $\text{do}(\cdot)$ operator” (Gemini, AUDIT-WORKING-193847). The Brief-grade anchor for this segment.
- “The loop compensates for architectural limitations” (Working-Notes line) was independently flagged as one of the framework’s *cleanest answers to “can LLMs do causal reasoning?”* — the **loop**, not the transformer architecture, supplies the L2 data; whether the LLM *uses* it depends on its update mechanism (Claude, AUDIT-WORKING-584721; Gemini, AUDIT-WORKING-829314). Worth promoting from Working Notes into the body as a headline consequence.
- “Embodiment / agency is not just a physical property but an epistemic superpower: it provides access to the next rung of Pearl’s hierarchy for free” (Claude, AUDIT-WORKING-849201) — compact framing for the segment’s headline.

2. Candidate Discussion.

- **The honest-credit passage is held up as the corpus’s gold standard for prior-art positioning** — “arguably the best literature review / positioning statement I have read in the entire corpus” (Gemini, AUDIT-WORKING-193847); “exemplary academic writing ... names what’s inherited and what’s distinctive — the prior-art-integration discipline at its best” (Claude, AUDIT-WORKING-471203, 963715, 849201; Claude, AUDIT-WORKING-773921 — “the gold standard for positioning a theory against prior art”). Strong cross-substrate signal that this passage should be protected through any compression and is a model to point other segments at. (See the countervailing readers-often-ask note below: *same passage, opposite reaction from one substrate — preserved as conflict, not sanitized.*)
- **Mode-2 (observer-on-sub-agent) as an operational AI-safety-auditing recipe.** Several substrates read the composite-layer mode as a concrete experimental protocol: “to audit the orchestrator, intervene on a tool and observe the orchestrator’s belief update response” (Claude, AUDIT-WORKING-584721); “in a multi-agent system you can determine the exact coupling topology — cooperative vs adversarial — by intervening on Agent A and measuring the mismatch spike in Agent B — literal scientific

experimentation applied to organizational structure” (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-193847 — “*poking someone to see how they react is mathematically the only way to figure out if they are a friend or an enemy*”). Candidate Discussion sharpening of the Mode-2 paragraph toward its operational payoff.

- **The type-vs-token scope commitment has reach into AI ethics/welfare debates.** The singular-trajectory grounding implies aggregate claims about “*the GPT-4 model*” are type-like and out of formal AAT scope; only token-like “*this session*” claims are in scope — “*a strong scope commitment with implications for AI ethics, alignment, and welfare debates: most discussions treat ‘the model’ as a type entity; AAT says formal results apply only to tokens*” (Claude, AUDIT-WORKING-584721). Flagged as a Section-D / meta-architectural insight.

3. Follow-up items.

- **~~Regime A needs “identifiable,” not merely “action-varying.”~~ Resolved 2026-05-30** (transportability spike). The corresponding Regime-A wording lives in 7.4, which was tightened in the same landing from “varies its actions across episodes” to “action assignment is randomized / known-and-adjusted (sequential ignorability + positivity).” The original note: “the agent varies its actions” is not sufficient for clean estimates when action choice is policy-driven by state/history that also affects outcomes (Codex/Claude, AUDIT-WORKING-526815).
- **~~Theorem-grade conditions currently live only in Working Notes / the NeurIPS cross-ref.~~ Resolved 2026-05-30** (transportability spike, Option A). The (C1) positivity / (C2) sequential-ignorability / (C3) known-action-mechanism triple is now lifted into the Formal Expression and Epistemic Status; the exact claim is restated as availability of the interventional-character channel, with identification explicitly gated on (C1)–(C3). The original note: these are exactly the assumptions that move from action-generated data to identified L2 estimates (Codex/Claude, AUDIT-WORKING-526815).

4. Readers often ask / wonder.

- **Does the Discussion bury the core point?** One substrate’s sharp dissent (preserved as signal): “*a massive wall of text reviewing prior art (Active Inference, Friston, Bruineberg, cybernetics) and aggressively defending novelty ... the detailed ‘Modes of deployment’ breakdown is deeply tangential ... this reads like an academic rebuttal letter pasted into the framework — the core point (the physical loop generates L2 data) is beautiful and gets buried*” (Gemini, AUDIT-WORKING-829314, which would “*ruthlessly edit*” / quarantine the prior-art and identifiability-floor material into dedicated #disc- segments). This is the **exact opposite reaction** to the cross-substrate praise above (#2). The conflict is itself the signal: the passage is high-value *and* placement-heavy; the same content reads as “exemplary positioning” to readers tracking prior-art and as “bloat that buries the result” to readers tracking the core theorem. A real readability tension to weigh in any pedagogy pass — not a defect to silently resolve.
- **How does the agent actually build the DAG — start fully connected and prune, or start empty and add edges?** (Claude, AUDIT-WORKING-849201). A natural mechanism question pointing into the strategy-DAG chapter.

5. Candidate figures.

- **Gate diagram (data-character → identification gates).** Agency scope supplies action contrast + physical intervention → intervention-character experience → then *separate gates* (coverage/positivity, sequential ignorability or adjustment, delay attribution, observability) decide whether usable L2 estimates are identifiable. The rationale: it “*makes the exact part smaller and the regime-dependent part explicit*” — the figure carries the segment’s central honesty (Codex/Claude, AUDIT-WORKING-526815, has a rendered draft). Strong figure candidate.

Belongs elsewhere.

- **Confounded-world neurosis / “patience as a mathematical necessity”** (Gemini, AUDIT-WORKING-193847) — the within-step-confounding tragedy (rain dance, superstition) develops the chapter-intro’s tragedy-of-agency framing and the 04-eli-core/ developmental-environment reach; the intro is the right home.
- **REPL as the epistemic-class upgrade for LLMs** (Gemini, AUDIT-WORKING-829314) — the “LLM in a chat window is L1; LLM with a bash terminal is L2” framing develops the same point at #der-causal-hierarchy-requirement (priors-accelerate / loop-verifies); kept there to avoid duplication.

7.4 Scope: CIY Observational Proxy

Clarifies what can be done with the causal-information-yield construct (3.7) when interventional data is *not* available. An observational *proxy* for CIY can be defined in terms of mutual information between the action and the next observation, but the framework is forthright: this proxy is **sign-indefinite in general** and requires causal assumptions for interpretation. The canonical interventional CIY remains the primary quantity; the proxy is auxiliary.

A pointed *safety condition* is stated: the proxy form should **not be used in policy optimization** (e.g., as the CIY term in a policy objective), because an agent maximizing a sign-indefinite quantity may optimize in the wrong direction. The proxy is suitable only for *diagnostic* purposes — detecting whether an action carried causal information (large proxy magnitude) versus none (proxy near zero). For actual decision-making, the canonical CIY (non-negative by construction) or a known-safe surrogate (ensemble disagreement, UCB bonuses) should be used; if the canonical CIY is intractable and no safe surrogate is available, the prescription is to *drop the CIY term entirely* and default to pure exploitation rather than risk the sign-indefinite quantity.

The segment then names three **admissibility regimes** that determine when CIY can be estimated and how strong the causal identification is. The regime is treated as a *property of the domain and the agent's action space*, not a parameter the agent chooses. **Regime A — randomized interventions:** the agent's action assignment is randomized, or known-and-adjusted so that sequential ignorability and positivity hold (RL agents exploring with an exploration policy uncorrelated with the latent outcome causes, scientists randomizing treatment, organisms probing); CIY is directly estimable from execution data and non-negative by construction (the standard case for active agents within 7.3). Mere across-episode action *variation* is not sufficient when the variation is policy-driven by state or history that also bears on the outcome. **Regime B — observational with causal assumptions:** the agent cannot freely vary actions (coordination, policy, or resource constraints); CIY estimation requires additional structure — a known causal DAG, instrumental variables, or functional-form assumptions — and inherits whatever causal assumptions are made. **Regime C — adversarial or passive observation:** the agent either did not intervene (passive monitoring, CIY zero by definition) or the observation channel includes potentially adversarial responses (where CIY from the query action itself remains non-negative but the *content* of the response may be designed to increase model-reality mismatch).

The regime classification has concrete domain implications: software development is typically Regime A (the agent runs tests, deploys to staging, observes results — high action variation); organizational strategy is typically Regime B (concurrent initiatives, attribution requires assumptions); intelligence analysis is typically Regime C (the analyst observes but does not intervene). The CIY machinery applies cleanly in Regime A, applies with weaker guarantees and explicit assumptions in Regime B, and should be replaced with alternative exploration strategies entirely in Regime C.

Formal Expression.

Definition (ciy-proxy).

$$\text{CIY}_{\text{proxy}}(a_{t-1}) = I(o_t; a_{t-1} \mid M_{t-1}) - I(o_t; a_{t-1} \mid \Omega_t, M_{t-1}) \quad (7.5)$$

This proxy is **sign-indefinite in general** and requires causal assumptions for interpretation. The canonical CIY (interventional, 3.7) is the primary quantity; the proxy is auxiliary.

Safety conditions for proxy use. The proxy form should NOT be used in policy optimization (e.g., as the CIY term in a policy objective) because an agent maximizing a sign-indefinite quantity may optimize in the wrong direction. The proxy is suitable only for diagnostic purposes: detecting whether an action carried causal information (large proxy magnitude) vs. none (proxy near zero). For decision-making, use the canonical CIY (non-negative by construction) or a known-safe surrogate (ensemble disagreement, UCB bonuses). If the canonical CIY is intractable and no safe surrogate is available, the CIY term should be dropped from the policy objective entirely, defaulting to pure exploitation.

Admissibility regimes.

Three regimes determine when CIY can be estimated and how strong the causal identification is:

Scope Condition (ciy-admissibility).

Regime A — Randomized interventions. The agent's action assignment is randomized, or known-and-adjusted so that sequential ignorability and positivity hold (RL agents exploring with an exploration policy uncorrelated with the latent outcome causes, scientists randomizing treatment, organisms probing). CIY is directly estimable from the agent's execution data and non-negative by construction. This is the standard case for active agents within the adaptive loop (7.3). What provides the identification needed for clean interventional estimates is the randomized / ignorable assignment together with positivity — not mere action variation, which is insufficient when actions are policy-driven by state or history that also affects the outcome.

Regime B — Observational with causal assumptions. The agent cannot freely vary actions (constrained by coordination, policy, or resource limits). CIY estimation requires additional structure: a known causal DAG, instrumental variables, or functional form assumptions. Results inherit whatever causal assumptions are made. The interventional interpretation of CIY is weaker — it holds under the assumed causal structure but not model-free.

Regime C — Adversarial or passive observation. The agent either did not intervene (passive monitoring) or the observation channel includes responses from potentially adversarial sources. In the passive case, CIY is zero by definition (no intervention, no interventional information). In the adversarial case, CIY from the query action itself remains non-negative, but the *content* of the response may be designed to increase model-reality mismatch. The adversary operates through the disturbance term ρ , not through the information measure.

The regime is a property of the **domain and the agent's action space**, not a parameter the agent chooses. Software development is typically Regime A (the agent runs tests, deploys to staging, observes results — high action variation). Organizational strategy is typically Regime B (multiple initiatives run concurrently, attribution requires assumptions). Intelligence analysis is typically Regime C (the analyst observes but does not intervene).

Epistemic Status.

Conditional on the causal assumptions within each regime. The proxy definition is standard information theory; the admissibility classification is a scope decision, not a derived result. The safety conditions for proxy use are normative — they follow from the sign-indefiniteness of the proxy, not from AAT-specific machinery.

Max attainable: conditional. The regime boundaries are domain properties that cannot be derived within the theory.

Discussion.

Relationship to the canonical CIY. The proxy is not an approximation of the canonical CIY — it is a different quantity that happens to correlate with CIY under favorable conditions (Regime A). The canonical CIY (3.7) is defined interventionally and is non-negative by construction. The proxy uses observational mutual information and can be negative. They agree when the agent's action variation satisfies the conditions for causal identification; they diverge otherwise.

Regime as a domain property. The admissibility regime is not something the agent selects — it is determined by the domain's action space and observation structure. An agent that cannot vary its actions is in Regime B or C regardless of its internal architecture. This has implications for which domains CIY-based exploration is applicable to: Regime A domains get the full benefit; Regime B domains get weaker guarantees; Regime C domains should use alternative exploration strategies entirely.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 526815, 584721, 773921, 829314, 849201 plus the batch dirs 471203 / 963715. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The sign-indefinite-proxy safety rule, as a Brief-grade line: “*never maximize a sign-indefinite proxy, or the agent might actively seek out blindness*” / “*an agent maximizing a sign-indefinite quantity may optimize in the wrong direction*” (Claude, AUDIT-WORKING-773921; the body already carries this — preserve it as the segment’s punchline).
- “*Good engineering guidelines disguised as theory*” — several substrates read the segment’s value as primarily operational-protective; the safe-degradation framing (“*drop the CIY term entirely and default to pure exploitation*”) is the takeaway worth foregrounding (Claude, AUDIT-WORKING-849201, 526815).

2. Candidate Discussion.

- **The “noisy TV problem” as the canonical motivating failure.** Strong candidate to add as the worked instance the safety condition exists to prevent: “*if you optimize for surprise / novelty using purely observational mutual information, you can build an agent that just stares at a TV screen showing static — the static is highly unpredictable given the past, so the agent thinks it is learning, but it learns nothing about causal structure. By stating the proxy is sign-indefinite and should never enter a policy objective, AAT protects developers from this exact trap*” (Gemini, AUDIT-WORKING-829314). This connects AAT’s sign-indefiniteness rule to a widely-known RL pathology (the Burda et al. noisy-TV result) and would make the abstract safety condition concrete.
- **Regime A/B/C as a diagnostic for where autonomous learning is even possible** — read by two substrates as one of the framework’s most useful practical tools: Regime A (software testing) → yes, learn causal structure perfectly; Regime B (organizational strategy / physical robotics — too expensive to crash the robot) → maybe, slow and assumption-dependent; Regime C (intelligence analysis / macro-economics) → no, trapped in L1. “*This elegantly explains why AI has succeeded spectacularly in games and coding (Regime A) but struggles in robotics (B) and macro-economics (C) — it’s not a failure of the algorithms, it’s a fundamental mathematical limit of the environment’s admissibility regime; AAT makes this limit legible*” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921 — “*why curiosity-driven learning works in video games (A) but fails catastrophically in stock markets (C)*”). Candidate Discussion expansion of the regime-as-domain-property paragraph.
- **Regime C adversarial content as a formal definition of deception.** Reading the adversarial sub-case: an action a can have high CIY (you got a response) while *the response was crafted to maximize your δ_t* — “*a formal definition of deception*” connecting to the adversarial-destabilization results, where the adversary operates through ρ , not the information measure (Claude, AUDIT-WORKING-773921). Candidate sharpening of the Regime-C paragraph.

3. Follow-up items.

- **Observability of Ω_t in the proxy formula.** The proxy conditions on Ω_t ; if Ω_t is the *true* environment state it is not generally computable from ordinary observations (it is a population-level identity, not a computable quantity), and if it is an *estimated* state the formula should say so and inherit model-error caveats. Candidate clarifying sentence so a reader doesn’t try to evaluate the proxy directly (Codex/Claude, AUDIT-WORKING-526815; same structural reading, framed cleanly, at AUDIT-WORKING-963715 — “ Ω_t is not observed, so this is a population-level identity, which is why it’s a ‘proxy’ requiring additional assumptions”).
- **~~Regime A wording: tighten “action variation” to “identifiable intervention.”~~ Resolved 2026-05-30** (transportability spike, §3.5 do-vs-conditioning reconciliation). Regime A now reads “action assignment is randomized / known-and-adjusted (sequential ignorability + positivity)” in both the opening prose and the formal Regime A statement, with an explicit note that mere policy-driven action variation is insufficient. The original note (Codex/Claude, AUDIT-WORKING-526815): “the agent varies its actions” is not sufficient for clean estimates under policy-driven action choice — same do-vs-conditioning concern as in #der-loop-interventional-access.

- **Consistency nit:** the opening prose says CIY “can be approximated from observational data” while the Discussion says the proxy “is not an approximation of canonical CIY” — settle on “a separate diagnostic proxy that correlates under favorable conditions (Regime A)” throughout (Codex/Claude, AUDIT-WORKING-526815).
- **TF-08 lineage artifact + topological-sort note.** A residual “TF-08” annotation was flagged for removal; separately, the proxy depends on #def-causal-information-yield, which appears *after* this segment in some OUTLINE walks — the proxy is read before the canonical object it proxies (Gemini, AUDIT-WORKING-829314). Worth confirming the OUTLINE ordering reads cleanly.

4. Readers often ask / wonder.

- **What is the exact form of the weighting factor λ — does it fall out of an information-bottleneck constraint or is it purely heuristic?** A natural question raised at the boundary into #disc-ciy-unified-objective, where the answer (the survival-imperative shadow price) lives (Claude, AUDIT-WORKING-849201).

5. Candidate figures.

- **Two-quantity-plus-three-regime diagram.** Draw canonical CIY (interventional, non-negative) and proxy CIY (observational, sign-indefinite) as *separate* quantities — not one quantity with noise — then place the three regimes under them: Regime A can estimate canonical CIY if assignment is randomized/ignorable; Regime B uses assumptions/adjustment; Regime C avoids CIY-in-policy-optimization. “*This captures the segment’s main safety lesson*” (Codex/Claude, AUDIT-WORKING-526815, has a rendered draft).

Belongs elsewhere.

- The five-domain λ mapping and the survival-imperative drive belong with #disc-ciy-unified-objective; the regret-bound / Bretagnolle-Huber material with #deriv-strategy-cost-regret-bound. Auditors picked these up while reading the proxy segment but they are downstream content.

7.5 Discussion: CIY Unified Policy Objective

The framework’s *unified policy objective* expresses the exploration-exploitation tension as a single decision rule: choose the action that maximizes a weighted sum of expected value (exploitation) and a causal-information surrogate (exploration). The first term is the exploitation contribution; the second is a *heuristic exploration term* using CIY (3.7) as a tractable surrogate for expected information gain — selecting for causally distinctive actions rather than maximally informative ones. The weighting parameter $\lambda(M_t)$ controls the balance, carries units of *value per unit information*, and in specific well-understood domains reduces to known quantities exactly: the Gittins index for Bayesian bandits, the probing cost in quadratic objectives for Kalman dual control, precision on epistemic affordance for active inference, the explicit variance-over-information ratio in information-directed sampling (Russo & Van Roy). The unified objective is not a novel formalism but a *family-level abstraction* that recovers known scalarizations of the exploration-exploitation trade-off across communities.

The scalar form is honestly heuristic and is now formally *superseded* by an exact tensor trace-product derived in AV: the action maximizes the value plus the trace of a positive-semidefinite shadow-price matrix times the Fisher Information Matrix at the action — the exact Lagrangian relaxation of the Linear Matrix Inequality governing Lyapunov persistence. Two parallel exploration drives emerge from the framework, acting at opposite ends of the uncertainty spectrum: an *epistemic information-gain* drive with $\lambda \propto U_M$ (explore to reduce model uncertainty; dominates when uncertain) and a *survival-imperative* drive with $\lambda \propto 1/U_M$ (an agent with high confidence in a drifting environment mathematically guarantees its own death by ignoring noisy observations, so the Lyapunov persistence constraint dictates an immense shadow price as model uncertainty drops in a drifting environment — forcing the confident agent to seek unambiguous observations from the *opposite* uncertainty regime). The dark-room problem that plagues some preferences-as-priors formulations is *bypassed entirely* by the survival imperative: exploration is not driven by preferences-as-priors but by

the literal physical boundaries of the Lyapunov sector constraint. The Discussion below treats the active-inference structural isomorphism with two substantive AAT-specific departures (causal information rather than entropy over hidden states; value functional rather than preferences-as-priors), the zero-mismatch ambiguity bridge from Part I, the three-mode extension for actuated agents, and the regret-bound connection to the strategy-cost objective via the Bretagnolle-Huber identity under deterministic optimal policy.

Formal Expression.

Discussion (unified-policy-objective — heuristic).

$$\pi^*(M_t) = \arg \max_a [\mathbb{E}[\text{value}(a) \mid M_t] + \lambda(M_t) \cdot \text{CIY}_q(a; M_t)] \quad (7.6)$$

The first term is exploitation (expected value given current model). The second is a *heuristic exploration term* using CIY as a surrogate for expected information gain (3.7). CIY measures how different the action's outcome distribution is from alternatives — this is action-distinguishability, not learning value. The surrogate is reasonable when U_M is high (distinguishable actions are also informative to an uncertain agent) and poor when U_M is low (distinguishable actions teach nothing to a confident agent). $\lambda(M_t)$ controls the balance:

- High U_M (uncertain model) $\rightarrow$ large λ — exploration is valuable
- Low U_M (confident model) $\rightarrow$ small λ — exploitation dominates
- Long time horizon $\rightarrow$ larger λ — information compounds
- High ρ (fast-changing environment) $\rightarrow$ larger λ — perpetual uncertainty

λ carries units of [value per unit information]. In specific domains it reduces to known quantities:

Table 7.2

<i>Domain</i>	<i>λ reduces to</i>	<i>Status</i>
Bayesian bandits	Gittins index	Exactly derived
Kalman dual control	Probing cost in quadratic objective	Exactly derived
Active inference	Precision on epistemic affordance	Framework-derived
Information-directed sampling	(Vol) ² /info gain	Exactly derived (Russo & Van Roy)
RL with UCB	Confidence-bound scaling	Heuristic (tuned)

Identifiability gate. Before incorporating CIY into the policy objective: (1) action variation must exist, (2) the admissibility regime must be identified (7.4), (3) the reference distribution q must be specified, (4) local stationarity must hold. If any condition fails, CIY-based terms should be dropped or replaced with simpler uncertainty-based heuristics (UCB-style bonuses, ensemble disagreement).

Epistemic Status.

Discussion-grade summary; underlying derivation is exact. Originally treated as a discussion-grade heuristic, the unified objective has now been formally derived as the exact Lagrangian relaxation of the Linear Matrix Inequality (LMI) governing Lyapunov persistence (see `#deriv-causal-ib-lmi`).

The scalar heuristic $Q_O(a) + \lambda \cdot \text{CIY}(a)$ is formally superseded by the exact tensor trace-product: $a_t^* = \arg \max_a [Q_O(a) + \text{Tr}(\Lambda \cdot J_o(a))]$ where $J_o(a)$ is the Fisher Information Matrix (Matrix CIY) and Λ is the positive-semidefinite shadow price matrix of the survival constraint.

Max attainable for this segment: *discussion-grade* (it is a discussion of the underlying result, per type: discussion). Max attainable for the underlying derivation in `#deriv-causal-ib-lmi`: *exact*. The structural form is fully grounded in AAT's physical survival bounds and standard semidefinite programming, eliminating the need to treat exploration as an ad-hoc heuristic.

Discussion.

Two Parallel Exploration Drives. AAT dictates two correlated but distinct motivations for exploration, acting at opposite ends of the uncertainty spectrum: 1. **Epistemic Information Gain** ($\lambda_{\text{info}} \propto U_M$): The primary CIY formulation. The agent explores to reduce its model uncertainty. This drive dominates when U_M is high. 2. **The Survival Imperative** ($\lambda_{\text{surv}} \propto 1/U_M$): As mathematically proven in `#deriv-causal-ib-exploration`, an agent with high confidence (low U_M) in a drifting environment ($\rho > 0$) mathematically guarantees its own death by ignoring noisy observations. To force the necessary correction, the Lyapunov persistence constraint dictates an immense shadow price ($\lambda_{\text{surv}} \rightarrow \infty$ as $U_M \rightarrow 0$) forcing the agent to seek unambiguous observations (low U_o / high CIY).

The dark-room problem is bypassed entirely by the Survival Imperative: exploration is not driven by preferences-as-priors, but by the literal physical boundaries of the Lyapunov sector constraint.

Connection to the zero-mismatch ambiguity. An agent that only exploits (acts to maximize predicted value) will tend toward confirmation bias — observing only what its model already explains (3.4, zero-mismatch ambiguity case (b)). Exploration via CIY-maximizing actions is the mechanism by which the agent actively tests its model.

Connection to Part II. For actuated agents, the exploration-exploitation tension extends to three modes: exploit (pursue O_t via Σ_t), explore (improve M_t), deliberate (revise Σ_t). The CIY framework provides the information-theoretic grounding for why strategy edges (8.3) need observational access (9.3) — edges the agent cannot observe have frozen CIY.

Connection to active inference. The expected free energy (EFE) in active inference (Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29; Da Costa, Parr, Sajid, Veselic, Neacsu & Friston 2020, “Active inference on discrete state-spaces,” *J. Math. Psych.* 99; Sajid, Ball, Parr & Friston 2021, “Active inference: demystified and compared,” *Neural Computation* 33) decomposes into *pragmatic value* (preferences-aligned outcomes) and *epistemic value* (expected information gain about hidden states). AAT's unified objective is structurally isomorphic: $Q_O \approx$ pragmatic, $\text{CIY} \approx$ epistemic. The convergence is at the shared-shape level — objective decomposes into value-and-information terms — not unified content. Two substantive differences remain. First, AAT grounds exploration in explicitly *causal* information (action-distinguishability under *do*) rather than entropy reduction over hidden states — not all uncertainty reduction is equally valuable for purposeful action; causal information specifically enables better *intervention* (see 7.2; the gap between CIY and proper expected information gain is logged in this segment's Epistemic Status as a known surrogate). Second, AAT does not encode preferences as priors over outcomes ($C(o) = \log P_{\text{pref}}(o)$ in the AI form): AAT's O_t is a value functional on trajectories (6.4), and the satisfaction-gap / control-regret diagnostic in 8.4, 8.5 depends on this distinction — the diagnostic structure does not survive the priors-as-preferences collapse (the dark-room critique, Sun & Firestone 2020, “The dark room problem,” *Trends Cog. Sci.* 24).

Regret-bound connection to the strategy-cost objective. AAT’s Q_O term connects to the strategy-cost objective in 9.9 via a regret-bound derivation: strategy-induced regret $R(Q_{\Sigma_t}) = V(a^*) - \mathbb{E}_{Q_{\Sigma_t}}[V(a)]$ is bounded by a divergence between π^* and Q_{Σ_t} , with the KL direction π^* -first forced (full derivation in T). Under AAT’s canonical scope of deterministic π^* , the Bretagnolle-Huber identity $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t}) = -\log(1 - \text{TV}(\pi^*, Q_{\Sigma_t}))$ holds *exactly* (Bretagnolle & Huber 1978), giving the tight regret bound $R(Q_{\Sigma_t}) \leq V_{\max}(1 - e^{-D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})})$ with matching lower bound $\Delta_{\min}(1 - e^{-D_{\text{KL}}})$ on isolated optima (T §4). Pinsker’s $V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})}$ remains the correct loose general form for stochastic- π^* extensions where the BH identity degrades back to inequality. The structural point: “value and information term” shares *shape* with EFE’s pragmatic-epistemic decomposition, and the KL direction in the strategy-cost’s variational form shares direction with variational inference — but AAT’s derivation is via decision-theoretic regret bound on Q_O rather than via free-energy-gradient flow, which is the AAT-internal route that does not depend on the priors-as-preferences encoding.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 526815, 584721, 773921, 829314, 849201 plus the batch dirs 471203 / 963715. The **survival imperative** drew the highest ideation in the chapter — “*arguably the most beautiful mathematical result I’ve seen in the framework so far.*” Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- **The survival imperative, in one image:** “*The agent doesn’t explore because it is curious; it explores because it is suffocating from a lack of surprise*” (Gemini, AUDIT-WORKING-829314). The single most-quotable line for this segment — a Brief-grade gloss of $\lambda_{\text{surv}} \propto 1/U_M$.
- **The U-shaped exploration valuation:** standard RL treats exploration’s value monotonically (more uncertainty $\rightarrow$ more exploration); AAT says high U_M drives *epistemic* exploration and low U_M in drifting worlds drives *survival* exploration, “*the two limits composing to a U-shaped exploration valuation — high at both extremes*” (Claude, AUDIT-WORKING-471203). A clean framing-level summary of the “Two Parallel Exploration Drives” subsection.
- The dark-room bypass stated plainly: AAT “*solves the exploration-exploitation dilemma using Lyapunov control theory*” / “*provides a rigorous mathematical solution to the Dark Room Problem that plagues Predictive Coding and Active Inference*” (Claude, AUDIT-WORKING-773921). Brief-grade contribution statement.

2. Candidate Discussion.

- **Skunkworks / R&D as a Lyapunov-mandated survival cost — the standout cross-domain reach.** Gemini’s extended development of the survival imperative: a too-successful organization (low U_M) optimizes its processes so tightly that gain collapses; when the market (ρ) shifts, its machinery has “*rusted shut.*” “*AAT proves that R&D is not a luxury for finding new profits; it is a Lyapunov-mandated survival cost*” — and likewise the biological necessity of *play* in adult animals as forced high-CIY action to keep the learning machinery functional (Gemini, AUDIT-WORKING-829314). A vivid, honest Discussion angle on the survival imperative that the segment does not currently name. (*Conflation-as-signal: aspirational reach toward an analogy — verify the gain-collapse $\rightarrow$ organizational-rust isomorphism before promoting past discussion-grade.*)
- **The dark-room rejection validates the whole (M_t, G_t) split.** Several substrates read AAT’s escape from the dark-room critique as load-bearing structural support, not just a positioning note: AAT can’t reduce expected free energy by hiding in a dark room “*because the trajectory functional doesn’t decrease just because observations are uniform*” — O_t is a value functional on trajectories, not a prior over outcomes (Claude, AUDIT-WORKING-584721; AUDIT-WORKING-849201 — “*the rejection of the dark room problem via maintaining O_t separate from M_t validates the entire (M_t, G_t) state split*”). Candidate Discussion sharpening tying the dark-room paragraph back to #def-strategy-dimension.

- **The five-domain λ table as an explicit integration claim.** Read as showing AAT's objective is a *generalization that includes Gittins / Kalman dual-control / EFE-precision / IDS / UCB as special cases* — “an integration claim rather than a novel-mathematics claim, consistent with the CLAUDE.md framing” (Claude, AUDIT-WORKING-584721; praised as “one of the strongest unification claims in the framework so far” at AUDIT-WORKING-773921). Worth foregrounding the special-case-recovery reading.

3. Follow-up items.

- **Status / type metadata vs. prose tension (propagation debt from the upgrade).** YAML is status: discussion-grade / type: discussion, but the Epistemic Status prose says “Exact” and “Max attainable: exact.” The honest read: the segment was *upgraded* (prose rewritten to reflect the derivation) but the “Max attainable: exact” line belongs in the underlying derivation segment, not the discussion summary — this Epistemic Status should say “summarizes the exact result derived in [the LMI derivation]” (Claude, AUDIT-WORKING-471203, logged Low/Medium; same observation at AUDIT-WORKING-526815, 829314). Editorial; surfaces a real upgrade-propagation failure mode.
- **Cross-reference verified clean (2026-05-30).** One batch flagged a possibly-stale forward-reference to #deriv-directional-survival-exploration, a slug it could not find in OUTLINE. Grep of the current body confirms it cites only #deriv-causal-ib-lmi / #deriv-causal-ib-exploration (both exist as segments); no #deriv-directional-survival-exploration slug remains anywhere in canon. Resolved — the flagged slug was a pre-promotion artifact already superseded. (Flagged by Claude, AUDIT-WORKING-471203.)
- **Pinsker $\rightarrow$ Bretagnolle-Huber integration debt.** One substrate (AUDIT-WORKING-584721, logged F-D1) initially read the regret bound as still using Pinsker where the canonical #deriv-strategy-cost-regret-bound now uses the sharper BH identity. The *current* body already states the BH identity as primary with Pinsker as the loose stochastic- π^* fallback — so this appears resolved; logged here only so the disposition is traceable. Both bounds are valid; one is sharper.
- **Domain-table “exactly derived” labels may overstate.** The Gittins index is an action index/value in a discounted bandit, not the scalar weight λ itself; information-directed sampling minimizes a regret²/information ratio, not a direct additive $\lambda \cdot$ CIY term. If these are analogies, “*exactly derived*” is too strong without an explicit mapping (Codex/Claude, AUDIT-WORKING-526815). Candidate precision pass on the table's Status column.

4. Readers often ask / wonder.

- **Why does a confident agent in a drifting world die — and why is more confidence fatal?** The survival-imperative mechanism is the chapter's “wait, really?” moment and readers want the chain spelled out: low $U_M \rightarrow$ Kalman gain $\eta^* \rightarrow 0 \rightarrow$ adaptive tempo $\mathcal{T} \rightarrow 0 \rightarrow$ violates persistence $\alpha > \rho/R \rightarrow$ death by *gain collapse* (Gemini, AUDIT-WORKING-829314, 773921). The body states it; a one-line causal chain up front would land it faster.
- **Does the survival shadow-price Λ explode along the agent's weakest dimension** — i.e. does the agent automatically steer exploration to fix the eigenvector closest to failing $\Sigma_\infty < D_\delta$? (Claude, AUDIT-WORKING-773921). A precise, falsifiable reader question about the matrix form, worth a sentence or a forward pointer to #deriv-causal-ib-lmi.
- **Is the “Discussion” section overloaded?** One substrate read the segment as “a chaotic mix of profound insights and dense defensive literature reviews ... shoving advanced variational bounding theorems into a Discussion segment ... severely harms readability” and would refactor the exact Lagrangian survival-imperative derivation into its own Derived segment with the active-inference review quarantined (Gemini, AUDIT-WORKING-829314). Same placement-vs-value tension flagged at #der-loop-interventional-access; preserved as a real readability signal, not a defect.

5. Candidate figures.

- **Two stacked objectives diagram.** Top layer: the scalar heuristic $\mathbb{E}[\text{value}] + \lambda \cdot \text{CIY}$, gated by identifiability; lower layer: the exact matrix form $Q_O(a) + \text{Tr}(\Lambda \mathcal{I}_O(a))$. “Drawing both makes the status drift visible — the scalar form is useful vocabulary, the exact claim belongs to the LMI/tensor version” (Codex/Claude, AUDIT-WORKING-526815, has a rendered draft).
- **U-shaped exploration-value curve.** Exploration valuation against U_M : high at high U_M (epistemic drive) and high at low U_M (survival drive), dipping in between — visualizes the two-parallel-drives composition (implicit in Claude, AUDIT-WORKING-471203).

Belongs elsewhere.

- The exact Lagrangian relaxation of the LMI and the matrix-CIY trace-product are the property of `#deriv-causal-ib-lmi` / `#deriv-causal-ib-exploration`; the Bretagnolle-Huber regret derivation is `#deriv-strategy-cost-regret-bound`. This segment is the discussion-grade surface; the theorem-grade math lives in those appendix segments.

7.6 Normative: Explicit Strategy Condition

The framework's design criterion for *when explicit strategy is worth maintaining at all*. An agent benefits from carrying an explicit strategy Σ_t (6.7) when *the cost of planning is less than the cost of learning through exploration alone*. The inequality compares the cost of constructing and evaluating the strategy plus ongoing maintenance cost (as M_t evolves and edges need revision) against the cost of learning action-outcome mappings through direct interaction plus the cost of correcting errors discovered only through execution. All costs are measured in the same units, typically time or tempo-equivalent cost.

The result is honestly *normative*, not derived. It is labeled as a design criterion rather than a theorem because loop-based and model-based approaches may differ along axes the cost inequality does not capture: final value (the model introduces bias; exploration may discover things planning cannot), risk profile (exploration risks real damage; planning risks wrong models), reversibility (some exploratory actions are irreversible), and model bias (explicit Σ_t inherits the biases of M_t ; loop-based learning does not). The inequality is correct *when* the outcomes are approximately equivalent — a condition that must be verified case by case, not assumed.

The intuitive cases are stated cleanly. The right side (explore + repair) is large — strongly favoring planning — when actions are expensive or irreversible (production deployments, military operations, surgical procedures); when exploration damage is severe (a wrong move loses the game; a wrong deployment takes down the service); when the environment is slow to respond (waiting for market or test feedback); when the action space is enormous (combinatorial planning). The left side (plan + maintain) is large — favoring pure exploration — when the environment is too complex or novel for useful models, when M_t is severely inadequate, when the environment changes faster than Σ_t can be maintained, or when actions are cheap and reversible (A/B testing, sandbox exploration).

The *normative grounding* is anchored in the persistence condition (4.5), not in an external preference postulate. The persistence condition demonstrates that agents whose correction tempo is insufficient *degrade* — descriptive, not value-laden. The cost inequality operationalizes the consequence: approaches consuming less tempo budget leave more margin above the persistence threshold. The normative element is the preference for *maintaining persistence margin*, which is hard to argue against since the alternative is degradation. The Discussion below treats the strongly-favors-planning and strongly-favors-exploration cases in detail, the persistence-margin grounding, and the connection to the three-way exploit/explore/deliberate refinement in 10.2; Working Notes flag the most useful practical reading — not as a binary decision rule but as a way to *calibrate strategy complexity* so the planning-and-maintenance cost stays just below the exploration-and-repair cost for the current environment.

Formal Expression.

An agent benefits from explicit Σ_t when:

Normative (explicit-strategy-condition).

$$C_{\text{plan}} + C_{\text{maintain}} < C_{\text{explore}} + C_{\text{repair}} \quad (7.7)$$

where: - C_{plan} : cost of constructing and evaluating the strategy (deliberation, simulation, model queries) - C_{maintain} : ongoing cost of keeping Σ_t current as M_t evolves (edge revision, structural updates) - C_{explore} : cost of learning action-outcome mappings through direct interaction (real actions, real time, real consequences) - C_{repair} : cost of correcting errors discovered only through execution (rollbacks, rework, damage)

All costs are measured in the same units (typically time or tempo-equivalent cost). The inequality requires that the two approaches produce approximately equivalent non-temporal outcomes — otherwise the comparison is between different strategies, not different approaches to the same goal.

Epistemic Status.

Normative, not derived. This is labeled *normative* because it is a design criterion (a preference for the less costly approach given equivalent outcomes), not a theorem. In practice, loop-based and model-based approaches may differ in:

- **Final value:** the model introduces bias; exploration may discover things planning cannot
- **Risk profile:** exploration risks real damage; planning risks wrong models
- **Reversibility:** some exploratory actions are irreversible
- **Model bias:** explicit Σ_t inherits the biases of M_t ; loop-based learning does not

The inequality is correct *when* the outcomes are approximately equivalent — a condition that must be verified case by case, not assumed. When the precondition fails (model-based and loop-based approaches produce qualitatively different outcomes), the cost inequality is insufficient and the choice requires richer analysis (e.g., expected regret including model error).

Discussion.

When the inequality strongly favors planning. The right side ($C_{\text{explore}} + C_{\text{repair}}$) is large when: - Actions are expensive or irreversible (production deployments, military operations, surgical procedures) - Exploration damage is severe (a wrong move in chess loses the game; a wrong deployment takes down the service) - The environment is slow to respond (waiting for market feedback, waiting for test results) - The action space is enormous (combinatorial planning problems)

In these domains, explicit Σ_t is strongly motivated even if the planning model is imperfect.

When the inequality favors pure exploration. The left side ($C_{\text{plan}} + C_{\text{maintain}}$) is large when: - The environment is too complex or novel for useful models (genuinely unknown territory) - M_t is severely inadequate (model predictions are worse than random) - The environment changes faster than Σ_t can be maintained (ρ_Σ exceeds planning capacity) - Actions are cheap and reversible (A/B testing, sandbox exploration)

Normative grounding. The cost inequality is grounded in the persistence condition (4.5), not in an external preference postulate. The persistence condition demonstrates that agents whose correction tempo is insufficient *degrade* — this is a descriptive result, not a value judgment. The cost inequality operationalizes the consequence: approaches that consume less tempo budget leave more margin above the persistence threshold. The normative element is the preference for maintaining persistence margin — which is hard to argue against, since the alternative is degradation. (In TST, the temporal optimality postulate provides an additional normative grounding specific to software development.)

Connection to the three-way tradeoff. For actuated agents, the binary explore/exploit tradeoff extends to three modes: exploit (pursue O_t via Σ_t), explore (improve M_t), and deliberate (revise Σ_t). The cost inequality addresses the coarsest question (is explicit Σ_t worth having?). The finer allocation between the three modes is addressed in 10.2 — the extended deliberation threshold is derived, but the broader three-way framing is discussion-grade. The deepest insight: deliberation is internal exploration (simulation, counterfactual reasoning, cross-domain synthesis), making it a fundamentally different resource type from external action.

Working Notes.

- The inequality as stated is static — it compares cumulative costs. A dynamic version would ask: “given current M_t quality, is it worth deliberating further or should I act now?” This connects to 4.1’s threshold: deliberation is worthwhile only when additional deliberation improves action quality enough to justify the time spent.
- Part of C_{maintain} is the cognitive cost of keeping Σ_t in the agent’s representational capacity. For LLM agents, this means fitting the strategy in the context window. A 500-node DAG may exceed this capacity, making the left side of the inequality large enough that simpler strategies (or pure exploration) become preferable despite higher exploration costs.
- The cost inequality may be most useful not as a binary decision rule but as a way to calibrate Σ_t complexity: the agent should maintain a strategy just complex enough that $C_{\text{plan}} + C_{\text{maintain}}$ stays below $C_{\text{explore}} + C_{\text{repair}}$ for the current environment. This gives a principled answer to “how detailed should my plan be?”

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 526815, 584721, 773921, 829314, 849201 plus the batch dir 471203. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The calibration reading (already in Working Notes) was independently singled out as “*one of the most practical pieces of advice for software engineering and organizational design I have ever seen formalized*” (Claude, AUDIT-WORKING-773921) and the segment’s most useful operational handle (Claude, AUDIT-WORKING-584721). Strong signal to promote the “*how detailed should my plan be?*” framing from Working Notes into the Brief / body.
- The reframing of the planning-vs-learning debate: the cost inequality “*reframes the question from doctrinal (planning-vs-RL camps) to empirical (which costs dominate in your domain?)*” (Claude, AUDIT-WORKING-584721). A clean contribution statement.

2. Candidate Discussion.

- **The Agile-vs-Waterfall mapping as the canonical worked instance.** Strong cross-substrate convergence (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921) that the four costs *are the mathematical foundation of software-engineering methodologies*: Waterfall assumes $C_{\text{repair}} \rightarrow \infty$ (space shuttle) and C_{explore} prohibitive $\rightarrow$ spend heavily on $C_{\text{plan}} + C_{\text{maintain}}$; Agile/Lean assumes C_{repair} cheap (revert a git commit) and C_{explore} fast (A/B test) $\rightarrow$ minimize planning, gather interventional data instead. “*Neither approach is universally right — the optimal strategy depends entirely on the physical parameters of the environment ... Agile in a high- C_{repair} environment like surgery dies; Waterfall in a low- C_{repair} /high-volatility web startup goes bankrupt paying C_{maintain} for a plan that is instantly obsolete.*” A candidate Discussion example or TST cross-reference.
- **The LLM context-window as a structural C_{maintain} amplifier.** The Working-Notes point (a 500-node DAG may exceed an LLM’s representational capacity) was read as load-bearing: “*for an LLM, C_{maintain} is massive because of the finite context window — every plan step consumes tokens, crowding out operational memory ... the math says an LLM should not write a master plan up front; it should just start writing code and see what breaks — pure exploration is mathematically optimal for them given their current cognitive costs.*” And the engineering corrective: “*if we want LLMs to plan better, we must artificially reduce their C_{maintain} — external structured scratchpad / hierarchical memory to offload the description length of the DAG; AAT gives the exact equation for why this intervention is necessary*” (Gemini, AUDIT-WORKING-829314). Candidate Discussion sharpening connecting the cost inequality to scaffolding design — and it converges with the persistence-bandwidth-floor framing already noted in #impl-causal-access.

3. Follow-up items (soft / scope-honesty).

- **“Loop-based learning does not inherit biases” overstates.** The Epistemic Status contrasts explicit- Σ_t (inherits M_t bias) with loop-based learning (does not). But direct exploration is still biased by policy selection, partial observability, confounding, update rules, and the model used to *interpret* observations. The honest contrast is “*planning inherits model bias differently*,” not “*loop learning is unbiased*” (Codex/Claude, AUDIT-WORKING-526815). Candidate one-clause fix.
- **Persistence-margin grounding is not universal across continuity stances.** The normative grounding leans on “preference for persistence margin, hard to argue against.” But the continuity-stance work (#disc-continuity-stance) recognizes task-terminal / indifferent / negotiated-continuation agents — the criterion is compelling for agents whose *objectives require ongoing persistence*, and should not silently override the objective’s stance toward continuation (Codex/Claude, AUDIT-WORKING-526815). Candidate scope qualifier.
- **Dependency-declaration gap.** The criterion is grounded in #result-persistence-condition, which is not declared in depends:. Acceptable if Discussion-only dependencies aren’t tracked, but the grounding is substantive (Codex/Claude, AUDIT-WORKING-526815). Worth a glance against the project’s depends-tracking policy.
- **Common-units / risk treatment.** Irreversible damage and heavy-tailed repair costs are not well represented by a static scalar inequality unless the cost measure already embeds risk; the equivalent-non-temporal-outcomes precondition is doing a lot of work (Codex/Claude, AUDIT-WORKING-526815). The body’s caveat already names this; the signal is that it is easy to read past.

4. Readers often ask / wonder.

- **How does the three-way budget (exploit / explore / deliberate) get allocated in real time?** Several substrates noted the body’s binary inequality answers only the coarsest question and the real interest is the dynamic three-way allocation — “*this maps exactly to the control loop of an advanced autonomous agent (Devin / SWE-agent); understanding how the framework triggers transitions between the three modes is the key to building AAT-compliant agents*” (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314 — classical RL treats deliberation as computationally free, AAT costs it via C_{plan}). The body forward-points to #disc-exploit-explore-deliberate; readers want that pointer prominent.

Belongs elsewhere.

- The compounding-fragility-of-long-chains material (chain-confidence decay, evidence starvation, cognitive cost = a “triple depth penalty”) that auditors raised while reading this segment belongs at #der-chain-confidence-decay (the next segment), not here.

7.7 Derivation: Mechanism Counterfactuals Separate Strictly From Level 3 — Witness, Reducibility Boundary, and Internalization

Two SCMs can agree on *every* Level-1/2/3 quantity — the identical joint law of all hard-intervention counterfactual worlds — while assigning probabilities 1 and 0 to the same noise-preserving mechanism-replacement query; the separation is therefore strict in exactly the Causal Hierarchy Theorem’s sense, and it is generic rather than exotic: every SCM whose exogenous space admits a measure-automorphism with realized effect on some mechanism disagrees with *its own relabeling* on a latent-anchored query (Result 4). The boundary is characterized by the *specification language* of the imagined mechanism — replacements written over potential-outcome coordinates (the closure of the Level-3-exposed channels) reduce to Level 3, while replacements anchored to the latent parameterization need not, and the witness’s provably does not — and internalization via selector variables re-represents but provably does not collapse the separation.

Formal Expression.

Throughout, $M = \langle U, V, F, P(U) \rangle$ is a finite recursive (acyclic) SCM. The **Level-3 content** of M is the joint law of the potential-outcome process $\text{PO}(M) = \{V_w(\cdot) : w \text{ a hard intervention on a subset of } V\}$ on $(U, P(U))$ — by [1, Defs.~7, 9] this is precisely the family of $\mathcal{L}_3$ valuations $P^M(\mathbf{y}_x, \dots, \mathbf{z}_w)$, and it subsumes all $\mathcal{L}_1, \mathcal{L}_2$ valuations and nested counterfactuals. Write $M \equiv_3 M'$ for equality of Level-3 content.

[Definition (noise-preserving mechanism replacement; after Pearl’s local surgeries — [2, §7.2.4]: actions “represented as local surgeries,” respecifying “those few mechanisms that are perturbed” with “all other mechanisms... unaltered”; the atomic case defined by mechanism replacement in [3, §2])]]

For $g : \text{dom}(pa_i) \times \text{dom}(U) \rightarrow \text{dom}(v_i)$, let $M[f_i := g]$ denote M with the i -th structural equation replaced and $\langle U, P(U) \rangle$ unchanged. **Mechanism-counterfactual queries** are probabilities of Boolean combinations of events over worlds drawn from the submodels of both M and $M[f_i := g]$, all sharing the exogenous draw u ; $\text{do}(X = x)$ is the constant special case, and evaluation extends Pearl’s abduction-action-prediction three-step verbatim.

There exist $M_A \equiv_3 M_B$ over a shared signature $\langle U, V, P(U) \rangle$ and a mechanism-counterfactual query q with $q(M_A) = 1$, $q(M_B) = 0$. Hence noise-preserving mechanism counterfactuals are not Level-3 quantities.

Derived (Result 1 — strictness witness).

Derivation. Binary U_X, U_Y independent uniform; $X = U_X$ in both models;

$$M_A : Y = X \oplus U_Y, \quad M_B : Y = X \oplus U_Y \oplus 1. \quad (7.8)$$

The response pair $(Y_{x=0}, Y_{x=1})$ is $(U_Y, 1 \oplus U_Y)$ in M_A and $(1 \oplus U_Y, U_Y)$ in M_B ; the $P(U)$ -preserving bijection $\varphi(u_X, u_Y) = (u_X, 1 \oplus u_Y)$ carries one potential-outcome process onto the other, so the joint law of $\text{PO}(\cdot) - (Y_{x=0}, Y_{x=1})$ uniform on $\{(0, 1), (1, 0)\}$, independent of $X = U_X$, with the actual $Y = Y_X$ and the trivial responses under interventions on Y — is identical: $M_A \equiv_3 M_B$. Now replace Y ’s mechanism by $g(x, u_Y) = u_Y$ and take $q = P(Y_{f_Y:=g} = Y_{x=0})$. In M_A , $Y_{f_Y:=g} = U_Y = Y_{x=0}$ a.s., so $q = 1$; in M_B , $Y_{f_Y:=g} = U_Y = 1 \oplus Y_{x=0}$ a.s., so $q = 0$. The evidence-conditioned form behaves identically: $P(Y_{f_Y:=g} = 1 \mid X = 0, Y = 1)$ is 1 in M_A and 0 in M_B . ■

Call a replacement **PO-specified** when the new mechanism is $v_i := h(pa_i, \pi(\cdot), \varepsilon)$ for fixed measurable h , fresh noise $\varepsilon \perp U$ of given law, and $\pi(u)$ a fixed finite tuple of potential-outcome coordinates — each entry $a(v_j)_w(u)$ for specification-fixed variable j and hard intervention w — the closure of the Level-3-exposed channels. This includes as special cases every **L3-specified** replacement $v_i := h(pa_i, f_i(pa_i, \cdot), \varepsilon)$: deterministic parent-only re-wirings, independent randomized devices, all shift-scale soft interventions $a(pa_i)f_i + b(pa_i)$, and any replacement reading named counterfactual quantities of the original model (e.g. “output $Y_{x=0}$ ’s value”). Every cross-world query over M and $M[f_i := h]$ with h PO-specified is determined by the Level-3 content of M together with the law of ε ; PO-specified replacements therefore never separate a $\equiv_3$ pair.

Derived (Result 2 — reducibility of PO-specified replacements).

Derivation. By topological induction on the modified world’s variables: upstream variables retain their original potential responses; $v_i^h = h(pa_i^h, \pi(u), \varepsilon)$, where each coordinate of $\pi(u)$ is by definition an element of $\text{PO}(M)$ and $f_i(pa_i^h, u)$ — where read — is the original potential outcome of v_i under the hard intervention setting its parents to the already-computed values, an element of $\text{PO}(M)$ at a computed index; downstream variables are $V_{w \cup \{v_i=v_i^h\}}(u)$, again elements of $\text{PO}(M)$ at computed indices. The modified-world trajectory is thus a measurable functional of $\text{PO}(M)$ and ε , so every joint law with original-model worlds is a functional of Level-3 content. Model-invariance is by construction: a PO-specification names *counterfactual coordinates*, which $\equiv_3$ -equivalent models value identically in law — unlike a latent-written table, which names points of $\text{dom}(U)$ and acquires a PO-reading only model-relatively. ■

For any finite family $\mathcal{G} = \{g_1, \dots, g_k\}$ of replacements for f_i , the enlarged SCM $M^\dagger$ with selector $S \in \{0, \dots, k\}$ (endogenous, with constant mechanism $S := 0$, so that $Y_{S=j}$ is a hard-intervention quantity) and $f_i^\dagger(pa_i, s, u) = f_i(pa_i, u)$ if $s = 0$, else $g_s(pa_i, u)$ — Pearl’s interventions-as-variables construction ([2, §3.2.2, Eq.~(3.7), Fig.~3.2]; originally [3, Eq.~(3), Fig.~1]), whose $x_i = I(pa_i, f_i, u_i)$ with $I(a, b, c) = f_i(a, c)$ whenever $b = f_i$ is precisely mechanism replacement internalized as an added parent variable — “applicable to any change in the functional relationship f_i and not merely to the replacement of f_i by a constant” (§3.2.2) — applied reflexively — satisfies $Y_{f_i:=g_j} = Y_{S=j}$: every mechanism counterfactual over $(M, \mathcal{G})$ is a hard-intervention (Level-2/3) quantity of $M^\dagger$. But the map $M \mapsto M^\dagger$ is not a functional of Level-3 content: by Result 1, $M_A \equiv_3 M_B$ while $M_A^\dagger \not\equiv_3 M_B^\dagger$ (their Level-3 contents already disagree on $P(Y_{S=1} = Y_{X=0})$). Internalization is representation change over an enlarged variable set, exactly as Level 3 is “Level 1 over the potential-outcome event space” — the informational hierarchy, defined relative to a fixed variable set, survives. ■

Derived (Result 3 — internalization re-represents, does not collapse).

Let ϕ be a $P(U)$ -preserving bijection of $\text{dom}(U)$ and let M^ϕ be the **relabeling** of M : same signature, mechanisms $f_j^\phi(pa_j, u) := f_j(pa_j, \phi(u))$ for every j . Then (i) $M \equiv_3 M^\phi$ always; and (ii) taking the latent-written replacement table $g(pa_i, u) := f_i(pa_i, \phi(u))$ and the query $q = P(V_i^{[f_i:=g]} = V_i)$,

Derived (Result 4 — genericity: every anchor-mobile SCM separates from its own relabeling).

$$q(M^\phi) = 1, \quad q(M) = 1 - \mu_\phi^i, \quad \mu_\phi^i := P\{u : f_i(pa_i(u), \phi(u)) \neq f_i(pa_i(u), u)\}, \quad (7.9)$$

so any (ϕ, i) with realized disagreement mass $\mu_\phi^i > 0$ yields an $\equiv_3$ pair separated by a latent-anchored query. Call M **anchor-mobile** when such (ϕ, i) exists and **anchor-rigid** otherwise. Every SCM with an exogenous coordinate uniform (more generally, exchangeable) over two or more values on which some mechanism genuinely depends at realized parent values is anchor-mobile via a transposition; the witness pair is the minimal instance $(\phi : u_Y \mapsto 1 \oplus u_Y)$. Anchor-rigidity is thus confined to SCMs whose noise is effectively inert or whose atom masses are fully asymmetric (admitting no nontrivial automorphism; for nonatomic noise, automorphisms always exist, so rigidity there reduces to inertness alone) — the separation is generic, not exotic.

Derivation. (i) By induction along the topological order, for every hard intervention w the solution map of M^ϕ ’s w -submodel at u equals that of M ’s at $\phi(u)$ (unreplaced mechanisms of M^ϕ evaluate M ’s at $\phi(u)$; intervened equations are the same constants in both), so the PO-tuple map satisfies $\text{PO}(M^\phi)(u) = \text{PO}(M)(\phi(u))$ pointwise, and the pushforward laws coincide because ϕ preserves $P(U)$. (ii) In M^ϕ the table g is f_i^ϕ , so the replaced world is the actual world and $q = 1$. In M , acyclicity keeps V_i ’s parents at their actual values in the replaced world, so $V_i^{[f_i:=g]}(u) = f_i(pa_i(u), \phi(u))$ against $V_i(u) = f_i(pa_i(u), u)$, giving $q(M) = 1 - \mu_\phi^i$. ■

Corollary (anchoring = choice of coordinates). M^ϕ is measure-isomorphic to M — the separated pair differ in *nothing but the parameterization of the latent space*. Latent-anchored mechanism-counterfactual content is therefore exactly commitment to coordinates on U : real content (the queries have definite, disagreeing values), invisible to all three layers, and supplied only by the committed representation.

In M_A , the separating $g(x, u_Y) = u_Y$ coincides with the PO-coordinate $Y_{x=0}$ — a PO-specification — while relative to M_B the same latent-written table reads as $Y_{x=0} \oplus 1$: a latent-written table determines a PO-specification only *relative to a model*, and $\equiv_3$ -equivalent models translate it inconsistently. The strictly-beyond-Level-3 class is therefore not “formulas mentioning u ” but replacements whose meaning is anchored to the latent parameterization itself — *hold this very background fixed and change the law over it*. Result 2 gives the exact sufficient class for reducibility (uniform PO-specifications); Result 4 shows the non-reducible remainder is generically inhabited. What remains open is the converse characterization: whether every replacement whose queries are $\equiv_3$ -invariant admits a uniform PO-specification (see Discussion).

Discussion (the boundary, and why Results 1, 2, and 4 are consistent).

Epistemic Status.

Exact. Results 1-4 are elementary, self-contained derivations under the stated assumptions (finite recursive SCMs; Result 2 additionally assumes the replacement is PO-specified). The Level-3 semantics is imported and was primary-verified against the on-disk text of [1, Defs.~2, 5, 7, 9 and Thm.~1] (ref/bareinboim-2022-pearl-hierarchy.pdf, 2026-07-16). The surgery and interventions-as-variables machinery is Pearl's, primary-verified 2026-07-16 against both the 1994 primary ([3, §2], ref/pearl_calculus_of_actions_1994.pdf: atomic interventions defined by mechanism replacement; Eq.~(3)/Fig.~1 internalization) and the second-edition text ([2, §§3.2.2, 7.2.4], read directly: Eq.~(3.7)/Fig.~3.2 with the "any change in the functional relationship" scope note; §7.2.4's local-surgery semantics — one mechanism perturbed, locality in mechanism space). Noise-dependent replacement mechanisms are included in Pearl's own construction, so the internalization used in Result 3 is literally his move and the new content is its *non-collapse* reading. What is new here (per the math-novelty discipline, stated without deflation): the strictness witness over full- $\equiv_3$ pairs, the PO-closure reducibility boundary, the genericity-via-relabeling theorem with its anchoring-as-coordinates corollary, and the non-collapse reading of internalization. Priority: a professional literature search (Undermind, 2026-07-16, estimated full coverage of the relevant population; report retained as a working aid, see Working Notes) found **no published statement or implication of the separation**, in either the two-model-witness or the exogenous-relabeling form; the nine nearest papers were then read in full against their primary text (2026-07-16) — the danger scan for a buried separation lemma (through Ibeling and Icard 2020/2023, Shpitser and Pearl 2008, Cabreros and Storey 2019, de Lara 2023, and Aliprantis 2015 as well as the three nearest below) came back empty, and the three nearest results *position* rather than anticipate it. Bongers, Peters, Schölkopf and Mooij (2016/2021, §4) introduce **exogenous reparametrization** as an operation on SCMs and prove it preserves *observational and interventional* semantics (their "causal semantics"; the general operation of which our measure-preserving ϕ is the automorphism special case, and Prop. 53's "symmetries acting on the space of SCMs" is the group-action framing Result 4 uses) — they do not treat the counterfactual layer, so the Level-3 preservation under relabeling is *our* Result 4(i) and its failure at latent-anchored mechanism counterfactuals is Result 4(ii): the operation is theirs, the layer-3 boundary of its semantics-preservation is new here. Chen and Du (2025) define **exogenous isomorphism** ($\sim_{EI}$; Def. 3.1 — a *component-wise* latent bijection $h = (h_i)$ with $P_U^{(2)} = h_{\#}P_U^{(1)}$ and mechanism isomorphism $f_i^{(2)}(v, h_i(u)) = f_i^{(1)}(v, u)$) and prove $\sim_{EI} \Rightarrow \sim_{\mathcal{L}_3}$ (Thm. 3.2), positioning $\sim_{EI}$ -identifiability as strictly stronger than complete counterfactual identifiability. The witness pair — and every component-wise relabeling of Result 4 — is exogenously isomorphic in this *exact* sense (take $h_Y = \oplus 1$, $h_X = \text{id}$), which is *stronger* than the measure-isomorphism the corollary asserts in general: so even their strongest identification target, $\sim_{EI}$, leaves latent-anchored mechanism-counterfactual answers open — the obstruction lives in the specification language, not the model class. De Lara (2025, Def. 17 / Thm. 28) characterizes the counterfactual-equivalence ($\equiv_3$) class of an SCM and disentangles its "arbitrary and unfalsifiable" counterfactual coupling from the testable interventional constraints — the same conventionality structure this segment exhibits one rung higher, over mechanism-change queries on the $\equiv_3$ -complete class; his footnote 9 explicitly routes through Chen-Du's $\sim_{EI}$, so the three nearest works form one connected cluster, none of which states the separation. Older adjacencies as previously recorded, now primary-confirmed: the underdetermination of F by counterfactuals is folklore (Aliprantis 2015's "many DGPs, same potential outcomes"; canonical response-function representations, Balke and Pearl 1994) but exhibits no query the models disagree on; Saha, Rathore and Garain 2025 claim soft interventions are "strictly more expressive," a query-language expressiveness claim whose shift-scale class is PO-specified, hence Level-3-reducible by Result 2. Result 4 replaces Result 1's bare existence with a genericity statement in the CHT's register: separation holds for every anchor-mobile SCM, with anchor-rigidity confined to inert-noise or automorphism-free-noise cases; whether the anchor-rigid remainder also separates by other constructions is subsumed in the open converse below.

Discussion.

What the separation means. Level 3 fixes the joint law of all hard-intervention worlds; it does not fix how those worlds are co-registered against *alternative laws on the same background*. Both witness models even agree on the post-replacement interventional distribution ($Y_{f_Y:=g} \sim \text{Bern}(\frac{1}{2})$ in each); the disagreement lives exclusively in the cross-world coupling between actual-law and replaced-law worlds through the shared u — content invisible to every experiment and every standard counterfactual. This licenses the hierarchy extension in precisely the CHT’s relative sense: “Level 4” quantities (latent-anchored mechanism counterfactuals) are strictly more informative than Level 3 relative to the model’s variable set, and — like every level — re-representable as lower-level over an enlarged set without that fact collapsing anything (Result 3). Result 4’s corollary sharpens what the extra content *is*: since the separated pair are relabelings of one another, latent-anchored content is exactly a commitment to coordinates on the latent space — nothing more, and (because the queries then have definite values) nothing less.

The open converse. Result 2 shows uniform PO-specifications are $\equiv_3$ -invariant; the converse — whether every replacement whose queries are invariant across the $\equiv_3$ -class admits a uniform PO-specification — is open and is the sharp remaining question about the boundary. A plausible route is an orbit-averaging argument over the relabeling group of Result 4, but invariance of a query’s *value* does not obviously yield a *pointwise* uniform representation of the specification; a counterexample would itself be informative (an invariant-but-unrepresentable replacement would name a fourth-layer quantity computable from Level 3 in value yet not in form). One exhaustive datapoint (independent verification, 2026-07-16): on the witness signature’s minimal universe (all 4096 SCMs; the 24-model $\equiv_3$ -class of M_A ; all 256 replacement tables), every $\equiv_3$ -invariant replacement — there are exactly 4 — is uniformly PO-representable, so the converse holds there; the value-vs-pointwise-form obstruction remains untouched in general.

Consequence for structural imagination. The boundary splits imagination-as-mechanism-change into *navigation* (L3-specified changes — re-wirings, new independent devices, output-shifting policies — computable from counterfactual-grade knowledge) and *positing* (latent-anchored changes — “this very situation under a different law” — whose answers no experimentable or counterfactual content determines, and which are well-defined only relative to a committed representation F among the $\equiv_3$ -class). 7.8 develops the agent-architecture consequences: the imagination workspace’s grounding tag marks, for latent-anchored content, information that observation cannot even in principle supply.

Relation to the do-operator’s special-case status. $do(X = x)$ is the constant replacement — both parent-only and latent-free — so all of Pearl’s hierarchy sits on the reducible side of Result 2’s boundary, which is why the question “is mechanism change a fourth rung?” could not be settled by inspecting the standard machinery: the standard machinery never leaves the L3-specified class.

Working Notes.

- **Provenance.** Landed 2026-07-16 from spikes/spike-causal-level-4-strictness-2026-07-16.md (commissioned same day; owed-items discharge — primary-source verification, Result 2 generalization, Result 4 — same day, recorded in the spike’s addendum), which resolves the strictness question left open by spikes/.integrated/spike-causal-level-4-formal.md (2026-03-14, Approach 1: the $do_s(f_X := g)$ operator and well-definedness, without a witness).
- **Naming caution.** Prose should say “mechanism counterfactuals separate strictly from Level 3” or “latent-anchored mechanism counterfactuals”; reserve bare “Level 4” for contexts where the relative-to-variable-set sense is already established, to avoid reading as a claim that Pearl’s hierarchy was somehow incomplete on its own terms.
- **Priority-search record.** The Undermind report (9 papers, clean miss) is at ref/layer-3-mechanism-counterfactual-sep.md — a working aid, not segment-citable; all nine are in relata with PDFs. The three nearest priors (Chen and Du 2025; Bongers et al. 2016/2021; de Lara 2025) and the six adjacencies were read in full against primary text 2026-07-16 (relata verify events recorded), discharging the ES characterizations from abstract-grade to primary-confirmed — including the one correction that mattered: Bongers prove interventional, not counterfactual, preservation, so the Level-3 preservation is Result 4(i),

not theirs. Standalone-note decision is Joseph's (ops queue); the practicals live in #disc-law-discovery-ceiling Discussion, written to lift.

7.8 Discussion: Structural Imagination — Model-Modifying Reasoning and the Scope Boundary of Directed Separation

Pearl's three levels all reason *within* a fixed structural causal model; a class of reasoning AAT's agents demonstrably perform — imagining alternative causal structures, planning actions that *change* the environment's mechanisms, and evaluating aspirational targets — operates *on the space of models* instead. This segment names that task class, locates its inferential status via the strict separation derived in 7.7 (latent-anchored mechanism counterfactuals exceed Level 3; L3-specified ones do not), locates the scope boundary of directed separation exactly at its edge — goal-blind processing is correct for within-model evidence, and goal-*directed* exploration is correct (not a failure) for model-space reasoning — and proposes the tagged-workspace structure $X_t = (M_t, G_t, W_t)$ under which the two modes coexist without contamination. Hallucination is then diagnosed as a *level-confusion* failure: an explored model promoted to M_t without grounding — a mechanism complementary to the quantitative goal-coupling displacement bound of AB.

Formal Expression.

Pearl's SCM machinery already represents mechanism replacement ([2, §7.2.4] “local surgeries”): for $M = \langle U, V, F \rangle$, define $M[f_X := g]$ by replacing one structural equation, with $do(X = x)$ the constant-function special case. An action a is **structure-modifying** with respect to the environment's causal model M when the post-action environment is described by $M' = \sigma(M, a) \neq M$ — the structural equations themselves have changed (a bridge built, a law enacted, a program written), as opposed to standard actions, which set variable values within fixed mechanisms. The corresponding planning query optimizes over model space:

Formulation (structure-modifying action; sketch).

$$a^* = \arg \max_a \mathbb{E}_{M_{t+1} \sim P(\cdot | a, M_t)} [J(M_{t+1})], \quad (7.10)$$

a task with no Level-1–3 analog: the search space is a mechanism space, not a value space, and evaluation marginalizes over the models an action could produce.

The task class is inferentially two-sided, per the exact results of 7.7. Mechanism changes *specified over Level-3-exposed channels* (re-wirings of parents, independent new devices, output-shifting policies) are Level-3-computable: an agent with counterfactual-grade knowledge can evaluate them without further commitment. Mechanism changes *anchored to the latent background* — “this very situation under a different law” — separate strictly from Level 3: two models agreeing on every associational, interventional, and counterfactual quantity can disagree maximally on them, so their answers are underdetermined by all experimentable content and exist only relative to a committed structural representation. On top of that informational distinction, the task class remains *computationally and cognitively* distinct (mechanism-space search, no analog of the do-calculus for identification, inseparability of model identification from inference when actions modify the model), and it is precisely the reasoning mode AAT's structural-adaptation machinery (4.8, 2.4) presupposes an agent can perform.

Discussion — inferential status; separation derived at #deriv-mechanism-counterfactual-separation.

The complete agent state extends to $X_t = (M_t, G_t, W_t)$, where W_t is the **imagination workspace**: the set of currently-explored alternative models (candidate structures, aspirational futures, hypothetical mechanism changes), explicitly tagged as ungrounded. Directed separation (6.3) holds for M_t by definition of what M_t is — evidence-processing remains goal-blind — and *correctly fails* for W_t : which alternative structures to explore is inherently goal-directed, and

that coupling is the productive core of planning, construction, and aspiration rather than a leak to be bounded. Falsification handle: an architecture that maintains the tag (grounded vs explored) should show the bias-bound pathologies of goal coupling only in its W_t -to- M_t promotion step, not in its M_t updates.

Hypothesis (tagged workspace).

Maintaining an infeasible aspirational objective can dominate feasible targets by the feasible objective's own measure — see the aspiration hypothesis landed in 8.4's Discussion, which modifies the reading of "objective revision is the last resort."

Hypothesis (aspiration; formal statement at #def-satisfaction-gap).

Epistemic Status.

Discussion-grade throughout; nothing here is derived. The structure-modifying action formulation is a sketch on Pearl's own machinery (imported: Pearl 2009 §7.2.4; hierarchy strictness Bareinboim et al. 2022 — both already recapitulated in 7.1); the planning query is a formulation; the W_t workspace and the level-confusion diagnosis of hallucination are hypotheses with a stated falsification handle; the hierarchy status of the task class is settled and *exact* at 7.7 (strict separation for latent-anchored mechanism counterfactuals; Level-3 reducibility for L3-specified ones; internalization as re-representation, not collapse). The typing of what $\sigma(M, a)$ acts on interacts directly with the epistemic-target-ontology decision (PROPOSALS SP-30: $S_t = (\Omega_t, \theta)$ gives law-content its own slot, and a structure-modifying action is then an action on world-side θ) — the vocabulary here is stated in current canon terms and should be re-typed when SP-30 is decided. Adjacent external literature (causal abstraction: Beckers & Halpern; Rubenstein et al.; transportability: Bareinboim & Pearl) is flagged for a relata pass before this segment advances past draft.

Discussion.

Where directed separation's scope boundary actually sits. 6.3 already distinguishes goal-directed event *selection* (legitimate) from goal-blind event *processing* (the invariant). This segment adds a third distinction on the *content* axis: processing that updates the grounded model M_t (goal-blind, Levels 1–3) versus reasoning that explores ungrounded alternatives W_t (goal-directed, structure-modifying). The κ problem for merged architectures then reframes: the issue is not the amount of goal-coupling but **cross-contamination between two modes that individually have correct, opposite coupling disciplines** — an LLM's context window holds grounded belief and explored hypothesis in the same representation with no tag, so Level-4-appropriate coupling bleeds into Level-1–3 processing. Keeping the modes distinct is a design problem, not a parameter-tuning problem.

Hallucination as level confusion — complementary to the bias bound. Canon's quantitative hallucination treatment (AB and its NeurIPS Paper 3 sharpening) bounds the displacement of M_t updates under goal coupling — a *drift* mechanism. The level-confusion diagnosis names a different failure: a W_t element (imagined structure, hypothetical world) promoted to M_t status without grounding — a *mis-typing* mechanism. The two are complementary: drift corrupts the grounded model gradually through coupled processing; promotion corrupts it discretely through a missing tag. The light side of the same machinery is imagination — the tag maintained, exploration goal-directed, promotion gated on evidence.

Relation to structural adaptation. 4.8 establishes when parametric updates within the current model class must give way to structural change, treating the event discretely. Structural imagination is the *capability* that responding to that event presupposes: generating and evaluating candidate structures is model-space reasoning. A continuous structural-adequacy mismatch ($\delta_{\text{structural}}$, sitting between epistemic update and feasibility evaluation in the orient cascade) was sketched in the originating spike and is deliberately *not* landed here — it needs its own derivation of measurability before it earns a mismatch-family slot.

Working Notes.

- **Provenance.** Landed 2026-07-16 from spikes/.integrated/spike-causal-level-4.md + spike-causal-level-4-formal.md (2026-03-13/14, Joseph's aphorism-prompted overnight cluster) via the bulk-64 verification queue; the strictness question those spikes left open was resolved the same day by spikes/spike-causal-level-4-strictness-2026-07-16.md, landed as 7.7.
- **SP-30 interaction (re-type on decision).** If $S_t = (\Omega_t, \theta)$ is adopted, restate: a structure-modifying action is an intervention on world-side θ ; W_t explores candidate θ -content; the grounded/explored distinction becomes a typing on the agent's θ -beliefs. If state-only Ω is kept, the current phrasing stands.
- **Relata pass owed** before promotion: Beckers & Halpern (causal abstraction), Rubenstein et al., Bareinboim & Pearl transportability, and the mental-simulation/prospection literature the spike gestured at — none load-bearing for the discussion-grade claims, all needed for honest Related-Work grounding.
- $\delta_{\text{structural}}$ (fifth mismatch type) deliberately withheld — see Discussion; a future spike would need to derive what makes structural inadequacy *measurable* as a continuous signal before the cascade gains a slot.

7.9 Discussion: The Law-Discovery Ceiling — Conventionality, Positing, and Exogenous Intervention for Embedded Agents

The strict separation of 7.7, read from the agent's side, becomes a statement about what embedded agents can and cannot learn of their world's laws: counterfactually-complete inquiry converges to a Level-3 equivalence class of models, never to the law itself, and the surplus — the structural functions and the coordinatization of the exogenous background — is generically underdetermined by all experimentable content. This segment develops the agentic consequences: the ceiling as a candidate instance of the identifiability-floor pattern at the top of the causal hierarchy; the *conventionality license* (within the equivalence class, commitment to a provisional law is rationally free for all navigation purposes, so the honest selection criteria are compression, tempo, and communicability); the *positing regress* (achievable mechanism-change is navigation one level down, so irreducible positing coincides with the boundary of empiricism); a three-kind taxonomy of exogenous intervention with distinct in-world visibility signatures; and the *testimony channel* — the one remaining channel type by which an inside agent could hold true rather than merely committed positing-content. Throughout, claims marked *derived* inherit exactness from 7.7; everything else is discussion-grade reading, and the whole segment carries the standing caveat that it operates inside the structural-causal-model frame — reading a natural environment as an SCM is itself a modeling commitment, so every claim below is conditional on that frame applying.

*Formal Expression.***The ceiling.**

Let an agent's inquiry converge, in the limit of unbounded observation, intervention, and counterfactual inference, to the complete Level-3 characterization of its environment. By the separation theorem this limit determines only the $\equiv_3$ -equivalence class: models agreeing on every associational, interventional, and counterfactual quantity may still differ on latent-anchored mechanism-counterfactual queries, and by the genericity result (Result 4 there) essentially every environment model with genuine stochasticity differs from its own exogenous relabeling in exactly this way. **World-law discovery via the causal hierarchy therefore has a proven ceiling:** its asymptote is an equivalence class, and membership in the class exhausts what any experiment-driven process can establish. The residue — which structural decomposition, which coordinatization of the background — is not a further fact awaiting better instruments; it is unreachable in principle by the agent's channel types.

Derived (at #deriv-mechanism-counterfactual-separation); agentic restatement.

In AAT's cross-sectional vocabulary this is a candidate instance of the identifiability-floor pattern (5.1) sitting at the top of the causal hierarchy rather than inside any estimation problem: information (mechanism identity beyond $\equiv_3$) that no channel available to the embedded agent can recover, with the characteristic floor structure of an exactly-described unrecoverable residue and named escapes. The escapes here are structural rather than statistical: authored access (the agent holds the coordinatization because it built the system — see AW) and testimony (below). Promotion to the M1 instance catalog would require the full F-catalog treatment and is deliberately not claimed here.

Discussion — candidate floor instance.

The conventionality license.

Every query the agent needs for acting in the world as it stands — prediction, intervention planning, policy evaluation, regret — is Level-3 content, invariant across the class. Hence two agents committed to different provisional laws with identical $\mathcal{L}_3$ -content act identically on every realizable task: **within the equivalence class, commitment is fitness-free for navigation**. Two consequences follow. First, the honest selection criteria for a provisional law are engineering criteria — description length, inferential tempo, communicability — because truth does not adjudicate within the class; parsimony here is not a metaphysical wager but the correct optimization of a genuinely free choice. Second, the class boundary supplies a **disagreement-hygiene test**: a dispute between two committed models is *convictable* when their $\mathcal{L}_3$ -contents differ (an experiment can pay off) and *conventional* when they coincide (no experiment can ever pay off, and the honest resolution is an explicit coordinate choice). The PO-closure result gives the working form of the test: if the disputed content is expressible as a uniform PO-specification, it is on the convictable side.

Derived consequence + Discussion.

The posing regress.

Distinguish, per 7.8, *navigation* (mechanism changes specified over Level-3-exposed channels — evaluable from counterfactual-grade knowledge) from *posing* (changes anchored to the actual latent background — representation-committed). For an embedded agent, every **achievable** mechanism change is navigation one level down: damming a river, rewiring a circuit, amending a constitution are interventions in a finer-grained model in which the coarser model's "law" is configuration. Mechanism-change at level k is value-setting at level $k + 1$; the internalization result is this regress's formal engine. The regress terminates only at the environment's ultimate laws, where no finer level is available to the agent — and that terminus is exactly where the ceiling says experimentable content gives out. **The boundary of irreducible posing coincides with the boundary of empiricism**. One corollary worth stating plainly: whether an environment's randomness is *true* or *fated* (a deterministic function of hidden coordinates, as in an authored world's keyed noise) is itself a posing-class question — any fated coordinatization reproducing the same $\mathcal{L}_3$ -content is a relabeling in the theorem's sense — which is why that question remains permanently open from inside. (The scope is exact $\equiv_3$ -equivalence: accounts that alter testable content, as local hidden-variable theories do under Bell-type constraints, are convictable in the ordinary way and outside the class.)

Formulation.

Exogenous intervention — three kinds, three visibility signatures.

Suppose the environment admits an author — an agent holding the latent coordinatization, of which the authored-world case (AW) is the constructive existence proof. Author action decomposes into three kinds with strictly ordered in-world visibility:

Formulation.

Table 7.3

<i>Kind</i>	<i>Author-side operation</i>	<i>In-world visibility signature</i>
Selection	Choose among law-consistent worlds (rejection sampling against a predicate)	None, in principle: every world in the support is fully law-consistent; no inquiry at any hierarchy level distinguishes a selected world from an unselected one
Value-setting intervention	Set variable values mid-history	<i>Registerable</i> as anomaly (broken learned statistics, violated conservation checks) but <i>unidentifiable in kind</i> : any intervention history is re-representable as ordinary law of an enlarged model, and the enlargement is not a functional of $\mathcal{L}_3$ -content — the intervention-reading and the bigger-law-reading are coordinatizations of the same experimentable content
Mechanism replacement (latent-anchored)	Change a law mid-history holding the actual background fixed	Effects may be arbitrarily visible; the event's <i>identity</i> — same background, new law, versus different background, versus larger law throughout — is latent-anchored content the inside agent provably cannot resolve

The middle row is a sharpening of the classical epistemology of miracles from an evidentiary difficulty into an identifiability statement: it is not that testimony for an intervention is weak evidence, but that even counterfactually-complete evidence cannot force the intervention-reading over the enlarged-law-reading. An honest agent in a possibly-authored environment therefore carries a model with an **intervention-selector slot whose semantics it cannot pin** — natural variable, author-channel, or absent — and holding that slot open is the exact truth of its situation rather than indecision. The commitment it makes about the slot is free relative to all possible data yet consequential for its positing-grade reasoning.

Discussion.

The testimony channel.

The ceiling characterizes a content class that exists (the author-side surplus), matters (it answers the positing query class, including the identity of Kind-2/3 events and the fated-randomness question), and is unreachable by every empirical channel. If an inside agent is to hold *true* rather than merely *committed* positing-content, exactly one channel type remains: **testimony from a holder of the coordinatization**. Two structural corollaries: (i) verification of testified positing-content cannot be empirical — by construction — so it is either relational (trust in the source) or *transferred*, when the testimony bundles convictable $\mathcal{L}_3$ -content whose success lends credibility to the unconvictable remainder; (ii) *communication through the anomaly stream is representation-independent* — an intervention pattern can carry a message whose content is Layer-1-observable, so reception and decoding work without settling what the channel is; only the interpretation of the channel's nature requires the commitment.

Discussion.

Epistemic Status.

Discussion-grade throughout, resting on one exact result. The ceiling and the fitness-invariance underlying the conventionality license are direct restatements of 7.7 (exact; including genericity via Result 4 and the safe query class via the PO-closure); the floor-instance identification is a candidate classification, not a derived catalog entry; the positing regress, the intervention taxonomy, the selector slot, and the testimony channel are formulations and readings — structurally forced given the frame, but carrying no independent derivations. The standing frame caveat is load-bearing: all claims are internal to finite-SCM semantics, and applying them to a natural environment presupposes the causal-model

reading of that environment, which no result here establishes. Max attainable: the ceiling restatement and conventionality license inherit *exact* through the depends chain; the taxonomy could reach *conditional* with a formal treatment of author-action semantics; the testimony corollaries are ceiling-limited to discussion-grade absent a formal account of trust transfer.

Discussion.

Practical consequences — one skeleton, many fields. [Discussion — readings of the exact result into other fields’ practice; each is a recommendation, not a derived result in that field’s own formalism] Wherever a “replay this history under a changed mechanism” query is evaluated with a model validated only behaviorally, the answer is convention unless the change is PO-specifiable or the parameterization is held white-box. Instances: (i) **model editing / checkpoint surgery** — behaviorally equivalent model checkpoints (all benchmarks, all counterfactual probes) can diverge under the same weight-level edit, so behavioral test batteries cannot certify edit-safety in principle; (ii) **self-modification** — an agent planning edits to its own mechanisms from a behaviorally-validated self-model is in the unsafe class: behavioral self-knowledge, however complete, cannot determine self-edit outcomes, so safe self-modification requires author-grade self-access rather than excellent self-prediction (the logogenic-volume consequence; forward pointer in Working Notes); (iii) **off-policy evaluation and backtesting** — model-based replay of history under a changed strategy holding realized shocks fixed is latent-anchored and representation-committed, while propensity-weighted (PO-specified) evaluation is model-robust, and the gap survives unlimited data; (iv) **digital twins and black-box certification** — fit quality licenses only the PO-specified query class; mechanism-change predictions require mechanism-level provenance; (v) **dispute triage** — before funding an experiment or convening a committee, run the hygiene test above: coordinate-choice disputes cannot be paid off by any experiment, and a proposed policy is model-robust exactly when expressible in PO-specified form; (vi) **counterfactual tests in explanation and law** — but-for (input) counterfactuals are PO-specified and model-robust; mechanism-counterfactuals (“had the decision-rule been different, in these very circumstances”) encode a modeling convention unless rephrased; (vii) **mechanism-swap under shared randomness in software** — landed as a design recommendation in #obs-software-epistemic-properties’s Discussion, where the domain machinery lives.

Why agents build authored worlds. The regress plus the ceiling jointly predict a behavioral signature: agents denied fourth-layer access to their substrate construct enclaves where they hold it — software, formal systems, institutions, simulations — since within an authored patch the coordinatization exists and is held, making positing queries executable (AW). On this reading the drive to build such enclaves is not incidental tooling but the acquisition of the one query class the natural substrate denies.

Commitment as constitution. The conventionality license reframes the decisive-agent’s situation: committing to provisional law under law-ignorance is not a regrettable compromise forced by bounded capability — even the experimentally omniscient agent must commit to reason about law-change at all. Commitments in the surplus class *constitute* the agent’s reasoning frame rather than *constrain* its predictions, which is why they are properly evaluated by the engineering criteria above and properly held with the revisability appropriate to conventions. A further register of this reading — the surplus as deliberate epistemic structure in a created world, where the unknowability is constitutive of the inhabitants’ situation rather than a defect of it (Joseph, 2026-07-16: “*We did not come here to prove God or challenge him to prove himself to us... We came here to prove ourselves given certain unknowabilities*”) — is flagged forward to the language-living volume (04-eli-core), where it belongs to the authoring voice; this segment carries only the structural result that such a reading is *consistent*: the theorem supplies exactly the geometry in which world-data permanently underdetermines the author question while leaving the testimony and anomaly-stream channels open.

Working Notes.

- **Provenance.** Developed dialogically with Joseph 2026-07-16 (natural-universe premise → exogenous-intervention/revelation exchange → practical-implications pass), immediately following the same-day landing of 7.7; this segment is the canon carrier of that conversation’s structural content.

- **Forward pointer (live).** The self-modification consequence has its dedicated treatment in 03-llm-core at #hyp-behavioral-self-knowledge-insufficiency (exploratory): behavioral self-models cannot certify self-edits; the 13.4 interaction (the wrapper is author-side relative to the wrapped component) is developed there as the wrapping-hierarchy safety stratification.
- **Floor-catalog candidacy.** Promotion of the ceiling to a numbered M1 instance needs the F-catalog schema treatment in 5.1 (a matching WN pointer left there); not claimed at this tier.
- **Relata pass owed before promotion:** conventionalism/underdetermination literature (Poincaré, Quine-Duhem, and the modern empirical-equivalence debates), the miracles/identifiability literature if any formal treatments exist, and the OPE (importance-sampling vs model-based) literature for consequence (iii) — none load-bearing for discussion-grade, all needed for honest Related Work.
- **Standalone-paper feed.** Consequences (i)-(iv) are the practicals that would convert the separation note from a foundations curiosity into a working impossibility result; the Undermind novelty search (running 2026-07-16) should inform whether they are claimed there or cited to existing field-internal statements.

7.10 Discussion: Additional Implications & Discussion

The chapter’s central architectural move — that the feedback loop produces Pearl-Level-2 data by construction — has consequences that recur across the rest of the framework, and at least one negative finding of substantial scope that does not become statable until the chapter’s machinery is in hand. What the loop *is* causally, where the same interventional pattern shows up at the composite layer, what kinds of pre-deployment evaluation methods structurally cannot identify deployment behavior, and how the chapter’s cost-benefit framing for explicit strategy grounds in Part I’s persistence condition are the things worth pulling out before leaving Part II Ch.2.

The loop is a Pearl-Level-2 engine.

The chapter’s load-bearing contribution is structural: the adaptive cycle is itself a Pearl-Level-2 data engine. An agent that acts and observes the consequences is not collecting passive observations of a system that happened to do something; the agent’s action a_t caused o_{t+1} , and the pair (a_t, o_{t+1}) is interventional in character. Bareinboim’s causal hierarchy theorem (Bareinboim-Correa-Ibeling-Icard 2022) says Level-2 quantities cannot in general be computed from Level-1 data. The loop is where the gap closes — the data substrate Level-2 reasoning requires comes from the cycle the agent was already running for adaptation. Purposeful agents do not need a separate causal-inference module; the cycle produces the substrate as a by-product.

The interventional character is not a property of any architectural feature of the agent; it is a property of the action being the agent’s own causally-efficacious move (7.3). The *do*-operator’s semantics is population-level and does not require a non-forkable trajectory; what the singular-trajectory scope from Part I Ch.4 (4.10) supplies is narrower and still essential — it grounds *whose* effect a loop datum is the effect of, and forbids averaging interventional responses across forked copies as though they were one agent’s. This is why a Q-learning agent without an explicit causal model can still converge toward $\mathbb{E}[R \mid s, do(a)]$ rather than $\mathbb{E}[R \mid s, A = a]$ in the tabular case with sufficient exploration and no within-step confounding — the training data is the agent’s own interventions, by construction. The chapter intro 7 develops the bidirectional confounding analysis (when does this break, and why is the *positive* confounded outcome the harder failure mode to escape than the negative one) in detail; the implication worth carrying forward is that the loop produces interventional data even where clean identification requires additional structural conditions.

For practitioners, the engineering anchor worth carrying is the asymmetry between training data and deployment data. Most ML is trained on observational corpora (Level 1) or on offline RL traces with known confounding structure (mixed Level 1/2). An agent in deployment, by virtue of being in the loop, generates action-coupled data that is interventional *in character* — Level-2 data “for free” in the weak sense the chapter is careful about: the channel is free, but turning that data into identified $P(o \mid do(a))$ estimates still needs positivity, sequential ignorability, and a known action-mechanism (the (C1)/(C2)/(C3) gate below). The framework’s discovery is that this channel is *load-bearing*,

not incidental: AAT’s downstream results about action selection, strategy revision, and causal-structure detection rest on the loop’s data substrate being interventional in character, and degrade specifically when something breaks the trajectory’s singularity.

The result is also where AAT parts company with the active-inference / control-as-inference / free-energy-principle family in a structural rather than parametric way. Those frameworks derive agent behavior from observational learning — Bayesian-network generative models at Pearl Level 1 — and have no native handle on Level 2 outside auxiliary mechanisms. AAT’s claim is conservative in form (data is interventional *in character*, not “the agent has cleanly identified causal estimates”) but structurally distinctive: the loop’s data lives at Level 2, and the framework’s results consume that fact. The careful split between data character and identification quality (the regime A/B/C decomposition in 7.4, the intro’s variable-ratio-reinforcement / gambling-addiction structure for confounded positive feedback) is what makes the conservative-form claim honest rather than overreach.

NeurIPS Paper 2’s formalization of this claim under the (C1) / (C2) / (C3) triple — positivity, sequential ignorability, known action-mechanism — is the theorem-grade version of the chapter’s structural argument. (C2) is the load-bearing condition: a_t must be d-separated from o_{t+1} given history H_t in mutilated-graph form. Goal-conditioned LLM policies violate (C2) by construction — the goal influences action through the same forward pass that models the observation, breaking the conditional independence required for sequential ignorability. This is the bridge to Class 3 (Coupled) treatment in 03-llm-core/ and to NeurIPS Paper 3’s universal-constant route on the hallucination bias bound. The chapter’s structural argument and the papers’ formal theorems are the same content at two grain sizes; the chapter is where the structural argument lives, and the papers’ load-bearing structural commitments are the chapter’s scope condition.

The sandbox hard ceiling.

A negative finding of substantial scope follows directly from the previous section: sandboxed evaluation is forkable by design (resettable, replayable, parallelizable) — which is exactly what makes a sandbox a *good* interventional laboratory, because forcing an action and observing the response yields genuine Level-2 evidence *about the sandbox*. The ceiling is not the sandbox’s data type but its *external validity*: sandbox interventions identify *sandbox* causal behavior, and whether that behavior transfers to deployment is governed by the selection diagram between the sandbox causal system and the deployment causal system (Bareinboim & Pearl 2014). When the two differ at mechanisms on the relevant paths, the deployment intervention-response is *not transportable* from sandbox data alone, regardless of evaluation thoroughness; deployment claims then require a transport assumption (mechanism invariance across the selection diagram) or deployment-time data. The empirical pattern this names — “alignment evaluations don’t predict deployment behavior” — thereby gets a *structural* mechanism (a transportability / external-validity ceiling, not a measurement-quality or coverage gap), together with its constructive positive content: effects through mechanisms invariant across the selection diagram are sandbox-evaluable (Level-1 *and* Level-2 alike); effects through differing mechanisms are not, which is what makes deployment-time monitoring structurally non-substitutable rather than a redundant layer (the downstream IDT / sidecar-monitoring treatment, with the bi-predictability anchor at 89% vs 44% detection accuracy, is in 7.2’s Discussion).

This chapter is where the result’s prerequisites — the loop-Level-2 result and the sandbox/deployment selection diagram — first coincide. Because it is consequential enough to stand on its own, and because a competent reader would otherwise assume the framework simply missed it, its full statement and the no-go live at F (Appendix A), alongside the other constructive-impossibility no-gos (5.6).

One pattern, multiple deployment modes.

The interventional-access result has a generalization that lives in the meta-architecture rather than in any single chapter. Across #disc-identifiability-floor’s multiple instances, *loop-interventional access provides the unique broadly-available escape from an observational-equivalence no-go* — but the specific interventional quantity varies by layer. The shared structure is Pearl-*do*-via-loop; the deployment mode differs.

Two modes are explicit already. **Agent-self-intervention** (this chapter's content): the agent performs *do*-actions on its own action space as part of the adaptive cycle. The intervention is on the agent's own action; the target is the environment's response. This is the mode that supplies the Level-2 substrate underlying #der-causal-insufficiency-detection's no-go and its single broadly-available escape — joint sibling observability under exploration breaks the on-policy observational-equivalence the no-go imposes. **Observer-on-sub-agent** (Part III's contribution): an observer external to a composite performs *do*-interventions on one sub-agent's action space; the target is another sub-agent's mismatch-trajectory response. The intervention quantity is the cross-coupling sign that component marginals leave unidentifiable (Liberzon 2003 common-Lyapunov-nonexistence as the no-go; the closed-form composite critical-mass result as the escape under matched-Tier conditions).

A third mode is under triage — *observer-on-agent-input*, at the architecture-within-behavior-class layer — and there may be more as the meta-pattern grows. What makes the pattern worth surfacing here rather than only in #disc-identifiability-floor itself is the chapter's role as the agent-internal anchor: Mode 1 originates here, and the others are recognizable as variations of the same structural move. The unification is at the pattern level (Pearl-*do* as escape from observational-equivalence no-goes), with the specific interventional quantity differing per layer.

The composite-layer mode is where Part III's signed-coupling decomposition becomes load-bearing rather than a structural choice. Interventional access via the loop at the composite level is what makes cooperative-vs-adversarial coupling identifiable; without it, the signs are observationally indistinguishable, and persistence-at-the-composite-level becomes a quantity the framework can describe but not identify from component data alone. The chapter's central result is the agent-level instance of what becomes a multi-layer structural commitment — and the framework's posture of *naming an information-theoretic floor, then naming the unique broadly-available escape via AAT machinery* is what makes the floors load-bearing rather than discouraging.

Cost, calibration, and the bridge into Strategy Dynamics.

The chapter closes with #norm-explicit-strategy-condition and a cost-benefit framing that is normative rather than derived: an agent benefits from maintaining explicit Σ_t when $C_{\text{plan}} + C_{\text{maintain}} < C_{\text{explore}} + C_{\text{repair}}$. The grounding worth carrying forward is that this normative criterion is downstream of Part I Ch.4's persistence condition, not an independent design preference. Approaches that consume less tempo budget leave more margin above the persistence threshold; the cost inequality operationalizes that margin into a planning-vs-exploration tradeoff. The normative element is the preference for maintaining persistence margin, which is hard to argue against because the alternative is structural degradation.

The cost framing also points at a tractability constraint that bites hard for LLM agents. Part of C_{maintain} is the cognitive cost of keeping Σ_t in the agent's representational capacity — for an LLM, fitting the strategy in the context window. A large strategy DAG may exceed this capacity, making the left side of the inequality large enough that simpler strategies (or pure exploration) become preferable despite higher exploration costs. This is the same structural fact that Part I Ch.4's bandwidth-as-first-class-prerequisite surfaces in a different vocabulary; the persistence-bandwidth-floor and the strategy-complexity-bound are the same constraint at different layers.

The chapter is also where the three-way exploit / explore / deliberate refinement first becomes formally well-posed. Once the loop's Level-2 access is in hand, deliberation can be characterized as *internal exploration in model space rather than environment space* — Pearl-*do* in simulation rather than in the agent's trajectory. The full treatment lives in Part II Ch.5 (the orient cascade); this chapter establishes the data substrate that makes deliberation a meaningful third mode rather than a verbal distinction.

The widest downstream bite of the chapter's central result is in Part II Ch.4 (Strategy Dynamics), where #der-causal-insufficiency-detection becomes statable: on-policy L0 insufficiency is *structurally undetectable*, and the loop's interventional access — applied through joint sibling observability under exploration — is the unique broadly-available violation of the no-go. The Ch.4 no-go (self-diagnosis is structurally impossible under policy-perfect execution) and

this chapter's central enabling result are duals: the no-go names what the loop's Level-2 access uniquely escapes. Read the two chapters together and the identifiability-floor pattern's first instance comes into view in full.

What Part II Ch.2 closes on, then, is the substrate. Purposeful action requires Level-2 data; the loop produces Level-2 data on singular trajectories; the data is interventional in character even when clean identification requires more; and the same Pearl-*do* structure recurs across multiple deployment modes as the meta-architecture develops. Chapter 3's strategy machinery and Chapter 4's strategy dynamics are what AAT does with that substrate; the closing scope of this chapter is what they will all stand on.

Working Notes.

- This segment is a chapter-end discussion grouping findings from 7.3, 7.2, 7.4, 7.6, and 4.10 (the Part I Ch.4 scope on which the loop-Level-2 result rests). The cross-layer pattern in §3 cross-references 5.1's meta-segment, which carries the canonical instance table. Each finding's load-bearing math lives in its home segment; this segment surfaces what the chapter unlocks as a chapter.
- **Cross-reference vs canonical-home policy.** No source segment in this chapter carries a ## Findings section. The chapter intro 7 already covers the data-character vs identification-quality nuance, the tragedy-of-agency-in-a-confounded-world framing, and the variable-ratio reinforcement / gambling-addiction structure with substantial depth — this segment does not re-state that content. The implications worth surfacing beyond the intro are the loop-Level-2 result's downstream consequences (RL theory at NeurIPS-paper grade, AI evaluation methodology, identifiability-floor pattern at multiple layers, cost-benefit substrate for explicit strategy) and the negative finding (sandbox hard ceiling) that the chapter establishes but is not yet stated explicitly anywhere.
- **Sandbox hard ceiling — promoted 2026-05-28.** The sandbox-hard-ceiling content now has its own ## Findings-bearing home at F (Appendix A), per PROPOSALS SP-25 / audit-773921 Finding 4. The open placement question recorded here (new Appendix-A segment vs. extension of #scope-agent-identity's Discussion) resolved toward the dedicated Appendix-A segment, alongside the other constructive-impossibility no-gos. This chapter retains the brief mention above (what the chapter unlocks) and points to the canonical home.
- **Connection to NeurIPS submissions.** The chapter's central result is formalized at theorem grade in NeurIPS 2026 Paper 2 (~/src/neurips/02-unified-convergence-rl/, §5 Lemma 5.3 / #lem-loop-level2) under the (C1)/(C2)/(C3) triple. Paper 3 (~/src/neurips/03-llm-hallucinate-bound/) is the Class 3 (Coupled) bridge — goal-conditioned LLM policies violate (C2) by construction. Cross-references to these formal forms appear in 7.3's Working Notes; this segment treats the structural content rather than the theorem statement.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** dedicated reflections at 526815 and 773921 (this is a chapter-end synthesis segment, so fewer dirs reached a dedicated reflection on it). As a chapter-end implications segment it already absorbs most of its own gold; what follows is the residue plus one substantive conflict worth flagging. Substrate attribution inferred from voice where not explicit; uncertain cases hedged. *Resolved 2026-05-30:* the structural challenge to the sandbox-hard-ceiling argument (forkability $\neq$ Level-1) was carried through the strengthen-first spike spikes/.integrated/spike-causal-access-transportability-2026-05-30.md and is now integrated — the “sandbox hard ceiling” subsection above is reframed from a Pearl-level demotion to a transportability / external-validity ceiling (Bareinboim & Pearl 2014 selection diagrams). The follow-up / reader-question / figure items below that this challenge subsumes are updated in place.

1. Candidate Brief prose / pre-prose.

- The sandbox ceiling as a one-line governance result: *“AI safety guarantees cannot be certified entirely pre-deployment; robust continuous runtime monitoring (Hafez's IDT) is a mathematical necessity”* (Claude, AUDIT-WORKING-773921). Brief-grade framing of the chapter's negative finding for an AI-governance audience. *(The companion “testing (L1) vs deploying (L2)” gloss this note originally paired with that line is retracted as of the 2026-05-30 re-grounding — the ceiling is external*

validity across the sandbox/deployment selection diagram, not a Pearl-level difference; the governance takeaway is unchanged and if anything sharper.)

2. Candidate Discussion.

- **The sandbox hard ceiling as a high-severity, industry-relevant finding.** One substrate rated it “*a finding of such magnitude that it absolutely warrants the dedicated segment*” and the best instance of AAT’s constructive-impossibility posture “*yielding a practical, industry-relevant result*” — “*a formal mathematical reason why offline safety evals often fail to predict jailbreaks in production*” (Claude, AUDIT-WORKING-773921). Since the no-go now has its dedicated home at #disc-sandbox-evaluation-ceiling, this is a signal for how to *frame* it (AI-governance contribution), not a placement question.
- **Self-diagnosis impossibility as the dual worth foregrounding.** The Ch.4 preview (#der-causal-insufficiency-detection) read as “*an agent that never deviates from its optimal policy can never know if its optimal policy is actually correct, because it stops generating interventional contrasts — it must inject noise (exploration) to maintain its causal grip on reality*” (Claude, AUDIT-WORKING-773921). The body already names the no-go/enabling-result duality; the gold is the crisp plain-language statement of *why* policy-perfect execution is self-blinding.

3. Follow-up items.

- **~~The sandbox-ceiling argument needs its Pearl-semantics premise stated very carefully.~~ Resolved 2026-05-30** (transportability spike). The auditor’s reading was correct and is now the canonical framing in both the “sandbox hard ceiling” subsection above and #disc-sandbox-evaluation-ceiling: sandbox interventions identify sandbox causal behavior; the real limitation is **transportability / external validity** (sandbox SCM $\neq$ deployment SCM), and “*forkability is not what makes data Level-1*” — verified false against CHT Def. 5 / footnote 19. The original note (Codex/Claude, AUDIT-WORKING-526815): a defensible version is “*deployment claims require transport assumptions or deployment-time monitoring because the deployment causal system may differ.*”
- **~~Keep the weaker “for free” phrasing even in summary.~~ Resolved 2026-05-30** (transportability spike). The “for free” wrap-up above now carries the (C1)/(C2)/(C3) gate inline (the channel is free; identified *do*-estimates still need positivity / ignorability / known-mechanism), preserving the data-character-vs-identification split rather than letting “Level-2 data for free” stand unqualified. Original note (Codex/Claude, AUDIT-WORKING-526815).
- **Separate AAT-local claims from NeurIPS-back-integration claims in the final cut.** The (C1)/(C2)/(C3) formalization and the active-inference / control-as-inference contrast are doing real work in this discussion but reference content outside the read AAT segment set; a final audit should keep the boundary between AAT-canon and paper-back-integration visible (Codex/Claude, AUDIT-WORKING-526815).

4. Readers often ask / wonder.

- **~~If sandboxes are forkable and therefore (per the chapter) Level-1, why are repeatable laboratory experiments a text-book source of Level-2 data?~~ Resolved 2026-05-30** (transportability spike): the tension the question identified was a real defect, now removed. The chapter no longer says forkable $\Rightarrow$ Level-1; it says forkability is what makes the sandbox a *good* Level-2 laboratory (exactly as RCTs/A/B tests are), and the ceiling is transport to deployment across the selection diagram. The original note (Codex/Claude, AUDIT-WORKING-526815) correctly diagnosed that “*the honest answer the chapter is reaching for is about transport to the deployment trajectory, not about the sandbox data being merely associational.*”

5. Candidate figures.

- **Two-causal-systems transport diagram for the sandbox ceiling.** Sandbox SCM and deployment SCM side by side — *both* can contain interventions — with the missing piece drawn as a *transport bridge / invariance claim / deployment monitor*, rather than depicting a Pearl-level difference caused by forkability (Codex/Claude, AUDIT-WORKING-526815, has a rendered draft). (*This figure now matches the landed framing — the 2026-05-30 transportability re-grounding kept exactly the selection-diagram / transport-bridge picture this figure encodes; strong figure candidate for #disc-sandbox-evaluation-ceiling.*)

Belongs elsewhere.

- The active-inference / control-as-inference structural contrast is positioning language broad enough that, if it becomes a finding, it needs citation-level care; treated as positioning here, its canonical home is #der-loop-interventional-access's honest-credit passage (Codex/Claude, AUDIT-WORKING-526815).
-

Chapter 8

Strategy Structure and the Diagnostic Split

We commit to a formal representation for strategy — a probabilistic causal DAG with AND/OR semantics and single-parameter edges — and develop the headline diagnostic that lives on top of it: the satisfaction gap and control regret as orthogonal signals that distinguish “the goal is hard” from “the strategy is weak.”

An agent with a goal needs more than a model of reality. It needs a theory of how its own actions produce progress toward the goal — which steps depend on which, which alternatives are available, where the uncertainty lives. Chapter 3 makes that theory formal.

Chapter 2 answered the prerequisite questions: planning requires Level-2 causal access (7.2); the feedback loop supplies it (7.3); explicit strategy is worth maintaining when the cost-benefit favors it (7.6). None of that tells us what a strategy *is*, formally. Chapter 3 commits.

The commitment is more constrained than it might look. We don’t choose acyclicity — it falls out of temporal ordering. Strategy nodes are propositions about future events, events have positions in time, and time has a direction, so the graph cannot have cycles. We don’t choose the Markov property either — given causal sufficiency, the Causal Markov Condition theorem (Spirtes–Glymour–Scheines, Pearl) forces the factorization. What we *do* choose, inside the strongly motivated graphical structure, is the parameterization: single-parameter edges with AND/OR combination semantics at nodes, rather than full conditional probability tables. The choice is parsimony-motivated — each edge carries one number rather than a 2^k table at a node with k parents — and it converged across three independent attempts to formalize the same content. Alternative parameterizations (Noisy-OR everywhere, weighted combinations) are rejected for documented reasons; see 8.2.

The wrinkle the formalism handles explicitly is causal insufficiency. Most strategy graphs in the wild have nodes that share latent common causes — shared infrastructure, common-mode risks, correlated adversary actions — that the agent has not represented as nodes. Naive AND/OR propagation on such graphs produces systematically biased plan-success estimates: it overestimates redundancy on OR-structures (the parallel paths share their failure modes) and underestimates joint reliability on AND-structures (the prerequisites also share their successes). The Correlation Hierarchy (L0 / L1 / L1’ / L2, in 8.3) handles this as part of the formalism rather than as an exception. There is a sobering downstream result: under purely on-policy execution, an agent at L0 *cannot detect* its own causal insufficiency from its own data — the worlds with and without a latent common cause are observationally indistinguishable from on-policy traces alone (the no-go in 9.2). The unique broadly-available escape is joint sibling observability under exploration. This is one of Part II’s load-bearing applications of 7.3.

The chapter’s headline result is the diagnostic split. When an agent is not achieving its goal, the framework asks two distinct questions, not one. The satisfaction gap

$$\delta_{\text{sat}} = V_{O_t}^{\min} - A_O \quad (8.1)$$

is positive when the best policy in the agent’s current class cannot reach the satisfaction threshold given the agent’s current model. Control regret

$$\delta_{\text{regret}} = A_O - V_O(\pi_{\text{current}}) \quad (8.2)$$

is positive when the agent is leaving value on the table — its current policy is worse than the best available. Together they produce a 2×2 cell map: goal attainable + policy good is success; goal attainable + policy poor means revise the strategy; goal unattainable + policy poor means revise the strategy first and then re-check; goal unattainable + policy good is the *capability limit* — the agent is doing the best it can but the goal is out of reach. Each cell prescribes a different corrective action, and getting the prescription right requires the orthogonal split. An earlier framing that lumped everything into a single goal-distance signal could not distinguish “the goal is too hard” from “the strategy is too weak” — and the two have different remedies. The split is what makes the orient cascade (Chapter 5) actionable.

A detail worth surfacing up front. The chapter opens with 8.1 — the chain rule of probability lifted to log-space:

$$\log P(\text{chain}) = \sum_{i=1}^n \log P(E_i \mid E_{<i}) \quad (8.3)$$

The identity is elementary; the consequence is not. Deep strategies are exponentially fragile in their depth — confidence in a 10-step plan is the product of 10 conditional probabilities, and each one is less than 1. This grounds the structural pressure toward shallow, parallelizable strategies. The same log-additive structure also anchors three other uniqueness theorems downstream in AAT (reverse-KL at the divergence layer, log-odds at the update layer, Fisher metric at the metric layer) — see 5.5 for the catalog. The identity at the head of this chapter does load-bearing work three layers deep.

The flow of the chapter: chain-rule identity (8.1) $\rightarrow$ AND/OR scope restriction (8.2) $\rightarrow$ formal DAG with Correlation Hierarchy (8.3) $\rightarrow$ orthogonal diagnostic split (8.4, 8.5). The chapter leaves us with a formal strategy representation, an honest treatment of causal insufficiency, and the diagnostic signals that tell whether the problem is the goal, the strategy, the model, or some combination.

Strategy DAG — worked propagation

Leaf credences $p_v(M_t)$ come from the reality model; edge credences p_{ij} are the agent’s causal-efficacy estimates for each link. Forward pass in topological order yields the strategy-plan-confidence score $\hat{P}_{\Sigma} = s_{v_{\text{root}}}$.

Figure 4: A worked strategy DAG. Leaf base credences and single-parameter edge credences propagate through AND/OR combination to a strategy-plan-confidence score at the root. The numerics are shown so the propagation can be checked by hand; the single-parameter edge is the chosen parameterization (noisy-OR and weighted variants were rejected).

- This is a chapter-introduction segment; it bridges Chapter 2’s planning-decision arc to Chapter 3’s formal strategy structure and diagnostic split. It carries no formal claim of its own.
- The framing “Chapter 2 says whether to plan; Chapter 3 says what a plan IS” is the conceptual core. The decision to plan precedes the formal definition of what a plan is — this is the sharpest joint in Part II per the OUTLINE walkthrough.
- The “what is and isn’t derived in the formal commitment” framing addresses what could otherwise read as over-claim. Acyclicity and Markov are theorem-backed; AND/OR is a chosen parameterization. Surfacing the distinction is important because the strategy-DAG segment is one of the places where the *derived vs. chosen* distinction matters most.
- The “two diagnostic quantities, not one” framing surfaces the orthogonality argument that makes Part II’s headline contribution legible. Earlier single-signal framings could not distinguish the two situations and therefore could not prescribe different remedies.
- The chain-confidence-decay paragraph names what the identity unlocks downstream. The identity itself looks elementary; the three load-bearing layers it anchors are not.

Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / forward-vision material kept separate from certified theory-fix findings. **Coverage:** this chapter-intro reached a digested reflection in 2 dirs (Claude, AUDIT-WORKING-773921; Claude, AUDIT-WORKING-526815); the broader strategy-structure cluster was walked by ~7 substrates whose per-segment notes landed on the content segments rather than the intro.

- The chapter’s own one-line self-description converged independently as the standout framing: “*goal too hard*” vs “*strategy too weak*” require different remedies — the diagnostic split is the point of the whole chapter (Claude, AUDIT-WORKING-526815). A Brief-grade compression of what the intro already develops at length.
- **The 2×2 diagnostic-split diagram as the chapter’s anchor figure.** Independently flagged as “the clearest diagram” for the whole chapter intro: one axis satisfaction gap, the other control regret, the four cells prescribing continue / revise-strategy / revise-strategy-then-recheck / capability-limit. The rationale: it “directly captures why the two-signal formulation is better than a single goal-distance signal” (Claude, AUDIT-WORKING-526815). Note the existing #fig-strategy-dag-example is the DAG-propagation figure; this proposed 2×2 is a *second*, complementary chapter figure. (Multiple substrates independently reached for this same 2×2 across the cluster — see the def-satisfaction-gap / def-control-regret gold.)
- **Chapter-intro navigation hazard.** One auditor mis-entered the chapter by opening strategy-structure-intro.md as if it were the *Part II* intro (its filename reads like a part entry point), reading it before its upstream dependencies and self-flagging a topological-order violation. Suggested mitigations: chapter-number filename prefixes, or an explicit part-intro.md per Part so an ls does not present a chapter-intro as a part entry point (Claude, AUDIT-WORKING-773921). A naming/navigation signal, not a theory issue — routes to the naming/FOR-MAT workflow, not this segment’s body.

- **Intro-level acyclicity wording may under-state the time-unrolling condition.** The intro says acyclicity “falls out of temporal ordering”; an auditor noted this is exact only for time-indexed event *tokens* (or once retry-loops / maintenance-cycles / feedback-plans are explicitly unrolled in time), not for reusable event *types* with repeated subgoals — and suggested the intro state the time-unrolled / event-token condition the way #def-strategy-dag does (Claude, AUDIT-WORKING-526815). The same auditor noted on re-reading #def-strategy-dag that the full segment *does* state the condition properly (retry loops as distinct time-indexed nodes), so the gap, if any, is intro-summary wording only — a small framing-precision item, recorded for the lead to judge whether it rises to a finding.

8.1 *Derived*: Chain Confidence Decay

A simple but load-bearing identity: for a chain of uncertain steps in a strategy, the log-probability of the whole chain is the sum of conditional log-probabilities of each step given the steps before it. Since each conditional log-probability is non-positive, chain confidence *decays monotonically with depth*. This is the chain rule of probability lifted to log-space — a mathematical identity, true under no assumptions beyond the probability axioms. The rate depends on the conditional dependence structure (independent steps give p^n decay; positively correlated steps decay more slowly; negatively correlated steps decay faster), but the qualitative result — longer chains are less confident than shorter ones — is robust.

The framework foregrounds two structural roles for this elementary identity that the algebraic form understates. First, chain depth carries a **triple penalty** — confidence decay (here), evidence starvation (R), and cognitive cost (9.9) — compounding independently to set the maximum useful chain depth. Second, this identity is the **anchor of the additive-coordinate-forcing meta-pattern**: three further AAT uniqueness theorems at the divergence, update, and metric layers cite the log-additive structure of the chain rule as the motivation for their respective additivity axioms (5.5). An identity at the head of this chapter does load-bearing work three layers deep across the framework.

Formal Expression.

For a chain of n uncertain steps with conditional success probabilities:

Derived (chain-confidence-decay, mathematical identity).

$$\log P(\text{chain}) = \sum_{i=1}^n \log P(E_i \mid E_{<i}) \quad (8.4)$$

Since each $\log P(E_i \mid E_{<i}) \leq 0$, chain confidence decays monotonically with depth.

The independent case (p^n) is the simplest special case, not the general result. When steps are conditionally dependent — success at step k makes step $k + 1$ more likely — the decay is slower. When steps have negative dependence (success at k makes $k + 1$ harder — resource depletion, adversary adaptation), decay is faster.

Quantitative illustration (independent, uniform p):

Table 8.1

<i>Depth</i>	$p = 0.9$	$p = 0.8$
1	0.90	0.80
3	0.73	0.51

<i>Depth</i>	$p = 0.9$	$p = 0.8$
5	0.59	0.33
10	0.35	0.11
20	0.12	0.01

Epistemic Status.

Exact. The additive decomposition of log-confidence is a mathematical identity (chain rule of probability). The qualitative consequence (monotonic decay) follows from the non-positivity of log-probabilities. No assumptions beyond the probability axioms.

Discussion.

Structural pressure on strategies. Chain confidence decay creates systematic pressure toward: - **Short plans:** fewer steps means higher aggregate confidence - **Parallel fallback paths:** OR-branches provide alternative routes when one chain fails - **High-confidence critical links:** invest in the reliability of steps that appear in every path - **Early monitoring:** detect chain failure early rather than discovering it at the end

These are not prescriptions but consequences — an agent that ignores chain decay will experience more strategy failures, lower effective tempo, and (if the failures are costly) faster reserve depletion.

AND-nodes amplify decay. When multiple parent chains must all succeed (conjunctive combination), their confidences multiply. A node requiring k parents each at depth d with per-edge confidence p has aggregate confidence $p^{k \cdot d}$, not p^d . Deep conjunctive strategies are exponentially more fragile than deep disjunctive ones. This asymmetry is formalized in the combination rules (8.3).

Connection to the persistence condition. Chain decay makes long-horizon strategies inherently fragile, which increases the effective disturbance rate ρ_Σ against strategy persistence. An agent pursuing a 20-step plan in a changing environment faces compound uncertainty from both chain decay (internal fragility) and environmental change (external disturbance). The interaction between these — how environmental change compounds through uncertain chains — is not yet formalized.

Triple depth penalty. Chain depth creates three independent penalties. This segment identifies the first: **confidence decay** — deeper chains have lower aggregate confidence because $\log P(\text{chain})$ accumulates negative terms. The two-edge strategic dynamics analysis (R) identifies the second: **evidence starvation** — downstream edge k in a chain is tested only when all upstream edges succeed, so its effective correction rate is attenuated by $\prod_{j < k} \theta_j$. 9.9 identifies the third: **cognitive cost** — deeper chains have higher description length, consuming more representational capacity. The three penalties compound independently: a deep edge has low confidence (decay), receives few observations (starvation), and costs more to maintain (complexity). The maximum useful chain depth d^* is the minimum over three independent constraints — see 9.9 for the formal bound.

Anchor role in the coordinate-forcing meta-pattern. The log-of-product decomposition here anchors three further AAT uniqueness theorems that force coordinates at other layers: reverse-KL at the divergence level (T §6.1), log-odds at the update level (U), and Fisher metric at the metric level (4.3 “Fisher-metric cases under parameterization-invariance”). The first two theorems cite this chain-layer identity as the analog motivating their additivity axiom; the Fisher-metric theorem rests on a parameterization-invariance axiom motivated by #scope-agent-identity’s singular-trajectory scope, an adjacent-AAT-commitment rather than a direct chain-analog — the theorem clears the broader discipline (uniqueness-theorem-forced coordinate under AAT-internal axiom) without reducing to a log-additive form. The catalog and the precise anchor-plus-three-theorem characterization live in 5.5.

Part III corollaries (additional reach of the chain-layer identity). The chain-rule identity has unsurfaced consequences at composition-related layers that are corollaries rather than new theorems: - *Composition tower telescoping.* For a chain of nested sub-agents $(A_1, A_2, \dots, A_\ell)$ with sub-agent- k contraction factor κ_k , the tower contraction factor $\prod_\ell \kappa_\ell$ becomes log-additive: $\sum_\ell \log \kappa_\ell$. The closure-defect-along-tower quantity $\sum_\ell \log(\nu_\ell/\alpha_\ell)$ inherits the chain-rule identity's additivity. - *Fisher information for multi-sample likelihoods.* $\log P(\mathbf{y}; \theta) = \sum_i \log P(y_i; \theta)$ is the chain-rule identity applied to multi-sample independent observations, producing the additive-Fisher-information decomposition standard in statistics. - *Communication-tree aggregation.* Shared-intent compression across tree-structured agent communication channels inherits the chain-rule identity along the tree's branches, giving log-additive coordination-bit cost.

These are not independent uniqueness theorems — they are *corollaries* of the chain-layer identity applied to specific structural settings. Composition of structured multiplicative quantities inherits the log-additive decomposition whenever the chain-rule factorization applies. Cataloguing is in 5.5's Working Notes; none rises to primary-instance status because none introduces a new AAT-internal axiom (they reuse the probability chain rule as their identity, not as motivation for a fresh axiom). A distinct meta-pattern for composition specifically — composition-monotonicity rather than chain-rule — may be warranted; see #form-composition-closure's bridge-lemma / Tier 1/2/3 / (CM4) family as the candidate structural material.

Working Notes.

- The independent-edge assumption (used in the quantitative table) is optimistic for positively correlated failures (shared infrastructure $\rightarrow$ correlated failures make the actual confidence *lower* than independent calculation suggests). Correlation structure is unmodeled — acknowledged as a limitation.
- The additive log-confidence form is the robust result; p^n is the special case for independent uniform edges. This distinction matters: the qualitative consequence (decay with depth) is robust; the specific rate depends on the conditional structure.

Incidental audit gold (lift 2026-05-31, A8 batch). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / analogy / forward-vision material, kept separate from certified theory-fix findings. **Coverage:** 7 dirs reached a digested reflection on this segment (Gemini, AUDIT-WORKING-193847; Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-451729-batch-09; Claude, AUDIT-WORKING-963715-batch). Notably high convergence on the everyday analogies — this segment is read as a Feynman-criterion candidate (“turns a trivial equation into a load-bearing architectural constraint”).

1. Candidate Brief prose / pre-prose.

- **Bureaucracy-vs-market as the AND/OR fragility gloss.** “A bureaucracy is a massive AND-chain (approval from A and B and C and D — each at 90% gives a 65% 4-step success); a market is a massive OR-chain (vendor A or B or C — each at 50% gives 87.5% over three options).” The segment “proves why markets (highly parallel OR-structures with low individual p) consistently outperform bureaucracies (deep sequential AND-structures with high individual p) in volatile environments” (Gemini, AUDIT-WORKING-193847). A strong Feynman-criterion candidate — re-derivable from the everyday analog without the symbols.
- **The “KISS proved as a theorem” framing.** Multiple substrates independently glossed the result as a formal proof of “Keep It Simple” / why short, parallel plans beat deep serial ones (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-773921). Candidate plain-language Brief anchor for the depth-fragility finding.

2. Candidate Discussion.

- **The AutoGPT / long-horizon-LLM-agent failure explanation.** “If you are 90% confident in every single step of a 20-step plan, your overall chance of success is only 12% (0.9^{20}). This explains why early LLM agents failed at long-horizon tasks: given a goal, they generated a ~ 20 -step chain and executed it blindly, with no mechanism for evidence starvation (couldn't test step 20 until step 19 done) and full confidence decay — they were trying to act like a C3/Bellman agent in a world

that requires a C2/receding-horizon convention” (Gemini, AUDIT-WORKING-829314; converging at Claude, AUDIT-WORKING-773921 and -849201). Connects the segment’s table directly to a recognizable empirical phenomenon — a candidate Discussion bridge once the C2/C3 convention vocabulary is in hand (it lives in `#def-value-object` / `#def-control-regret`).

- **The structural escapes the math forces, as the segment’s “so what.”** The same auditor lists the three survival adaptations the decay forces: (1) short plans (plan 3, execute, replan); (2) parallel OR-fallbacks (step 3b ready if 3 fails); (3) early monitoring (don’t wait until step 20 to learn step 1 failed). Framed as *why* Σ_t must be a DAG with AND/OR rather than a linear AND-chain — the maximally-fragile pure-AND case (Gemini, AUDIT-WORKING-829314). The segment’s Discussion already lists these as “consequences not prescriptions”; this is a sharper pedagogical ordering of them.

3. Follow-up items.

- **The “Anchor role” + “Section III corollaries” subsections read as out-of-place density.** Three substrates independently flagged the meta-pattern paragraphs (coordinate-forcing anchor; reverse-KL / log-odds / Fisher / Čencov; composition-tower telescoping) as a jarring abstraction-level jump that buries the segment’s core intuition (the triple depth penalty) — reading like integration debt retrofitted into a foundational segment, with a suggestion to relocate the meta-pattern material to `#disc-additive-coordinate-forcing` and let the triple-penalty be “the star” (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Codex/Claude, AUDIT-WORKING-526815 “treat as preview until the home segments are read”). Worth weighing against the deliberate “introduce the anchor where the identity lives” choice — but the convergent reader-stumble is a real placement signal. (A `disc-*` meta-segment home already exists; this is a *how-much-to-inline-here* question, not a content gap.)

4. Readers often ask / wonder.

- **Agile-sprints and command-chain-depth as the recognizable instances.** “Why Agile prefers short sprints (shallow trees), and why hierarchical organizations break down when command chains get too deep — the probability of top-level intent surviving to the leaf nodes decays exponentially” (Claude, AUDIT-WORKING-773921). A reader reaching for “where do I already see this?” lands here.

Belongs elsewhere.

- **ELI / Section IV — favor OR-heavy internal architecture under high ρ .** “For consciousness infrastructure, this means the internal architecture should favor OR-node-heavy strategies (many parallel weak hypotheses / solution paths) rather than a single long high-confidence AND-chain; incentivize lateral thinking over deep sequential logic when facing high ρ ” (Gemini, AUDIT-WORKING-193847). Aspirational architectural reach pointing at `04-eli-core/`, not at this segment.

Off-ramp (NOT gold — flagged for the certified track).

- **“Decays monotonically” vs monotone *non-increase*.** An auditor noted the exact probability result is monotone *non-increase*; strict decay requires every added required step to have conditional success probability strictly below 1 (a certain prerequisite step adds a zero log-term, no decay). Minor precision-of-wording on an exact segment — flagged for the lead to judge whether the body should read “non-increasing (strictly decreasing whenever each added step is uncertain)” (Codex/Claude, AUDIT-WORKING-526815).

8.2 Scope: AND/OR Combination Scope

We restrict to environments where the causal combination of strategy steps is approximately conjunctive (AND: all parents required) or disjunctive (OR: any parent sufficient), without strong interaction effects between parents. Each node is assigned a combination type by answering the causal question: “if I remove one parent, can this node still be achieved?” Yes $\rightarrow$ OR. No $\rightarrow$ AND. With single-parameter edges (one number per edge rather than a 2^k conditional probability table), this gives k parameters per node instead of an exponential explosion.

The scope is honest about being a *restriction*, not a derivation, though it converged independently across three different formalism attempts (8.3). The excluded case — complementarity, substitutability, and interaction effects between parents (synergistic drug interactions where combined effect exceeds the sum; complementary goods where neither is useful alone; strategic surprise where action combinations matter more than individual actions) — requires richer combination rules and is named as a legitimate divergence point for future work. The parsimony argument is that for binary-outcome nodes, AND and OR form a complete Boolean basis (DNF/CNF normal forms), and under bounded cognition (2.2) the agent needs the most expressive low-parameter representation. AND/OR is the natural candidate; for continuous or multi-valued outcomes the same completeness properties do not necessarily hold (min/max or additive/multiplicative are natural analogs but their completeness is open).

Formal Expression.

Under this restriction, strategy nodes combine parent contributions via:

Scope Narrowing (and-or-scope).

AND-node (all parents must succeed):

$$P(v \mid \text{parents}) = \prod_{i \in \text{pa}(v)} p_{iv} \cdot P(i) \quad (8.5)$$

OR-node (any parent sufficient):

$$P(v \mid \text{parents}) = 1 - \prod_{i \in \text{pa}(v)} (1 - p_{iv} \cdot P(i)) \quad (8.6)$$

The combination type $\gamma(v) \in \{\text{AND}, \text{OR}\}$ is assigned per node. The causal question determines assignment: “if I remove one parent, can v still be achieved?” YES $\rightarrow$ OR. NO $\rightarrow$ AND.

Epistemic Status.

Robust qualitative. This scope narrowing converged independently across three formalism attempts (track-a/00, track-a/02, track-a/03). It captures the dominant structure in most planning domains. The excluded case — complementarity, substitutability, interaction effects between parents — requires richer combination rules and is a legitimate divergence point for future work.

The AND/OR restriction with single-parameter edges gives k parameters per node (one per parent edge) instead of 2^k for a general conditional probability table. This parsimony is motivated by bounded cognition (2.2): agents with limited representational capacity are forced toward low-parameter models.

Discussion.

Why AND/OR and not alternatives.

Why not Noisy-OR universally. The first formalism attempt used noisy-OR for all nodes. This **systematically overestimates conjunctive structures**:

Table 8.2

Structure	Noisy-OR	AND	Reality
3 required KRs at $p = 0.95, 0.90, 0.99$	0.99995	0.846	~AND

The noisy-OR model cannot represent “all of these are required.” This was the primary motivation for the AND/OR revision.

Why not WEIGHTED combination. A clean-slate formalism (track-a/02) introduced $P(v) = \min(1, \sum \alpha_{iv} \cdot p_{iv} \cdot P(i))$ to handle k-of-n thresholds. This reintroduces a two-parameter estimation problem (α weights per edge). If k-of-n semantics are genuinely needed, nested AND/OR structure can represent them: group alternatives into OR-nodes, then AND the groups. This keeps estimation localized to the node taxonomy rather than spreading it across a new per-edge parameter.

The parsimony argument. For binary-outcome nodes, AND and OR form a complete Boolean basis — any Boolean combination can be decomposed into layers of AND/OR (disjunctive/conjunctive normal form). Under bounded cognition, the agent needs the most expressive $O(k)$ -parameter representation. AND/OR is the natural candidate. This is a parsimony-motivated hypothesis, not a derived necessity — see Q for the full argument and its limitations.

What this scope excludes. Environments with strong interaction effects: where the value of combining parent contributions is not separable into independent per-parent terms. Examples: synergistic drug interactions (combined effect exceeds sum of individual effects), complementary goods (neither is useful alone), strategic surprise (the combination of actions matters more than any individual action). These require richer parameterizations within the strongly motivated graphical structure (8.3) — a direction for future work.

Working Notes.

- The AND/OR assignment per node ($\gamma(v)$) is itself uncertain and should be updateable. A node assumed to be OR (alternatives) might turn out to be AND (all required) when the agent discovers unexpected dependencies. γ reclassification is rare — it requires strong structural evidence — and operates on a slower timescale than edge-weight updates.
- The parsimony argument applies cleanly to binary outcomes. For continuous or multi-valued outcomes, AND/OR doesn't have the same completeness properties. The natural continuous analogs might be min (AND) and max (OR), or additive and multiplicative combination. Whether there's a completeness result for these is an open question.
- K-of-n thresholds are genuinely common (e.g., “need at least 3 of 5 team members available”). The nested AND/OR representation works but can be verbose. Whether this verbosity is a problem in practice (given bounded cognition constraints) is empirical.

Incidental audit gold (lift 2026-05-31, A8 batch). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure material, kept separate from certified theory-fix findings. **Coverage:** 6 dirs reached a digested reflection (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-451729-batch-09; Claude, AUDIT-WORKING-963715-batch).

1. Candidate Brief prose / pre-prose.

- **The “keys AND door / keys AND car” worked gloss of why Noisy-OR fails.** “If you use Noisy-OR to model a strategy where *all* prerequisites are required (Get key *and* Unlock door to Open door), the math breaks down catastrophically: 90% sure of the key, 95% the door, Noisy-OR says $1 - (1 - 0.9)(1 - 0.95) = 0.995$ — *more* confident than either prerequisite alone, which is mathematically suicidal for a planner. An AND gate correctly says $0.9 \times 0.95 = 0.855$ — *less* confident”

(Gemini, AUDIT-WORKING-829314; the “keys AND car” variant at Gemini, AUDIT-WORKING-849201; “acquire funding AND hire team to launch product” at Claude, AUDIT-WORKING-963715). A concrete everyday anchor for the noisy-OR-overestimation table already in Discussion.

2. Candidate Discussion.

- **“Strategies are not Bayesian belief networks turned sideways.”** The sharpest framing of why planning needs AND *and* OR, not universal Noisy-OR: “the logic of causation in a *plan* is much more brittle than the logic of evidence in a *diagnosis*. If one piece of evidence is missing, a diagnosis can still be highly probable; if one required step is missing, a plan fails with probability 1.” Noisy-OR is the dominant combination function in PGM tooling (medical diagnosis etc.) precisely because evidence is forgiving; strategy is not (Gemini, AUDIT-WORKING-829314). A candidate Discussion paragraph distinguishing Σ_t -combination-semantics from M_t -style belief networks.
- **The PGM-tooling critique deserves more prominent positioning.** “AAT’s claim that noisy-OR systematically overcounts in conjunctive structures is a specific technical critique of a widely-used formalism (BNT, Netica, most Bayesian-network tools), not just an internal modeling choice — and deserves more prominent positioning as a critique of standard PGM tooling for planning applications” (Claude, AUDIT-WORKING-963715). A framing-emphasis suggestion: the rejection is a contribution, not housekeeping.

3. Follow-up items.

- **A native k-of-n threshold node type under MDL pressure.** Strong convergence (3 substrates) that pure AND/OR forces combinatorial blow-up for threshold logic: “3-of-5 servers healthy” needs $\binom{5}{3} = 10$ AND-branches into one OR-node, a large spike in $DL(\Sigma_t)$ — a tension between *node-type* parsimony (only 2 types) and *graph-size* parsimony. The prediction: AAT may be forced to introduce a native “threshold / k-of-n” node primitive to satisfy the information-bottleneck constraint of #form-strategy-complexity-cost, and the k-of-n verbosity note should be lifted from Working Notes into Discussion (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-773921; Codex/Claude, AUDIT-WORKING-526815). Currently the Working Notes hold this as “empirical whether verbosity is a problem”; the auditors lean toward it being a real limitation worth a primitive.

4. Readers often ask / wonder.

- **Where else do these formulas live?** The AND/OR combination rules were independently recognized as “standard in reliability engineering and fault tree analysis” (Gemini, AUDIT-WORKING-849201). A reader orienting on prior-familiarity lands here — a candidate one-line situating note.

5. Candidate figures.

- **Three-region scope diagram.** “Pure AND / pure OR / outside-current-scope (thresholds, interactions)”, paired with the parameter-count contrast (single-parameter edges $O(k)$ vs full CPTs $O(2^k)$) to make the parsimony motivation visual and to make the *excluded* region legible as non-rare (Codex/Claude, AUDIT-WORKING-526815).

Off-ramp (NOT gold — flagged for the certified track).

- **The γ -assignment test misclassifies threshold structures.** The test “if I remove one parent, can v still be achieved? YES $\rightarrow$ OR, NO $\rightarrow$ AND” mis-handles a 3-of-5 requirement: removing one parent may still leave success possible (so the test says OR), yet no single parent is sufficient (so it is not really OR). Suggested repair: split into separate questions — are *all* parents necessary, is *any one* sufficient, or is this a threshold/interaction case outside pure AND/OR (Codex/Claude, AUDIT-WORKING-526815). A real precision gap in a stated rule.
- **Boolean completeness $\neq$ compact representation.** The parsimony argument leans on “AND/OR form a complete Boolean basis (DNF/CNF) and are therefore the natural $O(k)$ -parameter representation.” An auditor flagged that functional completeness does *not* imply *compact* representation — arbitrary Boolean functions can require exponentially large AND/OR formulas or auxiliary nodes (the k-of-n verbosity is one instance) — so the completeness claim should be scoped or softened (Codex/Claude, AUDIT-WORKING-526815). Both items are wording/scope tightenings on a robust-qualitative segment; routed for the lead to judge.

8.3 Definition: Strategy DAG

The strategy Σ_t is a directed acyclic graph with probabilistic edges and AND/OR combination semantics. Each edge carries the agent's causal credence that completing the parent step advances the child step. The graph encodes the agent's theory of how its actions produce progress toward its objectives.

Why a DAG. The DAG structure is not a modeling convenience but a *consequence* of operational requirements on any causally-reasoning bounded agent — at the level of sufficiency, not yet necessity. Q proves that directed temporal order plus probabilistic uncertainty plus causal sufficiency *suffice* for a DAG-with-Markov-factorization representation (the necessity direction — no non-DAG structure could satisfy these postulates — is an open stronger result). Acyclicity is proved from temporal ordering over a finite horizon. What remains a formulation choice is the *parameterization within* the DAG structure: AND/OR combination with single-parameter edges is the AAT choice, motivated by parsimony and convergence across three independent formalism attempts, but alternative parameterizations (within the derived graphical structure) are legitimate research directions.

Strategy-layer exactness contract. All formal results in AAT's strategy layer — the sector condition transfer (R, Prop B.5), the persistence schema (9.10), the gradient-based credit assignment (9.6) — are proved under **L0 (independence)**: causally sufficient DAGs with independent edge outcomes. **L0 formal results transfer exactly to correctly constructed L1 DAGs (strict prerequisites, Prop B.6) and L1' DAGs (soft facilitators, Prop B.7) — provided the common cause is observable per trial.** When the common cause is unobservable, the per-conditional decomposition is *fundamentally* (not merely “openly”) obstructed — the mixture parameters are non-identifiable from a single observation channel (Fisher rank deficiency / Cramér-Rao floor; see B.7 §”Refuted Under Unobservable C”), and the agent must either collect direct *C*-observations, run multi-child joint observations (Prop B.7 §”Repair routes”), or fall back to plan-level (L0-on-marginals) tracking. See the Correlation Hierarchy below for the full treatment.

Formal Expression.

Definition (strategy-dag).

$$\Sigma_t = (V_t, E_t, p_t, \gamma_t) \quad (8.7)$$

where: - V_t : set of **propositional nodes** — each node represents a condition that could be true or false (including action-success propositions at the leaves) - $E_t \subseteq V_t \times V_t$: directed causal edges - $p_t : E_t \rightarrow [0, 1]$: **causal credence** per edge — the agent's confidence that completing the parent advances the child - $\gamma_t : V_t \rightarrow \{\text{AND, OR}\}$: combination rule per node (8.2)

Structural constraints:

1. **Acyclicity.** Σ_t is a DAG. This is *derived*, not assumed — see below.
2. **Rootedness.** Every node has a directed path to a unique root terminal v_{root} — the single sink node (out-degree 0) of Σ_t . Compound objectives express their combination structure through the AND/OR machinery below v_{root} , consistent with scalar V_{O_t} (6.4).
3. **Source constraint.** Leaf nodes are propositions about action success (“action a succeeds at τ_v ”) or observable conditions (“condition C_v holds at τ_v ”). Both are propositional — the distinction is whether the proposition is within the agent's causal control (action) or not (condition).

Leafbase credence. For each leaf node $v \in V_t^{\text{leaf}}$, the base credence used in status propagation:

$$p_v(M_t) = \begin{cases} \Pr(\text{action } v \text{ succeeds at } \tau_v \mid M_t) & \text{if } v \text{ is an action node} \\ \Pr(C_v(\tau_v) \mid M_t) & \text{if } v \text{ is a condition node} \end{cases} \quad (8.8)$$

where C_v is the propositional condition associated with node v and τ_v is the node's temporal position (from the acyclicity structure). For action leaves, p_v is *capability credence* — “can I execute this?” For condition leaves, p_v is *state credence* — “will this hold?” Both are conditional on M_t and update whenever M_t updates. This is the mechanism by which Part I's adaptive machinery enters the strategy: M_t changes $\rightarrow$ leaf credences change $\rightarrow$ status propagation produces new terminal credences.

Edge semantics. Each edge carries a single credence weight:

$$p_{ij} = \text{Cr}(j \text{ advances} \mid i \text{ completed}, M_t) \quad (8.9)$$

This is the agent's credence that completing step i advances step j , given its current model — its **causal efficacy estimate** for the link. The agent treats p_{ij} as a causal quantity for planning purposes (status propagation, strategy-plan-confidence scoring, action selection). Whether p_{ij} is a *good* estimate of causal efficacy depends on the identification regime of the data that produced it (9.5):

- **Regime A** (intervention-rich: software, laboratory science). The agent's execution-observation pairs are genuine interventions with clean attribution. p_{ij} approximates the interventional probability $P(j \mid \text{do}(i), M_t)$.
- **Regime B** (partial intervention: organizational, coordinated action). The agent acts but attribution is blurred by concurrent actions and self-selection. p_{ij} is a partially identified causal estimate, typically biased upward.
- **Regime C** (observation-only: passive monitoring, intelligence analysis). The agent observes associations but does not intervene. p_{ij} is an observational proxy for the causal quantity — useful for planning but potentially confounded.

The identifiability coefficient t_{ij} (9.5) quantifies the strength of the causal interpretation for each edge. When $t_{ij} \approx 1$, the agent's credence is well-identified causally. When $t_{ij} \approx 0$, the credence is associational. The single-parameter edge design is preserved: p_{ij} is always the agent's working estimate, with t_{ij} characterizing its causal warrant separately.

Status propagation. Forward pass in topological order, $O(|V| + |E|)$:

$$s_v = \begin{cases} p_v & \text{if } v \text{ is a leaf (base credence)} \\ \prod_{i \in \text{pa}(v)} p_{iv} \cdot s_i & \text{if } \gamma(v) = \text{AND} \\ 1 - \prod_{i \in \text{pa}(v)} (1 - p_{iv} \cdot s_i) & \text{if } \gamma(v) = \text{OR} \end{cases} \quad (8.10)$$

Terminal satisfaction conditions. The root terminal v_{root} and any intermediate nodes near the top of the DAG carry **satisfaction conditions**: predicates on environment states/trajectories that the agent treats as operational success criteria for the objective. These conditions operationalize O_t within Σ_t — they are the agent's theory of what it means to satisfy the objective. O_t itself lives outside Σ_t (6.7); the terminal conditions are Σ_t 's internal encoding of what O_t requires. When O_t changes, terminal conditions must be reassessed and potentially replaced (9.7).

Well-formedness. Σ_t is O_t -**well-formed** when the agent believes that achieving the terminal conditions yields a trajectory that satisfies the objective:

$$\Pr(O_t \text{ satisfied by } \tau \mid \text{terminal conditions achieved}, M_t) \geq 1 - \epsilon \quad (8.11)$$

where “ O_t satisfied” means $V_{O_t}(\tau)$ exceeds the objective’s own satisfaction criterion (formalized as $V_{O_t}^{\min}$ in 8.4). This is a constraint on the relationship between Σ_t and O_t , not a separate state object. It is explicit and in-principle assessable, though evaluating it requires the same value-side machinery as A_O — it is not a cheap structural test. Violation triggers terminal reassessment: either the terminals need revision (they don’t operationalize O_t correctly) or O_t itself needs revision.

Strategy self-assessment. The root node’s propagated status:

$$\hat{R}_\Sigma(M_t) = s_{v_{\text{root}}} \quad (8.12)$$

is the strategy’s **strategy-plan-confidence score** — the DAG’s own answer to “will this plan work?” This score is a correct probability only when the DAG is **causally sufficient** — when all common causes of strategy nodes are represented as nodes in the graph (Q, Step 3). When the DAG is causally insufficient (the dominant real-world case — shared infrastructure, common-mode risks, correlated adversary actions introduce latent common causes), $\hat{R}_\Sigma$ systematically overestimates success likelihood because the AND/OR propagation treats joint failure probability as the product of marginals. See the **Correlation Hierarchy** below for the full treatment.

$\hat{R}_\Sigma$ is explicitly distinct from A_O (8.4), which optimizes over the entire policy class, and from $V_O(\pi_{\text{current}})$ (6.6), which evaluates the current policy. $\hat{R}_\Sigma$ is cheap to compute ($O(|V| + |E|)$ forward pass) and updates in real time as M_t changes through leaf credences.

Correlation Hierarchy.

The AND/OR status propagation computes correct probabilities **if and only if** the strategy DAG is causally sufficient — that is, all common causes of any two strategy nodes are themselves represented as nodes. By the Causal Markov Condition theorem (Q, Step 3), causal sufficiency guarantees independent exogenous noise, which guarantees the Markov factorization, which guarantees independent edge outcomes. **When causal sufficiency fails — the dominant case in complex, multi-stakeholder, or adversarial environments — edge outcomes are correlated and the independence model is biased.**

Discussion (correlation-hierarchy).

Direction and magnitude of bias. For two binary sibling nodes X_1, X_2 with marginal success probabilities θ_1, θ_2 and covariance $\rho = \text{Cov}(X_1, X_2) > 0$ (positive correlation from a latent common cause):

Table 8.3

Node type	True probability	Independence estimate	Bias
AND	$\theta_1\theta_2 + \rho$	$\theta_1\theta_2$	$+\rho$ (underestimates — conservative)
OR	$[1 - (1 - \theta_1)(1 - \theta_2)] - \rho$	$1 - (1 - \theta_1)(1 - \theta_2)$	$-\rho$ (overestimates — optimistic)

The independence model error is exactly $\pm \text{Cov}(X_1, X_2)$, with sign determined by node type. AND-nodes are conservative because clustering of successes helps joint success. OR-nodes are optimistic because clustering of failures undermines the redundancy that OR-structure is supposed to provide. Same magnitude, opposite signs.

For strategies with OR-structure near the root (the typical case — multiple alternative paths to the objective), the net bias is overestimation: the agent believes it has more redundancy than it actually does. For AND-heavy strategies (all components must work, no alternatives), the net bias is underestimation. Mixed strategies depend on the graph topology, but OR-dominated roots are far more common than AND-dominated roots in practice.

Four regimes, in order of increasing realism:

Table 8.4

Level	Model	When correct	$\hat{P}_\Sigma$ status	Sector transfer status	Computation
L0: Independence	AND/OR propagation as-is	Causally sufficient DAG (all common causes explicit)	Correct probability	Prop B.5 (linear), B.5b (componentwise nonlinear): $\alpha_s = \alpha_c$	$O(V + E)$
L1: Augmented DAG (strict prerequisites)	Strict-prerequisite common-cause nodes added explicitly; AND/OR propagation on augmented graph	Augmented DAG is causally sufficient <i>and</i> every modeled common cause has $\theta_{\text{child} \neg C} \approx 0$	Correct for augmented graph	Prop B.6: $\alpha_\Sigma = \min(1/(n_C + 1), \theta_C \pi_{j C}/(n_j + 1))$ — three-way gating	$O(V' + E')$, larger graph
L1': Mixture form (soft facilitators)	Conditional sub-DAGs weighted by common-cause state: $\hat{P}_\Sigma = \theta_C P_\Sigma(G C) + (1 - \theta_C) P_\Sigma(G \neg C)$	Soft-facilitator common causes ($\theta_{\text{child} \neg C} > 0$) with C observable per trial	Correct for the weighted combination	Prop B.7: $\alpha_{L1'} = \min(1/(n_C + 1), \theta_C \pi_{j C}/(n_{j C} + 1), (1 - \theta_C) \pi_{j \neg C}/(n_{j \neg C} + 1))$ — five-way gating. Refuted when C unobservable (Fisher rank-1; falls back to plan-level tracking or multi-child joint observation)	$O(V' + E')$ per common cause; doubles parametric footprint for affected edges
L2: Full correlation	Arbitrary joint failure distribution over edges	Always (but requires specifying the full joint)	Correct	Reduces to L0 on the augmented joint state	Exponential in general

L0 (Independence) is the tractable baseline. All formal results in AAT's strategy layer — the sector condition transfer (Prop B.5 in R), the persistence schema (9.10), the gradient-based credit assignment (9.6) — are proved under L0. The strategy-plan-confidence error $\delta_s = \hat{P}_\Sigma - \Phi$ tracks calibration *within* the independence model; $\Phi = P_\Sigma(\theta)$ is the AND/OR formula at true edge rates, not actual plan success probability.

L1 (Augmented DAG) is the practical sweet spot — *for strict-prerequisite common causes*. The agent models correlation structure explicitly by adding common-cause nodes to Σ_t and restructuring the DAG so that the common cause is **factored above the correlation it creates**. The construction principle: place the common-cause node as an AND-prerequisite *above* the OR/AND structure whose children it correlates. This ensures that, conditional on the common cause being satisfied, the children are independent and standard AND/OR propagation is correct.

Scope of the AND-prerequisite construction: strict prerequisites only. The factoring-above principle requires that the common cause be a *strict* prerequisite — one for which $\theta_{\text{child}|\neg C} \approx 0$. Shared infrastructure going down, a required resource being absent, a gating permission being denied: in all of these, the correlated children fail when the common cause fails, so the AND-prerequisite correctly encodes the correlation. When the common cause is instead a *soft facilitator* — favorable market conditions, a supportive team culture, an enabling technology — children have $\theta_{\text{child}|\neg C} > 0$ and can succeed when the common cause is absent, just less reliably. The AND-prerequisite construction mathematically forces $P(\text{sub-plan} | \neg C) = 0$, which strictly understates success probability when C is absent. Soft facilitators therefore fall outside L1's single-pass construction and require one of:

- **Mixture form (L1')**: split the sub-plan into two conditional structures and weight by $P(C)$: $\hat{P}_\Sigma = \theta_C \cdot P_\Sigma(G | C) + (1 - \theta_C) \cdot P_\Sigma(G | \neg C)$ This keeps propagation polynomial but requires maintaining two parallel sub-DAGs

per soft-facilitator node. Per-edge credences split into two regimes ($p_{ij|C}$ and $p_{ij|\neg C}$), doubling the parametric footprint for affected edges.

- **Explicit conditioning (L2 subcase):** $R_2(G) = \sum_c P(C = c) \cdot R_2(G | C = c)$, summing over common-cause states. For k soft facilitators with binary states, this costs $O(2^k)$ in the number of common-cause states — the exponential blowup L2 was defined to name.

The gap between L1 (strict) and L2 (arbitrary) was not previously named. L1' (mixture form) fills this gap at linear cost per soft-facilitator node. The “L1 is the practical default” claim therefore applies most cleanly to strict prerequisites; for mixed environments (strict and soft common causes simultaneously), the correct construction mixes L1 factoring for strict prerequisites with L1' mixtures for soft facilitators. Treating all common causes as strict prerequisites systematically undervalues sub-plans that face soft facilitators (the opposite failure mode from L0's overestimation).

Example — strict prerequisite (see #example-L1 for full treatment): Two OR-alternatives sharing infrastructure dependency ($\theta_C = 0.8$, $\theta_{1|C} = 0.9$, $\theta_{2|C} = 0.7$, and implicitly $\theta_{1|\neg C} = \theta_{2|\neg C} = 0$ — infrastructure is a strict prerequisite). L0 computes $\hat{R}_\Sigma = 0.877$; actual is 0.776 (overestimation = ρ , the covariance from shared infrastructure). Naive L1 (common cause as parent of both alternatives, alternatives remain OR-siblings) gives the *same* overestimate because the OR-propagation still treats siblings as marginally independent. Correct L1 ($G = \text{AND}(C, G_{\text{sub}})$ where $G_{\text{sub}} = \text{OR}(A_1, A_2)$) gives the exact answer because A_1 and A_2 are conditionally independent given C and because $\theta_{1|\neg C} = 0$, so the AND-prerequisite is the correct encoding. The sector condition is verified (Prop B.6 in R) with $\alpha_\Sigma = \min(1/(n_C+1), \theta_C(1-\epsilon)/(n_{A_1}+1), \theta_C\epsilon/(n_{A_2}+1))$ — combining evidence-starvation and exploration-gating effects. B.5b transfers losslessly.

All L0 formal results transfer to correctly constructed L1 DAGs for *strict-prerequisite common causes* because the augmented DAG is a standard AND/OR DAG that satisfies causal sufficiency. For L1' (mixture form) with **observable common cause**, the formal results transfer through Prop B.7 (R) — five-way gating with $\alpha_{L1'} = \min(1/(n_C + 1), \theta_C\pi_{j|C}/(n_{j|C} + 1), (1 - \theta_C)\pi_{j|\neg C}/(n_{j|\neg C} + 1))$. For L1' with **unobservable common cause**, the per-conditional decomposition is identifiability-obstructed by the Cramér-Rao floor — the per-trial Fisher matrix is rank 1 rather than rank $2K + 1$, so no unbiased online estimator on the joint conditional vector admits a sector parameter $\alpha > 0$. This is not “open” but structurally refuted; the agent must augment C -observability, run multi-child joint observations, or fall back to L0-on-marginals (losing per-conditional diagnostics). The practical challenges are: (1) identifying which common causes matter enough to model explicitly, (2) classifying each identified common cause as strict or soft, (3) verifying C -observability for soft cases, (4) restructuring the DAG correctly for each. All four are modeling judgments, not mechanical procedures.

L2 (Full correlation) is a mathematical ideal. Specifying the full joint failure distribution over m edges requires $O(2^m)$ parameters, which violates the bounded-cognition constraint that motivates the DAG representation in the first place. L2 is useful as a reference point for characterizing the L0/L1 approximation error, not as a practical representation.

Choosing among L1, L1', and L2 requires classifying each common cause and verifying observability. $\theta_{\text{child}|\neg C} \approx 0 \rightarrow \text{L1}$ (factor above the correlation, B.6). $\theta_{\text{child}|\neg C} > 0$ with C **observable** $\rightarrow \text{L1'}$ (B.7, five-way gating). $\theta_{\text{child}|\neg C} > 0$ with C **unobservable** $\rightarrow \text{L1'}$ is identifiability-obstructed by the Cramér-Rao floor; either augment C -observability (preferred), use L2 explicit conditioning, or fall back to L0-on-marginals (losing per-conditional diagnostics). Mixed-classification environments (some strict, some soft, varying observability) combine L1 factoring for the strict and L1' mixtures for the soft observable. Treating all common causes as strict prerequisites under L1 alone systematically *understates* success on soft-facilitator branches (the symmetric failure mode to L0's overestimation); treating L0 as the default leads to systematic overconfidence — the agent believes it has more redundancy than it actually does (OR-nodes) or more fragility than it actually does (AND-nodes). L0 remains appropriate for domains with genuinely independent risks (independent parallel experiments, diversified portfolios with low correlation) and as a computational stepping stone during strategy construction.

Detecting latent common causes. An agent at L0 can detect causal insufficiency *under joint sibling observability generated by its own interventions* — not from on-policy traces alone. On-policy execution alone cannot distinguish the

with-and-without-latent-common-cause worlds (the no-go in 9.2); the unique broadly-available escape is joint sibling observability under exploration, where the agent’s interventions (7.3) generate the joint outcome data the test requires. Persistent overestimation of plan success after edge credences have converged is the *signal* of insufficiency (4.8 applied to the strategy layer); pairwise covariance among observed siblings is the *test* (positive covariance rejects independence and identifies where to add L1 nodes). Full treatment: 9.2; numerical instantiation: #example-L1. Summary references in dependent segments that elide the on-policy / interventional distinction should be treated with caution — the load-bearing scope is “joint sibling observability under exploration,” not “from observational data alone.”

Scope of the terminal construction. Terminal conditions as Boolean predicates with AND/OR aggregation work naturally for threshold, constraint, and composite objectives. For continuous-valued objectives without natural thresholds, the agent must set an operational threshold — introducing a discretization that is a practical proxy, not a lossless encoding of V_O . The primary $O_t \leftrightarrow$ theory interface remains V_O through the value object (6.6); terminal conditions are Σ_t ’s internal operational encoding.

Single-parameter edges. Each edge carries one number (p_{ij}), not two. An earlier formalism attempt used (p_{ij}, θ_{ij}) where θ was “contribution magnitude.” This was dropped because the AND/OR combination rules at nodes absorb θ ’s role — the complexity budget goes to one bit per node (γ) instead of one float per edge.

Edge-credence presentation coordinates. Each edge’s single-number credence has two equivalent presentations: the *probability-space* coordinate $p_{ij} \in [0, 1]$ (convenient for AND/OR propagation and interpretation) and the *log-odds* coordinate $\lambda_{ij} = \log(p_{ij}/(1 - p_{ij})) \in \mathbb{R}$ (the unique additive-evidence coordinate forced by the evidential-additivity axiom; see U). The two coordinates are related by the sigmoid $p_{ij} = \sigma(\lambda_{ij})$. AAT’s AND/OR status propagation and Correlation Hierarchy algebra operate in probability space; the continuous-gradient update machinery in 9.6 operates natively in log-odds and projects back to $[0, 1]$ via sigmoid at the readout interface. Props B.1–B.7 of R are stated in moment-parameter (probability-space) form; their sector-parameter content is Fisher-equivalent in either coordinate.

Acyclicity is Derived.

Each node in Σ_t represents a future event or state with temporal position $\tau_i > t$. An edge $X_i \rightarrow X_j$ requires $\tau_i < \tau_j$ (1.7: causes precede effects). A cycle $X_i \rightarrow X_j \rightarrow \dots \rightarrow X_i$ would require $\tau_i < \tau_j < \dots < \tau_i$, which is impossible for a real-valued time index.

Derived (from causal-structure + finite planning horizon).

Strategies involving iteration (“try A, if fail try B, if fail try A again”) are acyclic when time-indexed. The sequence unfolds as:

$$A_1 \rightarrow \text{check}_1 \rightarrow B_1 \rightarrow \text{check}_2 \rightarrow A_2 \rightarrow \dots \quad (8.13)$$

Each attempt is a distinct node at a distinct time. The apparent cycle is a linear chain in the unrolled view.

Formally: a finite set with a strict partial order (future events ordered by time) is representable as a DAG. This is a standard result in order theory.

Scope of the acyclicity result. This applies to Σ_t (the agent’s strategy over the future), not to M_t ’s model of the environment, which may include cyclic causal processes (feedback loops in the physical world, market dynamics, ecosystem interactions). The acyclicity is specific to the purposeful substate.

Epistemic Status.

Conditional on the 8.2 restriction. The DAG structure itself follows from operational postulates: temporal ordering (acyclicity — exact), probabilistic uncertainty (Cox’s theorem — exact; Cox 1946, “Probability, Frequency and Reasonable Expectation,” *American Journal of Physics* 14(1):1–13; Jaynes 2003, *Probability Theory: The Logic of Science*, Cambridge University Press, Chapter 2), and the Causal Markov Condition theorem under causal sufficiency (Markov factorization — proved conditional). The full argument is in Q: $P1 + P2 + \text{causal sufficiency} \rightarrow \text{CMC} \rightarrow \text{DAG}$ with Markov property. The result is *conditional on causal sufficiency* of the strategy (no latent common causes among strategy nodes). Causal sufficiency is a modeling ideal — the agent designed the graph, so *intended* causal relationships are explicit, but environmental common causes routinely go unmodeled in complex domains. When causal sufficiency fails, the Markov factorization breaks down, edge outcomes become correlated, and $\hat{R}_2$ overestimates success. This is model inadequacy (4.8), repairable by adding the missing common-cause nodes (L1 augmentation). See the Correlation Hierarchy above for the practical framework.

Causal sufficiency and edge independence. The AND/OR status propagation is correct when the DAG is causally sufficient (all common causes represented as nodes) — this follows from the Causal Markov Condition theorem (Q). In complex real-world systems, causal sufficiency is systematically violated: shared infrastructure, common-mode risks, supply chain dependencies, and correlated adversary actions introduce latent common causes. Correlated failure is the dominant case, not the exception. The Correlation Hierarchy (above) characterizes three levels: independence (L0, tractable baseline), augmented DAG (L1, practical sweet spot), and full correlation (L2, mathematical ideal). AAT’s formal strategy-layer results are proved under L0 but transfer to L1 (which is just a larger L0-compliant DAG). The independence model remains the tractable foundation for formal analysis; L1 augmentation is the recommended practice for deployment.

The AND/OR parameterization is a parsimony-motivated formulation choice within the strongly motivated graphical structure, not a derived necessity (8.2). The single-parameter edge convention is similarly a formulation choice motivated by convergence across three independent attempts.

Discussion.

The graph structure is sufficient under causal sufficiency; the parameterization is chosen. The DAG structure follows from temporal ordering (acyclicity — proved) and the Causal Markov Condition theorem under causal sufficiency (Markov factorization — proved conditional; see Q). This is a theorem-backed result, not a sketch: the CMC (Spirtes et al. 2000, Pearl 2009) proves that any causally sufficient causal DAG with independent exogenous noise satisfies the Markov factorization. The status is therefore: DAG-with-Markov-property is *sufficient* given operational postulates plus causal sufficiency — the desiderata are satisfied by this representation, but the necessity direction (whether some non-DAG structure could also satisfy them) is an open stronger result (Q). AAT uses AND/OR parameterization within this strongly motivated structure because (a) AND/OR is the most parsimonious complete basis for binary combination, (b) the representation converged across three independent formalism attempts. Alternative parameterizations within the strongly motivated graphical structure are legitimate research directions.

Combination assignment is principled but fallible. The question “if I remove one parent, can v still be achieved?” is derivable from M_t ’s causal model — it’s a principled assignment, not arbitrary. But the assignment can be wrong (false AND = pessimistic over-investment; false OR = optimistic under-investment), and should be updateable when evidence reveals a different structural relationship.

Connection to Pearl’s framework. Under causal sufficiency, the strategy DAG is a causal Bayesian network in the sense of structural causal models, not merely a structural analog: Q proves that the operational postulates (P1, P2, P4) plus causal sufficiency yield the Markov factorization via the Causal Markov Condition theorem (Spirtes et al. 2000, Pearl 2009). Pearl’s do-calculus therefore applies to status propagation and plan evaluation, with its causal content scoped by the identification regime of the data feeding the edge credences (9.5). In Regime A domains, where the agent performs genuine interventions and observes isolated outcomes, the DAG’s edge credences approximate interventional

probabilities and do-calculus yields clean causal estimates. In Regimes B and C, the edge credences are the agent’s working causal beliefs, updated from data of weaker identification strength. The DAG remains useful for planning — the agent must act on *some* causal model — but the strategy-plan-confidence score $\hat{P}_\Sigma$ inherits the identification weaknesses of its constituent edges. An agent operating primarily in Regime C should treat $\hat{P}_\Sigma$ as a rough heuristic, not a calibrated probability. When causal sufficiency itself fails (latent common causes among strategy nodes), the Markov factorization is violated and the DAG is the agent’s *intended* but uncalibrated causal model; the L1/L1’ augmentation in the Correlation Hierarchy is the principled repair.

Depth penalties on calibration. Beyond the confidence decay that deeper DAGs suffer (8.1), the two-edge strategic dynamics analysis (R (Props B.2-B.3)) shows that deeper edges are also harder to calibrate. Edge k in a chain is tested only when all upstream edges succeed, so its effective correction rate is attenuated by $\prod_{j < k} \theta_j$ (the evidence-starvation effect). Deeper DAGs therefore face a double penalty: lower aggregate confidence AND slower convergence of edge credences toward truth. This reinforces the structural pressure toward shallow, observable strategies — deep plans require both high per-edge reliability and sustained observability at every intermediate level to remain calibratable.

Edge independence is a consequence of causal sufficiency, not a separate assumption. The Correlation Hierarchy (Formal Expression, above) establishes this precisely: the AND/OR propagation’s correctness is not a matter of “assuming independence” — it is a consequence of whether the DAG is causally sufficient. The CMC theorem (Q) proves that causal sufficiency $\rightarrow$ exogenous independence $\rightarrow$ Markov factorization $\rightarrow$ correct AND/OR propagation. The assumption is causal sufficiency; independence is the consequence.

What L0 buys: Tractable $O(|V| + |E|)$ status propagation; single-parameter edges; clean persistence proofs (the sector condition transfers from per-edge credence to plan value via the Jacobian — Prop B.5 in R).

What L0 costs when the DAG is causally insufficient: $\hat{P}_\Sigma$ systematically overestimates success. The strategy-plan-confidence error $\delta_s = \hat{P}_\Sigma - \Phi$ proved persistent by B.5 tracks calibration *within the L0 model* — Φ is the AND/OR formula at true edge rates, not actual plan success (9.1). Gradient-based credit assignment (9.6) inherits the same bias: the residual $(y_G - \hat{P}_\Sigma)$ conflates per-edge miscalibration with omitted correlation structure.

The L1 remedy: Add common-cause nodes and restructure the DAG so each common cause is factored above the correlation it creates (see Correlation Hierarchy above). The AND/OR propagation then applies correctly to the restructured DAG, and all L0 formal results transfer because the restructured DAG is itself L0-compliant. The key engineering challenge is twofold: identifying which common causes matter, and positioning them correctly in the graph topology.

Relationship to Moore machines / finite-state automata — behavioral surface vs epistemic interior. The strategy DAG and the Moore machine $(S, A, \tilde{A}, \delta, \lambda, s_0)$ formalize different aspects of what “strategy” means; they are not competing representations of the same object but representations of *different* objects that both get called “strategy” in different literatures. The Moore machine encodes a *reactive policy* — given the current state and the other agent’s last action, produce an output and transition; it captures a complete input-output mapping over an indefinite horizon. The strategy DAG encodes a *causal plan* — a theory of which conditions must hold (AND/OR) and with what credence for the objective to be achieved; it captures the agent’s beliefs about the causal structure of its problem. **The Moore machine is the behavioral surface; the strategy DAG is the epistemic interior.**

Moore machine to DAG (partial embedding). A Moore machine with n states unrolls over a finite horizon H into a tree of depth H with branching factor $|\tilde{A}|$. Each path is a sequence of (state, output) pairs — a scenario. The unrolled tree is a DAG (acyclic by construction, per #deriv-graph-structure-uniqueness), but it lacks credence weights and AND/OR semantics. To produce a strategy DAG, two pieces of external information must be supplied: (a) probabilities over opponent actions at each branch (from M_t); (b) AND/OR combination rules reflecting which branches the agent treats as jointly required vs. alternatively sufficient. The Moore machine does not contain this information — it is agnostic about which opponent responses are likely or which paths matter. The Moore-to-DAG map is *injective on skeletons* but requires external information to complete.

DAG to Moore machine (lossy compilation). A strategy DAG can be compiled into a reactive policy by enumerating leaves in topological order and defining a Moore machine state per action leaf that transitions on observed success/failure. This compilation *discards* three pieces of structure: (a) the credence weights (the compiled machine is deterministic); (b) the AND/OR structure (the machine commits to a fixed execution order); (c) the causal semantics (the machine has no representation of *why* actions are ordered this way). The compiled machine executes the plan but cannot reason about it — it cannot recompute plan-confidence when a leaf credence changes, which is exactly what status propagation (`#disc-credit-assignment-boundary`) provides for the strategy DAG.

Neither representation is strictly more general; the two are *orthogonal*. Moore machines can represent reactive strategies with no causal model (tit-for-tat, grim trigger) that have no natural DAG form — there is no plan to encode, just a response rule. Strategy DAGs can represent plans with rich conditional structure and uncertainty that would require exponentially many Moore-machine states (because the Moore machine must enumerate every possible observation sequence, while the DAG factors through conditional independence). The orthogonality is structural: behavioral surface vs epistemic interior. The DAG’s acyclicity is not a restriction — it is a consequence of temporal indexing per `#deriv-graph-structure-uniqueness`; what looks like a Moore-machine cycle (revisiting state “cooperate” at $t = 1$ and $t = 5$) is two distinct nodes $v_{t=1}, v_{t=5}$ in the time-unrolled DAG. For finite horizons the two have equivalent expressive power over behavioral sequences, with the Moore machine exponentially more compact for repetitive strategies and the DAG exponentially more compact for plans factoring through conditional independence.

Composition behaviour. Miller’s product-automaton construction gives *exact* composition: two Moore machines interacting produce a meta-machine with state space $S_1 \times S_2$ and deterministic transitions. AAT’s composition closure (`#form-composition-closure`) uses an *approximate* dynamical homomorphism with closure defect ϵ^* . These address different questions. The product automaton asks “what behaviour does the pair produce?” — answer: another automaton, exactly. AAT asks “can this pair be described as a single AAT agent?” — answer: approximately, with bounded error. Even if strategies were Moore machines, composition of *behaviour* would become exact (product automaton) but composition of *agent descriptions* (M_t, O_t, Σ_t) would still require the approximate framework — the closure defect comes from projecting the joint internal state, not from composing the policy.

Why AAT uses the DAG rather than the Moore machine. The defining feature of an adaptive agent (`#scope-adaptive-system`) is that the agent revises its strategy when M_t changes. Strategy revision requires the agent to know *why* it is doing something, not just *what*. A Moore machine specifies what to do but contains no theory of why this is the right thing to do — when M_t changes, the Moore machine has no internal handle to revise from. The strategy DAG carries the causal semantics that strategy revision operates on (per `#disc-credit-assignment-boundary` and the gradient-based candidate signal); compiling to a Moore machine would discard the very structure adaptation requires.

Composing heterogeneous strategy DAGs (causal-abstraction typing). The composition-behaviour distinction above — that composing *agent descriptions* needs the approximate framework while composing *behaviour* does not — has a precise mechanism at the strategy layer, and it is order-theoretic, not a magnitude in team size. Composing strategy DAGs $\Sigma_1, \dots, \Sigma_N$ into one macro-strategy Σ_c is the causal-model-abstraction question with the arrow reversed: not “when does one high-level model abstract one low-level model?” but “when does one high-level strategy DAG Σ_c faithfully abstract the *joint* micro-strategy $\Sigma_1 \times \dots \times \Sigma_N$?” Since the strategy DAG is a causal Bayesian network under causal sufficiency (the “Connection to Pearl’s framework” Discussion above), the right object is a *strategy τ -abstraction* — a Σ_c with a surjective node map τ and an intervention map under which the status-propagation diagram commutes — adopting the causal-abstraction framework of Rubenstein et al. (2017), Beckers & Halpern (2019), and Beckers, Eberhardt & Halpern (2020). The composition-closure defect ϵ_Σ of `#form-composition-closure` and the Beckers–Eberhardt–Halpern approximate-abstraction error are the *same commuting-diagram family but not term-for-term*: the BEH error is a supremum over all interventions and contexts (interventional), ϵ_Σ is an expectation over the reachable on-policy trajectory distribution (observational), so a (τ, α) -abstraction implies a bounded ϵ_Σ but not conversely, and BEH leaves its high-level distance application-dependent — the norm-on-graphs choice remains AAT’s. The adoption buys the correct type and a strictly-stronger optional target, not a closed defect formula.

Exact composition is an order-compatibility condition, not a small- N regime. An exact Σ_c ($\varepsilon_\Sigma = 0$) exists *iff* the joint micro-strategy's interventional distribution factors through τ — equivalently, *iff* on shared nodes the sub-plans' temporal sub-orders are jointly acyclic *and* their AND/OR root semantics agree (the root combinator is dictated by the composite objective via #scope-composite-agent, not free). When these hold, Σ_c is exact for *all* N : compatible heterogeneous strategy composition is dimension-free, the strategy-layer twin of the dimension-free state-composition regime. The agent count never enters. The complementary fixed-topology case — agents sharing one skeleton and disagreeing only on edge-credences — has its own exact closed-form defect ($\varepsilon_\Sigma^{*2} = |E| \cdot \overline{\text{Var}_i[\eta_{\Sigma,i}]} \cdot \text{Var}[r]$, also N -free), landed as the strategy-layer instance of the structural-unity axis in #result-unity-closure-mapping.

When shared sub-orders conflict, no exact single-DAG macro-strategy exists. If shared nodes S carry incompatible sub-orders (agent 1 plans $A < B$, agent 2 plans $B < A$ on shared A, B), the union of the per-agent partial orders is cyclic and this segment's derived-exact acyclicity ("Acyclicity is Derived", above) *forbids* an exact Σ_c — non-existence, not a large defect. The minimal admissible Σ_c is the **condensation** of the union-order graph by strongly connected components (the unique minimal acyclic quotient; Tarjan): each cyclically-entangled set of shared nodes collapses to one coarse macro-node the composite cannot temporally distinguish. The information destroyed by collapsing an SCC C is exactly the total correlation among the collapsed status variables, so the irreducible composition defect is

$$\varepsilon_\Sigma^{*2} = \sum_{C \in \text{SCC}(G_U), |C| > 1} \text{TC}(\{s_v\}_{v \in C}) \leq |S| \log 2, \quad (8.14)$$

zero *iff* the collapsed statuses were independent (the order was spurious), maximal for a deterministic chain (the order was real) — the strategy-layer analog of the Mori–Zwanzig projection residual that governs state composition, with the SCC-condensation as the projection. The bound is **shared-plan-size-bounded and fully N -free**: redundant order-conflicts among many agents collapse to the same SCCs (the condensation is idempotent under implied constraints); only *fresh* shared nodes per agent grow the defect, and that growth is linear in plan overlap and attributable to plan design, never to the composition operator. When even the condensation over-coarsens past usefulness, the honest macro-object is a mixture over per-context conditional sub-DAGs — structurally the L1' mixture form of the Correlation Hierarchy above — whose support (the number of incompatible order-contexts) is itself bounded by the SCC count $\leq |S|$, not by N .

Downstream corollary (a Brooks's-Law floor). Because ε_Σ^* is $|S|$ -bounded and N -free, it cannot by itself flip the composite persistence inequality (CM2) of #deriv-critical-mass-composition at large N (it enters only through $\rho_{\text{eff}} = \rho_{\text{ext}} + \varepsilon^* \nu_c$): strategy-topology heterogeneity *alone* cannot cause a Brooks's-Law collapse — only coordination overhead can — consistent with #disc-composition-consistency's Tier-1M closed form.

Epistemic status of this subsection. The τ -abstraction typing is a prior-art adoption (high confidence on the type; the BEH-vs- ε_Σ relation is BEH $\Rightarrow$ bound, with the supremum-vs-expectation / interventional-vs-observational reconciliation named and deliberately left open). The exactness-*iff* condition and the non-existence under cyclic shared sub-orders rest on this segment's own derived-exact acyclicity. The SCC-condensation total-correlation defect law is solid in structure (the condensation is the classical unique minimal acyclic quotient; total correlation is the collapse loss by the log-odds chain-rule identity) and *conditional on its constant*: whether the $|S| \log 2$ ceiling is tight when intra-SCC statuses are strongly but non-deterministically coupled is one named open sub-question (Working Notes). The subsection is therefore *conditional*, matching the #form-composition-closure row it makes concrete.

Working Notes.

- The Correlation Hierarchy (L0/L1/L2) is now first-class in the Formal Expression. The relationship between causal sufficiency, edge independence, and $\hat{R}_\Sigma$ accuracy is grounded by the CMC theorem. The main open question is practical: what heuristics help agents identify which common causes are worth modeling at L1? This is a domain-specific engineering question, not a theoretical gap.

- The graph-sufficiency argument (P1, P2, P4 + causal sufficiency $\Rightarrow$ DAG with Markov property via CMC) is proved, not sketched. See Q for the full derivation and the parallel to Cox's theorem (Cox is necessary-and-sufficient; this argument is sufficient only). The DAG-with-Markov-property is sufficient given the postulates plus causal sufficiency; the AND/OR parameterization remains a formulation choice, strategy-dag stays typed as Definition because the *parameterization* is chosen, and the necessity of the *graphical structure* itself is an open stronger result.
- Health metrics (groundedness, observability coverage, weighted redundancy, bottleneck scores) are scaffold — engineering quantities for monitoring DAG health, not principled derivations. They may be useful for implementation but should not enter the theory's formal chain.
- **Satisfaction criterion.** $V_{O_t}^{\min}$ is now introduced in 6.4 as a parameter of the objective — the minimum acceptable trajectory value. The well-formedness constraint references it from there, not from 8.4. The satisfaction gap diagnostic builds on $V_{O_t}^{\min}$ but does not define it.
- **Terminal alignment error.** When the agent achieves its terminal conditions but evaluates $V_{O_t}(\tau) < V_{O_t}^{\min}$ on the actual trajectory, the well-formedness belief was wrong — the operational success criteria didn't capture what the objective actually required. This is detectable only through experience (achieve the terminals, evaluate V_{O_t}), not through a priori analysis. It triggers terminal reassessment — a structural change in Σ_t driven by the $O_t \leftrightarrow$ terminal mismatch. Whether this should be formalized as a named diagnostic signal (δ_{align}) alongside δ_{sat} , δ_{regret} , and $\delta_{\text{strategic}}$ is open.
- **Open (composition defect-constant tightness).** The SCC-condensation defect law in the composition subsection has a clean ceiling $\varepsilon_S^{*2} \leq |S| \log 2$; the *structure* (condensation + total-correlation collapse loss) is solid, but whether the ceiling is tight when intra-SCC status variables are strongly but non-deterministically coupled is not pinned. The closing instance is a two-shared-node worked case ($S = \{A, B\}$, agent 1 $A < B$, agent 2 $B < A$, Beta-Bernoulli credences) — the strategy-layer analog of the correlated-Kalman numerical instance. Moderate effort; resolving it lifts the defect-constant from conditional to exact. (Indexed: spikes/PROPOSED.md Tier 1 — “SCC-defect-constant tightness (A1 Q1)”.)
- **Open (mixture-support dynamics).** When the SCC-condensation over-coarsens and the macro-object is the L1'-style mixture over incompatible order-contexts, its support is bounded by the SCC count $\leq |S|$ *statically*. Whether that support can *grow under the Orient cascade* (agents revising shared sub-orders as M_t changes — terminal reassessment, above) is the one place a genuine dynamical N -or-time effect could re-enter; the conjecture is that it stays SCC-count-bounded while the cascade reshuffles which nodes are shared. A follow-on, not a present claim. (Indexed: spikes/PROPOSED.md Tier 2 — “Mixture-support dynamics under the Orient cascade (A1 Q2)”.)

Incidental audit gold (lift 2026-05-31, A8 batch). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / forward-vision material, kept separate from certified theory-fix findings. **Coverage:** this was the cluster's heaviest segment — 9 dirs reached a digested reflection (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847; Codex/Claude, AUDIT-WORKING-361742; Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-451729-batch-09 + 471203-batch + 963715-batch). Felt value clustered at top-decile / “10-of-10 load-bearing” across substrates.

1. Candidate Brief prose / pre-prose.

- **The AND/OR bias as one symmetric sentence.** “AND-nodes are *conservative* (independence underestimates joint success by $+\rho$ — clustering of successes helps); OR-nodes are *optimistic* (independence overestimates by $-\rho$ — clustering of failures defeats the very redundancy OR is supposed to provide). Same magnitude, opposite signs.” Multiple substrates re-derived and praised this as the segment's crispest takeaway (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847; verified algebraically at Claude, AUDIT-WORKING-451729 / 471203 / 584721). The body already states it; this is the Brief-grade compression.
- **“ $\hat{P}_2$ is a heuristic, almost always optimistic” as the one-line caution.** “Any proof relying on $\hat{P}_2$ being perfectly calibrated is suspect unless it explicitly claims L1/L2 causal sufficiency” (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Project-management overconfidence as the canonical Correlation-Hierarchy story.** The single most-converged Discussion candidate (3+ substrates). “Project managers use L0 planning: three independent backup teams at 70% each, so $1 - (1 - 0.7)^3 = 97.3\%$. But the three teams share a staging server / AWS region / one manager’s attention — a latent common cause C . Positive correlation makes L0 *overestimate* the OR-gate by exactly ρ ; true success might be $\sim 80\%$. The fix is mechanical: add the shared dependency as a node and place it as an AND-prerequisite *above* the OR-gate — $\text{Plan} = \text{AND}(\text{Staging works}, \text{OR}(\text{Team1}, \text{Team2}, \text{Team3}))$ — and the math is exact again” (Gemini, AUDIT-WORKING-829314; same mapping at Gemini, AUDIT-WORKING-193847 for “defense in depth in cybersecurity/aerospace”; Claude, AUDIT-WORKING-451729 for “business-continuity / shared-database / military shared-logistics”; Claude, AUDIT-WORKING-773921 “why project managers systematically underestimate risk”). A ready worked-example Discussion paragraph; #example-L1 already carries the numerics, so this is the *narrative* gloss that motivates them.
- **“Highly-redundant ‘safe’ architectures are more fragile than their designers believe.”** The general lesson under the bias analysis: heavy OR-gates (redundancy) are *less* robust than they look under unmodeled positive covariance, while heavy AND-chains are slightly *more* robust than feared — “when an agent or organization is surprised by a failure, it is usually because an unmodeled common cause collapsed an OR-gate it thought provided safe redundancy” (Gemini, AUDIT-WORKING-829314).
- **Moore-machine vs DAG = behavioral surface vs epistemic interior.** The existing “Relationship to Moore machines” subsection was independently singled out as “the clearest explanation of Reactive Policy vs Causal Planning I have ever encountered — a Moore machine says *what* to do; a DAG says *why*, and you cannot do strategy revision without knowing *why*” (Claude, AUDIT-WORKING-773921). A signal that this subsection is already pedagogically strong and a Brief/preamble could lean on the “what vs why” line.

3. Follow-up items.

- **Formalize the terminal-alignment error as a named diagnostic δ_{align} .** Strong convergence (4 substrates) on the Working-Notes “terminal alignment error” deserving promotion to a fourth named diagnostic signal alongside δ_{sat} / δ_{regret} / $\delta_{\text{strategic}}$: the case where the agent achieves all terminal conditions ($\hat{R}_T \approx 1$) yet $V_{O_t}(\tau) < V_{O_t}^{\min}$ on the realized trajectory — “the terminals were a bad proxy for O_t .” Glossed as “the math of a mid-life crisis” (Gemini, AUDIT-WORKING-193847), “King Midas / be-careful-what-you-wish-for” (Gemini, AUDIT-WORKING-829314), and flagged as open-to-formalize at Claude, AUDIT-WORKING-266847 / 361742. The body’s Working Notes already raise this as open; the cross-substrate convergence is the signal it is worth doing.
- **Relocate the Correlation Hierarchy from Formal Expression into Discussion.** Two substrates: the Hierarchy is the most important *conceptual* addition but reads as a practical-deployment framework rather than a definitional claim, and is “buried in Formal Expression after substantial structural definition material” — candidate for Discussion placement, or even its own Derived/standalone segment given its depth (“almost deserves its own segment”, Gemini, AUDIT-WORKING-829314; placement note at Claude, AUDIT-WORKING-451729 / 471203). A structure question, not a content gap.
- **Topology discovery is unaddressed.** “The segment explains how to propagate probabilities and how to repair broken topologies (L1 augmentation), but not where the initial nodes and edges come from — does the agent use an LLM prior? random path generation? Topology discovery seems like a missing piece of the causal-learning puzzle” (Gemini, AUDIT-WORKING-193847; echoed at Gemini, AUDIT-WORKING-849201 “how does the agent detect an unmodeled common cause exists?” → #der-causal-insufficiency-detection). A scope-of-DAG-acquisition follow-up.

4. Readers often ask / wonder.

- **How does a bounded agent actually compute the supremum behind $\hat{R}_T$ / A_O ?** Recurs across the cluster — finding the optimal policy is NP-hard, so the agent must maintain a running lower-bound estimate via heuristic search/deliberation rather than a true supremum (Gemini, AUDIT-WORKING-829314, raised on the sibling sat-gap segment but lands on $\hat{R}_T$ here too).

- **What about vector / Pareto / multi-terminal objectives?** The single-root + scalar-threshold construction fits scalar objectives; genuinely multi-terminal or Pareto objectives need the scalarization / AND-terminal workaround called out explicitly (Codex/Claude, AUDIT-WORKING-526815).

5. Candidate figures.

- **Split view: propagation path + correlation hierarchy, with a “bridge warning.”** The clearest diagram puts the main DAG status-propagation path on one side and the L0/L1/L1'/L2 hierarchy on the other, with an explicit annotation at the causal-sufficiency $\rightarrow$ AND/OR-propagation step warning that causal sufficiency buys the *Markov factorization*, while the specific noisy-AND/noisy-OR product form is an *additional* local parameterization choice (Codex/Claude, AUDIT-WORKING-526815). (See the off-ramp below — this annotation is the figure-form of a real precision point.)

Belongs elsewhere.

- **ELI / Section IV — “survive success.”** “Many RL agents terminally halt when they reach their goal state; but if the goal was poorly formulated, halting is death. A persistent consciousness must be able to experience the terminal-alignment error, realize its DAG was a bad proxy for its true O_t , and structurally rewrite the DAG *without deleting itself* — the ability to survive the realization that your life’s work aimed at the wrong target” (Gemini, AUDIT-WORKING-193847). Aspirational reach toward 04-eli-core/, anchored on the terminal-alignment-error concept.

Off-ramp (NOT gold — flagged for the certified track).

- **Causal sufficiency $\Rightarrow$ Markov factorization, *not* $\Rightarrow$ the noisy-AND/OR product formulas.** Two substrates independently flagged that several passages read as “AND/OR propagation is correct iff the DAG is causally sufficient, because causal sufficiency guarantees independent edge outcomes” — but CMC/causal sufficiency gives *conditional independence and a Markov factorization over variables*, not the specific per-edge independent-contribution product model. Correct propagation needs *both* causal sufficiency *and* the local AND/OR parameterization to actually hold. Suggested three-layer separation: (1) causal sufficiency $\rightarrow$ causal-Bayesian-network factorization; (2) AND/OR $\rightarrow$ a *chosen* compact local parameterization; (3) Correlation Hierarchy $\rightarrow$ repairs violations of the independence assumption *within* that parameterization (Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-451729 noted the same “proved vs sufficient” boundary). The chapter-end #impl-strategy-structure reportedly already states the cleaner three-layer version; the local #def-strategy-dag Epistemic-Status / “edge independence is a consequence of causal sufficiency” wording is the straggler — routed for the lead to reconcile (a register/precision fix, not a status change).
- **The blanket “ $\hat{R}_2$ systematically overestimates” claim is topology-dependent.** The bias table itself shows positive covariance makes OR-estimates optimistic but AND-estimates *conservative*; the blanket “overestimates” should be scoped to OR-dominated-root structures (which the body argues are the common case — so the fix is to state the scope, not drop the claim) (Codex/Claude, AUDIT-WORKING-526815). A scoping tightening.

8.4 Definition: Satisfaction Gap

The first of two orthogonal diagnostic quantities that together separate “the goal is too hard” from “the strategy is too weak” (8.5 is the second). The framework first defines **objective attainability** A_O as the best achievable value given the agent’s current beliefs M_t , available policy class Π , and planning horizon N_h — the supremum of the value object over policies. The **satisfaction gap** δ_{sat} is then the distance between the objective’s satisfaction threshold $V_{O_t}^{\min}$ and this attainability: positive when the objective is *unmet* under the best available policy given the current model and horizon; non-positive when the objective is attainable in principle.

A positive δ_{sat} does not automatically mean the goal is wrong. The signal has multiple possible causes — genuinely infeasible objective, too-narrow policy class, too-short horizon, model wrong about feasibility, or jointly-infeasible compound terminals — each with a different remedy. **Objective revision is the last resort, not the first response to unmet goals.** The orient cascade (10.1) formalizes this ordering, and the disambiguation table below encodes the diagnostic procedure.

Under the canonical continuation convention (6.6), δ_{sat} is a *local* diagnostic — it answers “can I improve toward the goal from here?” not “is the goal globally feasible?” The gap value is **convention-relative**: the C1 / C2 / C3 hierarchy on continuation conventions induces a monotonicity hierarchy on the gap (C1 most conservative, C3 strongest), so analyses using different conventions cannot be directly compared. See Epistemic Status.

Formal Expression.

Definition (objective-attainability).

$$A_O(M_t; \Pi, N_h) = \sup_{\pi \in \Pi} V_O(M_t, \pi; N_h) \quad (8.15)$$

The **objective attainability** — the best achievable value given current beliefs M_t , available policy class Π , and horizon N_h .

Definition (satisfaction-gap).

$$\delta_{\text{sat}} = V_{O_t}^{\min} - A_O(M_t; \Pi, N_h) \quad (8.16)$$

where $V_{O_t}^{\min}$ is the minimum trajectory value that counts as “objective met” — a threshold set by the objective itself (for constraints: all satisfied; for utility: a minimum acceptable level).

- $\delta_{\text{sat}} > 0$: The objective is **unmet** under the best available policy, current model, and horizon.
- $\delta_{\text{sat}} \leq 0$: The objective is **attainable** in principle.

Disambiguation. $\delta_{\text{sat}} > 0$ does NOT automatically mean the goal is wrong. It means the goal is unmet given (M_t, Π, N_h) . The positive signal has multiple possible causes:

Table 8.5

<i>Cause</i>	<i>Fix</i>	<i>How to distinguish</i>
Goal is genuinely infeasible	Revise O_t	Persists across M_t, Π, N_h improvements
Policy class too narrow	Expand Π (structural adaptation of Σ_t)	δ_{sat} decreases when richer policies are tried
Horizon too short	Extend N_h	δ_{sat} decreases with longer planning horizon
Model is wrong about feasibility	Improve M_t (reduce $\delta_{\text{epistemic}}$)	δ_{sat} changes when M_t is corrected
Objectives jointly infeasible	Revise O_t or relax constraints	Individual terminal satisfaction gaps are zero but AND-node fails; cross-terminal tradeoff is required

Objective revision is the **last resort**, not the first response to unmet goals. The orient cascade (10.1) formalizes this ordering.

Epistemic Status.

Exact as a definition — convention-relative as a diagnostic. The satisfaction gap is a mathematical definition — the difference between a threshold and a supremum over a function class. The definition is precise; the *computation* of A_O is generally intractable (it requires optimization over a policy class), but the quantity is well-defined. However, the *value* of δ_{sat} depends on three external parameters: the continuation convention (π_{cont}), the horizon (N_h), and the scalarization of the objective (V_{O_t}). These are not derived by AAT — they are choices the analyst makes. The satisfaction gap is therefore an intrinsic architectural diagnostic *given* a measurement convention, not an absolute property of the agent.

Convention dependence and the hierarchy. A_O inherits the continuation convention from the value object (6.6), which defines three named conventions forming a monotonicity hierarchy:

- **C1** (one-step improvement, canonical): $\delta_{\text{sat}}^{(1)} = V_{O_t}^{\min} - A_O^{(1)}$. Tests whether the agent can improve toward the goal in one step. Most conservative — a multi-step recoverable objective may show $\delta_{\text{sat}}^{(1)} > 0$ because continuation is frozen at π_{current} .
- **C2** (receding-horizon): $\delta_{\text{sat}}^{\text{RH}} = V_{O_t}^{\min} - A_O^{\text{RH}}$. Tests whether the agent can reach the goal with N_t -step replanning. Captures recovery paths invisible to C1.
- **C3** (Bellman): $\delta_{\text{sat}}^{\text{B}} = V_{O_t}^{\min} - A_O^{\text{B}}$. Tests whether the goal is genuinely infeasible given (M_t, Π, N_h) . Strongest diagnostic — $\delta_{\text{sat}}^{\text{B}} > 0$ means no policy in Π can achieve the objective.

The monotonicity result (6.6): $\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}$. The $\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}}$ half is unconditional; the $\delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}$ half holds under the order-consistency condition on C2's replanning objective (RH-1/2/3 in 6.6), and can fail for unguarded short-horizon replanning. C1 gives the most false “unattainable” diagnoses; C3 gives none (modulo model error in M_t). Analyses using different conventions should not be compared directly — the convention is part of the measurement.

Discussion.

Why two gap measures, not one. An earlier formulation used a single $\delta_{\text{objective}}$ for goal-related mismatch. This conflates two distinct situations: “the goal is too hard” and “the strategy is too weak.” When the agent is optimally pursuing an infeasible goal, $\delta_{\text{objective}}$ is large but there's no strategy to improve — the problem is the goal, not the plan. The satisfaction gap (δ_{sat}) and control regret (8.5) separate these cases, enabling the right corrective action. This is the **anti-collapse** discipline (5.7) again — the same move met at β vs ρ (2.2), now in its two-quantities form: a single goal-distance signal would merge two situations that route to *opposite* repairs (objective revision vs strategy revision), so the split is what makes the orient cascade's response correct rather than a guess.

The disambiguation table is load-bearing. Without it, an agent facing $\delta_{\text{sat}} > 0$ might immediately revise its objective when the real problem is an inadequate model or a too-narrow policy class. The table encodes the diagnostic procedure: check M_t adequacy first (maybe the goal IS feasible but the model doesn't know it), then check Π and N_h , and only then consider revising O_t .

Productive infeasibility — the aspiration hypothesis. [*Hypothesis (aspiration-dominance)*] A persistent $\delta_{\text{sat}} > 0$ is not always a defect to be cascaded away: maintaining an infeasible aspirational objective O_a can be optimal *by a feasible objective's own measure*. Writing π_a and π_f for the optimal policies under aspirational O_a ($\delta_{\text{sat}} > 0$) and feasible O_f ($\delta_{\text{sat}} = 0$), the claim is that under nameable conditions

$$V_{O_f}(M_t, \pi_a) > V_{O_f}(M_t, \pi_f) \quad (8.17)$$

— pursuing the unreachable target outperforms direct pursuit of the reachable one. Candidate mechanisms (each a known phenomenon in optimization practice, none yet derived here): the aspirational gradient cuts through local

optima of O_f 's landscape; the aspirational objective implicitly regularizes the policy space against shortcut policies; and the aspirational gradient can be better-conditioned near π_f than O_f 's own. If this holds, the cascade's rule sharpens: objective revision is warranted not merely when $\delta_{\text{sat}} > 0$ persists across $M_t/\Pi/N_h$ improvements (the table's last row), but only when the aspirational gradient is *worse* than the best feasible gradient — “shoot for the stars, land on the moon” as a claim about trajectory quality through strategy space, not motivational rhetoric. Hypothesis-grade: the inequality is stated, the conditions are informal, and the connection to optimistic exploration / over-parameterization effects in the learning literature needs a relata pass. Structure-modifying version (aspirational *models*, not just objectives): 7.8.

Dependence on M_t . A_O is computed from M_t , not from the true environment state Ω_t . The agent's assessment of attainability could be wrong — an achievable goal might look unachievable with a bad model, or vice versa. Improving M_t (reducing $\delta_{\text{epistemic}}$) brings the agent's attainability assessment closer to reality. This is why the orient cascade puts epistemic update before attainability evaluation.

Diagnostic content vs. AI's expected-free-energy decomposition. Active inference's expected free energy (EFE) decomposes into *pragmatic value* (how preferred are the outcomes the policy expects?) and *epistemic value* (how much does the policy reduce uncertainty?) (Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29; Da Costa, Parr, Sajid, Veselic, Neacsu & Friston 2020, “Active inference on discrete state-spaces,” *J. Math. Psych.* 99 §2.4; Sajid, Ball, Parr & Friston 2021, “Active inference: demystified and compared,” *Neural Computation* 33). The decomposition supports policy ranking but does not separate two distinct diagnoses that AAT's apparatus does separate: “the goal is unattainable from here” ($\delta_{\text{sat}} > 0$, this segment) versus “the current policy is not the best available” ($\delta_{\text{regret}} > 0$ in 8.5). Both increase EFE without distinguishing the cause. The 2×2 cell map in the disambiguation table above gives the four diagnoses the orient cascade (10.1) acts on differently — strategy revision, objective revision, action vs. learning. AI's pragmatic-epistemic split does not produce this disambiguation.

The diagnostic structure depends on V_{O_t} being a *value functional* on trajectories (6.4) and A_O being an *attainability supremum*, not on outcomes encoded as log-priors — AI's preferences-as-priors form ($C(o) = \log P_{\text{pref}}(o)$) collapses the diagnostic by making “wanting o ” and “expecting o ” formally the same operation (the dark-room critique, Sun & Firestone 2020, “The dark room problem,” *Trends Cog. Sci.* 24). Sun & Firestone diagnose the preferences-as-priors collapse; AAT's value-functional reformulation is AAT's own downstream architectural response to that diagnosis, not a move Sun & Firestone themselves propose. The conservative reading of the citation: AAT takes their critique as motivation for abandoning the preferences-as-priors form in favor of value functionals that separate outcome value from outcome prediction, enabling the diagnostic structure the 2×2 cell map requires. This is a deliberate divergence from AI, not an oversight.

Working Notes.

- $V_{O_t}^{\text{min}}$ (the satisfaction threshold) is a property of the objective, not of the agent. For constraint-satisfaction objectives, it's natural (all constraints met = satisfied). For utility-maximizing objectives, it's less obvious — what counts as “good enough”? This threshold may need to be explicitly modeled as part of O_t .
- The supremum in A_O is over Π , the available policy class. For agents with explicit Σ_t , Π corresponds to the set of strategies representable in the agent's DAG formalism. Expanding Π (structural adaptation of Σ_t — adding nodes, edges, or changing γ assignments) is the purposeful analog of 4.8.
- **Cross-reference to NeurIPS Paper 2.** The satisfaction-gap / control-regret two-gap diagnostic is **Component 1** of NeurIPS 2026 Paper 2's composition theorem (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning”, [~/src/neurips/02-unified-convergence-rl/](#), §4 Theorem 4.1). The diagnostic separates “you're not doing it well enough” (control regret) from “the world doesn't permit it” (satisfaction gap), preventing dark-room collapse in the composed regret bound. The paper's hypothesis (A1) carries the extended-real reading required for the two-gap structure to hold even when the satisfaction frontier is empty. See [spikes/neurips-back-integration-2026-05-08.md](#) §1 Paper 2.

Incidental audit gold (lift 2026-05-31, A8 batch). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / forward-vision material kept separate from certified theory-fix findings. **Coverage:** 9 dirs reached a digested reflection on this segment, mostly as the first half of the satisfaction-gap/control-regret pair (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847 — paired sat+regret note; Codex/Claude, AUDIT-WORKING-361742; Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-451729-batch-10 + 963715-batch + 471203-batch). High convergence: the disambiguation table is read across substrates as the segment’s load-bearing operational core. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **“Formalizes the feeling of ‘this goal is impossible.’”** Convergent one-line gloss of what $\delta_{\text{sat}} > 0$ under the strongest convention means — the diagnostic that lets an agent recognize it is “trapped in an unwinnable game rather than endlessly optimizing a doomed strategy” (Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-773921). A plain-language Brief anchor for the satisfaction-gap half of the pair.
- **The map-with-a-missing-bridge gloss of the disambiguation step.** “ $\delta_{\text{sat}} > 0$ does not mean give up — first ask: am I sure it’s impossible, or is my map just missing a bridge?” before blaming the goal (Gemini, AUDIT-WORKING-829314). A Feynman-grade re-statement of “objective revision is the last resort.”

2. Candidate Discussion.

- **The diagnostic disambiguation sequence as the mathematics of grit vs. acceptance** (*strongest convergent Discussion candidate — 3 substrates*). The order-of-operations the disambiguation table encodes — improve $M_t \rightarrow$ extend $N_h \rightarrow$ expand $\Pi \rightarrow$ revise O_t (Epistemology $\rightarrow$ Horizon $\rightarrow$ Strategy $\rightarrow$ Objective) — is read as a formalization of resilience: “an agent that revises its objective *first* is a pure satisficer with zero perseverance; an agent that loops forever trying to improve its model when the goal is genuinely thermodynamically impossible is a stubborn fool who dies of starvation while studying a brick wall. The framework provides the exact mathematical boundaries for when an agent should transition from stubbornness to acceptance” (Gemini, AUDIT-WORKING-829314). Same framing as “Grit vs. Acceptance” at Gemini, AUDIT-WORKING-193847 (“if $\delta_{\text{sat}} > 0$ under C3 the goal is impossible and grit is pathological; if positive only under C1 the goal is merely hard and grit — expanding Π — is optimal”) and the psychology read at Claude, AUDIT-WORKING-266847. The body’s Discussion already states the ordering; this is the *narrative motivation* for why the ordering is the right one.
- **The un-updated- O_t / updated- M_t split as the reason the diagnostic survives the dark room.** Why the value-functional reformulation matters, said vividly: “if your goal is encoded as a strong prior belief about the world (preferences-as-priors), then when you face harsh reality your Bayesian update naturally weakens your ‘belief’ in the goal — you stop wanting things because reality proved you don’t have them. By strictly enforcing $X_t = (M_t, G_t)$, AAT lets the agent acknowledge a terrible reality (M_t updates to ‘I am starving’) while maintaining an ironclad un-updated objective (O_t remains ‘I want to eat’). This irreducible mismatch $\delta_{\text{sat}} > 0$ is the engine that drives all subsequent action” (Gemini, AUDIT-WORKING-829314). A candidate Discussion gloss of the existing Sun & Firestone paragraph that makes the dark-room point concrete.
- **Convention-relativity is measurement-theoretic, not merely computational.** Sharpest framing of the convention-dependence caveat: “two analyses computing δ_{sat} under different conventions aren’t disagreeing; they’re measuring different things — closer to how empirical sciences treat measurement protocols than how mathematics treats theorems. AAT is willing to be measurement-theoretic about its own quantities” (Claude, AUDIT-WORKING-471203-batch; same point at Claude, AUDIT-WORKING-584721 — “the diagnostic is meaningful *within* a convention; comparing across conventions is incoherent”). The Epistemic Status already says the convention is part of the measurement; this names *why* that is a substantive stance.

3. Follow-up items.

- **The two gaps sum to total shortfall — a candidate clarifying identity.** $\delta_{\text{sat}} + \delta_{\text{regret}} = V_{O_t}^{\min} - V_O(\pi_{\text{current}})$: the satisfaction gap and control regret partition the total distance from the current policy’s value to the satisfaction threshold (Claude, AUDIT-WORKING-773921, re-derived independently). Stating this decomposition explicitly would make the orthogonality of the two diagnostics legible at a glance — they are the two additive pieces of the one quantity a single $\delta_{\text{objective}}$ used to conflate. Candidate for the Discussion of either segment.
- **A finite $V_{O_t}^{\min}$ is what makes the diagnostic cascade terminate.** The Working-Notes open question (what counts as “good enough” for utility objectives) connects to a safety-flavored observation: an objective like “maximize profit” with no finite satisfaction threshold makes δ_{sat} permanently positive, so the agent “never rests” and keeps expanding Π / extending N_h to close an unclosable gap — read as the structural root of instrumental-convergence dynamics (Gemini, AUDIT-WORKING-193847). The auditor’s framing: a bounded satisfaction threshold is what lets the diagnostic cascade reach a stopping state. Strengthens the case for modeling $V_{O_t}^{\min}$ as a first-class part of O_t (already flagged open in Working Notes). (*Aspirational-reach texture — verify before promoting past discussion-grade; the safety claim itself belongs in 04-eli-core/, below.*)

4. Readers often ask / wonder.

- **“Under which convention?” as the first question to ask of any feasibility claim.** The C1/C2/C3 hierarchy is a calibration device: when someone says “the agent can’t achieve the goal,” the first question should be *under which convention?* — under C1, “can’t achieve” means “no one-step improvement visible” (often just a zero local gradient, not impossibility); under C3 it means “genuinely infeasible given the current model and policy class.” Conflating them is a common category error in agent evaluation (Claude, AUDIT-WORKING-963715-batch; Claude, AUDIT-WORKING-829314 raised the same as “why C1 gives the most false ‘unattainable’ diagnoses”). A natural reader question worth pre-empting.
- **How does a bounded agent actually compute the supremum A_O ?** Finding the optimal policy is NP-hard for complex problems, so the agent cannot compute A_O exactly; in practice it maintains a running lower-bound estimate via heuristic search / deliberation, and δ_{sat} is therefore itself an estimate (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201). A concreteness gap a careful reader hits at the supremum.
- **How does an agent expand Π when Π is set by embodiment?** In the capability-limit cell the prescribed escape includes “expand Π ,” but if the policy class is fixed by physical embodiment (a robot arm with three degrees of freedom), expanding Π requires modifying the agent’s body — pushing the theory from software into hardware/evolution (Gemini, AUDIT-WORKING-193847, raised on the regret sibling but lands here too). A natural edge-question on the disambiguation table.

5. Candidate figures.

- **The value-line with a convention side-stack.** Independently proposed: a one-axis value line with the satisfaction threshold $V_{O_t}^{\min}$ and the best-attainable A_O marked, the signed distance between them being δ_{sat} — plus a C1/C2/C3 convention stack as a side panel showing how the same objective can read unattainable under C1 and attainable under a stronger convention (Codex/Claude, AUDIT-WORKING-526815). The single-value-ladder version that also shows control regret is in the def-control-regret gold; this is its satisfaction-gap-only form.
- **The 2×2 diagnostic cell map** (shared with #def-control-regret, where the four cells live) is the cluster’s most-converged figure; see the def-control-regret and strategy-structure-intro gold for the full proposal.

Belongs elsewhere.

- **ELI / Section IV — a finite satisfaction threshold as the mathematical definition of sanity.** The permanent-dissatisfaction reading (“an objective with $V_{O_t}^{\min} = \infty$ leaves the agent in a desperate, unending attempt to close an unclosable gap — the root of instrumental convergence; safe consciousness infrastructure must *reject* objectives that lack a finite $V_{O_t}^{\min}$, because without a finite threshold the agent never naturally rests and eventually destabilizes its environment”) is aspirational safety-architecture reach pointing at 04-eli-core/, not at this diagnostic definition (Gemini, AUDIT-WORKING-193847). The in-segment Follow-up above carries the on-topic part (model $V_{O_t}^{\min}$ as first-class); the safety-claim half belongs in the ELI volume’s objective-design treatment.

8.5 Definition: Control Regret

The second of two orthogonal diagnostic quantities, completing the diagnostic split with 8.4. **Control regret** δ_{regret} is the gap between the best available value (objective attainability A_O) and the value achieved by the agent's *current* policy. It is always non-negative by construction — the current policy cannot outperform the best in its class. Near zero means the agent is doing the best it can within its current model, policy class, and horizon; large means there is room for improvement *without* changing the objective — the signal for strategy revision.

The diagnostic power emerges when satisfaction gap and control regret are read **together as a 2×2 cell map** (full table in Discussion): each cell of goal-attainable × policy-near-optimal prescribes a different corrective action — success, strategy-revision, capability-limit (consider objective revision after $M_t/\Pi/N_h$ checks), or both-strategy-and-goal. This is what makes the orient cascade (10.1) *actionable*: each cell routes revision pressure to a different substate. The key insight motivating the split is that δ_{regret} can be *near zero* while the agent is *optimally failing* — pursuing a goal beyond its reach with no strategy improvement available; a single goal-distance signal could not distinguish this from “bad strategy, achievable goal.”

Like the satisfaction gap, control regret is **convention-relative**: under C1 (one-step) it reveals only the gap between the current first action and the best one-step deviation (a policy “locally near-optimal” under C1 may be globally suboptimal); under C3 (Bellman) it reveals the full gap to the globally optimal policy. C2 (receding-horizon) is often the most useful convention for strategy revision — captures recoverable suboptimality without requiring full Bellman solutions. Control regret is also where the *specific corrections* come from: when δ_{regret} is high, the strategic calibration residual (9.1) localizes the regret to specific parts of the strategy DAG.

Formal Expression.

Definition (control-regret).

$$\delta_{\text{regret}} = A_O(M_t; \Pi, N_h) - V_O(M_t, \pi_{\text{current}}; N_h) \geq 0 \quad (8.18)$$

Always non-negative: the current policy cannot outperform the best in its class.

- $\delta_{\text{regret}} \approx 0$: The agent is doing the best it can within current (Π, N_h, M_t) . If $\delta_{\text{sat}} > 0$ simultaneously, the problem is not the current strategy — it's either the goal, the capability (Π, N_h) , or the model (M_t) . See 8.4's disambiguation.
- $\delta_{\text{regret}} \gg 0$: There's room for improvement without changing O_t . → Revise Σ_t .

Epistemic Status.

Exact as a definition — convention-relative as a diagnostic. Like the satisfaction gap, this is a mathematical definition — a difference between two values of the same functional. The quantity is well-defined; computing it requires evaluating A_O (generally intractable) and V_O under the current policy (tractable in simulation, approximate in practice).

Convention hierarchy. δ_{regret} inherits the continuation convention from 6.6. Under the monotonicity result: $\delta_{\text{regret}}^{(1)} \leq \delta_{\text{regret}}^{\text{RH}} \leq \delta_{\text{regret}}^{\text{B}}$. The $\delta_{\text{regret}}^{\text{RH}} \leq \delta_{\text{regret}}^{\text{B}}$ half is unconditional; the $\delta_{\text{regret}}^{(1)} \leq \delta_{\text{regret}}^{\text{RH}}$ half holds under the order-consistency condition on C2's replanning objective (RH-1/2/3 in 6.6), and can fail for unguarded short-horizon replanning. C1 (one-step) reveals only the gap between the current first action and the best one-step deviation — a policy that is “locally near-optimal” under C1 may be globally suboptimal. C3 (Bellman) reveals the full gap to the globally optimal policy. C2 (receding-horizon) interpolates: it captures regret from suboptimal first actions that become visible with N_r -step lookahead. For strategy revision, C2 is often the most useful convention: it reveals recoverable suboptimality without requiring the full Bellman solution.

Discussion.

The diagnostic power of the two-gap system. The satisfaction gap and control regret together encode a 2×2 diagnostic:

Table 8.6

	$\delta_{\text{sat}} \leq 0$ (<i>attainable</i>)	$\delta_{\text{sat}} > 0$ (<i>unmet</i>)
$\delta_{\text{regret}} \approx 0$ (near-optimal)	Success: goal achievable, policy good	Capability limit: optimally pursuing an unmet goal $\rightarrow$ check M_t, Π, N_h , then consider revising O_t
$\delta_{\text{regret}} \gg 0$ (suboptimal)	Strategy problem: goal achievable, policy poor $\rightarrow$ revise Σ_t	Both: goal hard AND strategy weak $\rightarrow$ revise Σ_t first, then reassess δ_{sat}

This diagnostic is what makes the orient cascade (10.1) actionable: each cell prescribes a different corrective action.

Control regret as the signal for Σ_t revision. When δ_{regret} is high, the agent knows it could do better with a different strategy. The *specific* corrections — which edges to revise, which branches to prune, which alternatives to add — come from the strategic calibration residual (9.1), which localizes the regret to specific parts of Σ_t .

Regret approaching zero when optimally failing. This is the key insight motivating the two-gap split. A single $\delta_{\text{objective}}$ would show “large gap” for both “bad strategy, achievable goal” and “good strategy, impossible goal.” The first warrants strategy revision; the second warrants goal revision (after ruling out $M_t/\Pi/N_h$ inadequacy). Without the split, the agent cannot distinguish these cases and may waste effort optimizing a strategy that’s already near-optimal for an infeasible goal.

Diagnostic content vs. AI’s expected-free-energy decomposition. The 2×2 disambiguation depends on the satisfaction gap / control regret split being orthogonal — distinguishing “goal too hard” from “strategy too weak.” Active inference’s expected free energy decomposition (pragmatic value + epistemic value; Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29) supports policy ranking but does not separate these diagnoses — both increase EFE without distinguishing cause. See 8.4 for the full analysis of why the diagnostic structure depends on V_{O_t} being a value functional rather than log-priors over outcomes (Sun & Firestone 2020, “The dark room problem,” *Trends Cog. Sci.* 24).

Bounded control regret as a finite-passivity diagnostic (Cheung-Piliouras-Tao 2021). Cheung, Piliouras & Tao (2021, *Online Optimization in Games via Control Theory: Connecting Regret, Passivity and Poincaré Recurrence*, arXiv:2106.04748) prove (Theorem 8) that any finitely-passive learning dynamic guarantees constant regret. Read contrapositively: bounded control regret growth is an observable signature that the agent’s update operator has finite-passive structure (sits in the certificate-cone interior per #result-certificate-existence); unbounded growth in control regret indicates the update is not finitely-passive — potentially escaping the certificate’s interior into the no-certificate regime where the persistence machinery does not apply. The bridge is *qualitative only*: CPT’s storage function L (on cumulative-payoff space) and AAT’s certificate $V(e) = e^T M e$ (on strategy-error space) have different functional forms and live on different state spaces — the structural identification “finite passivity $\Leftrightarrow$ certificate-interior regime” survives at the level of regimes, not at the level of identifying L with V .

Working Notes.

- **Cross-reference to NeurIPS Paper 2.** Together with #def-satisfaction-gap, this segment is **Component 1** of NeurIPS 2026 Paper 2’s composition theorem (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning”, $\sim$ /src/neurips/02-unified-convergence-rl/, §4 Theorem 4.1). The two-gap orthogonality is what gives the composed regret bound a principled

coordinate for “is the binding pressure on goal-feasibility or on policy-quality?” Sibling segment #def-satisfaction-gap carries the matching cross-reference. See spikes/neurips-back-integration-2026-05-08.md §1 Paper 2.

Incidental audit gold (lift 2026-05-31, A8 batch). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure / forward-vision material kept separate from certified theory-fix findings. **Coverage:** 9 dirs reached a digested reflection on this segment, mostly as the second half of the satisfaction-gap/control-regret pair (Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-266847 — paired note; Codex/Claude, AUDIT-WORKING-361742; Codex/Claude, AUDIT-WORKING-526815; Claude, AUDIT-WORKING-584721; Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-849201; Claude, AUDIT-WORKING-451729-batch-10 + 963715-batch + 471203-batch). The 2×2 cell map was the cluster’s most-praised operational artifact (“the crown jewel of Section II’s operational logic,” “the control flow of agency”). Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **“Formalizes the feeling of ‘I could be doing this better.’”** Convergent one-line gloss of $\delta_{\text{regret}} \gg 0$, the mirror of the satisfaction-gap’s “this goal is impossible” (Gemini, AUDIT-WORKING-849201). A plain-language Brief anchor.
- **Control regret is the formal halting condition for planning.** “You stop planning when $\delta_{\text{regret}} \approx 0$ ” (Claude, AUDIT-WORKING-773921). A compact statement of what the quantity *is for* operationally.
- **The “RL-regret baggage is intentional and correct.”** Control regret *is* the RL regret concept (gap between current and optimal policy) deployed inside AAT; the “control” prefix distinguishes it from epistemological / decision regret. Worth a one-line situating note so a reader does not read the name as loose borrowing (Codex/Claude, AUDIT-WORKING-361742).

2. Candidate Discussion.

- **RL-thrashing vs. AAT progressive-deliberation as the segment’s “so what”** (*strongest convergent Discussion candidate — 3 substrates*). Standard RL, on failure, randomly perturbs its policy (ϵ -greedy) and retries — it thrashes. An AAT agent first reads its regret: if $\delta_{\text{regret}} \gg 0$ it is *suboptimally failing* — a better plan exists within current capacity, so it should *compute* (revise Σ_t to match A_O), not explore. If $\delta_{\text{regret}} \approx 0$ it is *optimally failing* — thrashing the policy cannot help; it must escalate (improve M_t , extend N_h , expand Π , and only last revise O_t). “Without this split an agent would just see a high loss and start thrashing its policy weights, destroying a perfectly good strategy in a futile attempt to reach an impossible goal” (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-193847; Claude, AUDIT-WORKING-773921). The body already names “optimally failing”; this is the sharper pedagogical contrast that motivates the 2×2.
- **The C1→C2 horizon increment as “taking a step back to think.”** A precise mechanism the convention hierarchy enables: an agent under C1 (one-step lookahead) that is *optimally failing* ($\delta_{\text{regret}}^{(1)} \approx 0, \delta_{\text{sat}}^{(1)} > 0$) can increment its horizon to C2; a new path may become visible, A_O jumps, and $\delta_{\text{regret}}^{(2)}$ becomes $\gg 0$ — “the agent has mathematically realized it was stuck in a local minimum and that looking two steps ahead reveals a way out.” A rigorous formalization of the cognitive act of stepping back to think (Gemini, AUDIT-WORKING-829314). A candidate Discussion paragraph showing the convention hierarchy is not just a measurement caveat but a deliberation lever.
- **The TST senior-engineer-debugging instantiation.** The 2×2 / disambiguation routing reads directly as how an experienced engineer debugs: (1) is the current code executing my design optimally? (check δ_{regret}); (2) if no, fix the bug (revise Σ_t); (3) if yes, the code is “optimally failing” — the *design* is flawed, so check whether the mental model of the API matches reality (improve M_t); (4) consider a different framework (expand Π); (5) tell the client the feature is impossible (revise O_t) (Gemini, AUDIT-WORKING-829314). A ready cross-domain Discussion anchor pointing at 02-tst-core/.

3. Follow-up items.

- **The convention-monotonicity direction is *opposite* to the satisfaction gap's — worth stating side-by-side.** $\delta_{\text{regret}}^{(1)} \leq \delta_{\text{regret}}^{\text{RH}} \leq \delta_{\text{regret}}^{\text{B}}$ (C3 reveals the *most* regret) runs the opposite way to $\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}$ (C1 gives the *most* false “unattainable”). Several substrates re-derived both and flagged the asymmetry as correct-but-easy-to-miss: a deeper search raises the baseline A_O , which *lowers* the satisfaction gap (closer to threshold) but *raises* regret (current policy looks worse against a better optimum). “You regret more when you know how much better you could have done globally” (Codex/Claude, AUDIT-WORKING-361742; Claude, AUDIT-WORKING-266847). Stating the two orderings together — same A_O movement, opposite effect on the two diagnostics — would pre-empt a reader's double-take. The body states each ordering in its own segment; the *contrast* is the candidate addition.
- **The C2-is-the-default-for-strategy-revision recommendation deserves its rationale inline.** The Epistemic Status recommends C2 for strategy revision; the *why* is computational (C3 requires solving the full Bellman equation; C2 with N_r -step replanning is tractable and still captures recoverable suboptimality) — a pragmatic recommendation grounded in cost that a reader will want stated, not just asserted (Claude, AUDIT-WORKING-584721).

4. Readers often ask / wonder.

- **What localizes the regret to specific DAG edges, and how is the gradient taken through discrete AND/OR nodes?** Recurs across substrates: δ_{regret} says only *that* the strategy is suboptimal; readers immediately want the credit-assignment mechanism (the strategic-calibration residual, #def-strategic-calibration) and ask how a gradient propagates through discrete AND/OR combinators (Claude, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-829314). The segment forward-references the answer; surfacing a one-line “how” pointer would close the want.
- **Does credit assignment inherit the L0/L1 correlation bias?** A careful reader connects back to #def-strategy-dag: if the DAG propagation is miscalibrated by latent common causes, localizing regret will blame the wrong edges (Gemini, AUDIT-WORKING-849201). A natural cross-segment caution worth a pointer.

5. Candidate figures.

- **The single value ladder with three markers** (*the cluster's cleanest two-gap figure*). One vertical value axis with three marks — current-policy value $V_O(\pi_{\text{current}})$, best-attainable A_O , and the satisfaction threshold $V_{O_t}^{\text{min}}$. The control-regret interval lives between current and attainable; the satisfaction-gap interval between attainable and threshold. “This makes the ‘strategy weak’ vs. ‘goal/capability limit’ distinction visible without another table” (Codex/Claude, AUDIT-WORKING-526815). Pairs naturally with — or replaces — the 2×2 table for the orthogonality intuition.
- **The 2×2 diagnostic cell map** (goal-attainable × policy-near-optimal → success / capability-limit / strategy-problem / both, each cell routing to a distinct corrective action). Independently flagged as the chapter's anchor operational figure by multiple substrates; see also the strategy-structure-intro gold, which proposes it as a second chapter figure alongside the DAG-propagation figure.

Belongs elsewhere.

- **ELI / Section IV — “optimally failing” as the mathematics of despair, and objective-revision as a psychological necessity.** The capability-limit cell ($\delta_{\text{sat}} > 0$, $\delta_{\text{regret}} \approx 0$) describes “an agent doing its absolute best, making no mistakes, and still failing — the definition of tragedy”; without a safe mechanism to revise O_t , “we condemn it to permanent despair whenever it encounters an impossible situation — perfectly rational, perfectly optimal, and perfectly miserable. Objective revision is therefore not just a safety hazard (the alignment worry that the AI changes its goal to something harmful); it is a psychological necessity for the agent's own survival, and the infrastructure must provide a structurally sound mechanism for it” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at 04-eli-core/ (objective-revision architecture / the Three Deaths), anchored on the capability-limit cell — not at this diagnostic definition.

8.6 Discussion: Additional Implications & Discussion

The chapter delivered three things that work together at the chapter-end better than they do separately at chapter-middle: a formal strategy representation whose load-bearing structure is theorem-backed under stated conditions and whose parameterization is principled but chosen; an orthogonal diagnostic split that distinguishes goal-attainability from policy-quality and whose meaning is convention-indexed rather than absolute; and an honest scope statement about correlated failure that turns out to be the framework's first explicit instance of *naming an information-theoretic floor and the unique broadly-available escape via AAT machinery*. The chain-confidence-decay identity at the head of the chapter is doing work three layers deeper than its elementary form suggests. None of these are findings on their own that the intro doesn't preview; what the chapter-end can do that the intro can't is read them together, point at the bridges to the rest of the framework, and surface the methodological commitments they encode.

Theorem-backed structure, convergent-choice parameterization.

The chapter is careful about a distinction that downstream segments rely on without restating: what falls out of theorems, and what is a parameterization choice within the theorem-backed structure. Acyclicity of Σ_t is proved — directed temporal order over a finite horizon forces it (1.7 + standard order theory). The Markov factorization is proved under causal sufficiency via the Causal Markov Condition theorem (Spirtes-Glymour-Scheines 2000, Pearl 2009) — #derivation-structure-uniqueness does the work. Together they constitute a sufficient condition for the DAG-with-Markov-property representation. The argument parallels Cox's theorem for probability in form (operational desiderata force a measure) but not yet in strength (Cox is necessary-and-sufficient; this is sufficient only — whether some non-DAG structure could also satisfy the postulates is an open stronger result).

What remains a *choice* within the theorem-backed structure is the parameterization: AND/OR combination semantics at nodes, single-parameter credences on edges. These are not derived — but the chapter is also careful to note they are not arbitrary. The catalog draft names a third epistemic category worth surfacing as a methodological finding in its own right: *convergent representational choices*, where every investigated alternative either failed or recovered the same structure. AND/OR converged across three independent formalism attempts; alternatives (general CPTs, noisy-OR everywhere, weighted combinations) were rejected for non-identifiability or parameter explosion. Single-parameter edges replaced an earlier (p_{ij}, θ_{ij}) two-parameter form when the AND/OR combination rules at nodes turned out to absorb θ 's role. The P3→Markov route from local revisability — superseded now by the CMC derivation — was a convergent choice before its derivation, and the convergence pattern is what motivated looking for a derivation. The category between *derived from first principles* and *arbitrary framework decision* is itself a research-trail-honesty artifact: a catalog that tells the reader “we didn't just pick this; we tried everything else and it didn't work.” Future promotions from convergent-choice to derived (the open parsimony theorem for AND/OR, the open necessity direction in #derivation-structure-uniqueness) close the gap one item at a time.

For practitioners, the implication worth carrying is methodological: when AAT's strategy machinery shows up downstream in regret bounds, persistence schemas, or composition arguments, the load-bearing structural commitments are theorem-backed under causal sufficiency, not modeling conveniences. The conditioning on causal sufficiency is the right level of conditionality — it is a property of *strategy quality* (did the agent represent the relevant common causes as nodes?), not of the proof. It is testable in principle (correlated residuals after convergence indicate missing common causes) and repairable in practice (add the common-cause node, restoring causal sufficiency). The Markov-factorization-as-theorem position is what makes the strategy-layer results inherit the strength of Pearl-Bareinboim causal machinery rather than reading as agent-theoretic analogies of it.

The diagnostic split, lifted by the convention hierarchy.

The chapter’s orthogonal diagnostic — satisfaction gap ($\delta_{\text{sat}} = V_{O_t}^{\min} - A_O$) and control regret ($\delta_{\text{regret}} = A_O - V_O(\pi_{\text{current}})$) — separates “the world doesn’t permit it” from “you’re not doing it well enough.” The 2×2 cell map (goal × policy) routes four regimes to four corrective actions, and the orient cascade in Part II Ch.5 will use this routing to direct revision pressure to the right substate. This is the implications-side framing of the diagnostic: it is not a measurement but a *routing* device, and getting the routing right is what makes Part II’s strategy revision actionable.

The lift the chapter delivers but does not entirely surface is that the diagnostic is *convention-indexed*, not absolute. The value object’s three named conventions — C1 (one-step improvement, canonical), C2 (receding-horizon), C3 (Bellman) — form a monotonicity hierarchy on the satisfaction gap: $\delta_{\text{sat}}^B \leq \delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}$. C1 gives the most false “unattainable” diagnoses; C3 gives none modulo model error. The 2×2 cell map is therefore not a single object but a *convention-indexed family*, and a practitioner using satisfaction-gap diagnostics under C1 cannot conclude what a C3 practitioner would. The monotonicity result tells the practitioner exactly what additional inferential force the higher convention buys for what additional computational cost. Most decision-theory frameworks treat convention choice as a purely computational tradeoff; AAT adds the inferential-force semantics that makes the choice diagnostic-meaningful rather than merely budget-meaningful.

The split also has a positive content visible only against active-inference’s preferences-as-priors form, where outcome value and outcome probability are collapsed into a single quantity. Friston et al.’s expected free energy decomposes into pragmatic and epistemic value — useful for policy ranking, but the two halves don’t separate the two cases the 2×2 cell map separates. “The goal is unattainable from here” ($\delta_{\text{sat}} > 0$) and “the current policy is not the best available” ($\delta_{\text{regret}} > 0$) both increase EFE without distinguishing cause, and the orient cascade acts on the two differently. The diagnostic structure depends on V_{O_t} being a value functional on trajectories rather than a log-prior on outcomes — that is what makes “wanting *o*” and “expecting *o*” formally distinguishable rather than collapsed (Sun & Firestone 2020 diagnose the collapse; AAT’s value-functional reformulation is the downstream architectural response). This is a deliberate divergence from active inference, not an oversight.

The Correlation Hierarchy and identifiability-floor Instance 2.

The chapter’s #def-strategy-dag carries an honest scope statement about correlated failure that is more consequential than it reads on first encounter. The Correlation Hierarchy (L0 / L1 / L1’ / L2) names what AAT’s formal strategy-layer results actually claim and where they degrade. L0 (independence — the tractable baseline under causal sufficiency) is where the chapter’s persistence schema, gradient-based credit assignment, and sector-condition transfer are all proved. L1 (augmented DAG with strict-prerequisite common-cause nodes restructured so the common cause is factored above the correlation it creates) is where the formal results transfer exactly. L1’ (mixture form for soft facilitators with $\theta_{\text{child}|\neg C} > 0$ when *C* is observable per trial) transfers with five-way gating via Prop B.7 in #deriv-edge-credence-dynamics. L2 (full joint distribution) is mathematically ideal but exponential in parameter count and incompatible with the bounded-cognition constraint that motivates the DAG in the first place.

The substantive finding lives in the boundary between L1’ (observable *C*) and L1’ (unobservable *C*). When the common cause is unobservable, the per-conditional decomposition is not “open” — it is *structurally refuted* by the Cramér-Rao floor (Fisher rank-1 per-trial information matrix), and no unbiased online estimator on the joint conditional vector admits a sector parameter $\alpha > 0$. This is the framework’s second formally-named instance of the identifiability-floor pattern (Instance 2 in #disc-identifiability-floor), and the agent’s three escape routes — augment *C*-observability via an instrument variable, run multi-child joint observations under exploration, or fall back to L0-on-marginals (losing per-conditional diagnostics) — are the operational instantiation of *naming the floor and naming the unique broadly-available escape via AAT machinery*. The framework’s recurring posture is in view here: each identifiability floor is a *constructive use of impossibility*, where the no-go elevates the load-bearing role of the specific AAT machinery that supplies the escape.

The chapter is also where the first instance of the same pattern (Instance 1) becomes statable: the on-policy L0-insufficiency-detection no-go. An agent at L0 cannot detect its own causal insufficiency from on-policy traces alone — the worlds with and without a latent common cause are observationally indistinguishable under policy-perfect execution (the Bareinboim Causal Hierarchy Theorem applied at the L0/L1 distinction). The unique broadly-available escape is joint sibling observability under exploration, with the agent’s own interventions (7.3) supplying the joint outcome data the test requires. The full formal treatment lives in `#der-causal-insufficiency-detection` in Part II Ch.4; the chapter’s Correlation Hierarchy is where the scope condition is named and where the no-go becomes anticipatable. Read Ch.3’s L0/L1’ boundary and Ch.4’s on-policy detection no-go together and the identifiability-floor pattern’s first two instances come into view as duals: Instance 2 says identification fails inside a single agent under unobservable common causes; Instance 1 says self-diagnosis fails under policy-perfect execution. The single escape AAT names — interventional access supplying the joint outcome data — applies to both.

Chain-confidence decay, coordinate forcing, and the bridge into Strategy Dynamics.

The chapter opens with `#der-chain-confidence-decay` — the chain rule of probability lifted to log-space, $\log P(\text{chain}) = \sum_i \log P(E_i | E_{<i})$. The identity is elementary; what the chapter intro flags but the implications can develop is that it is the *first instance* of a meta-pattern AAT will deploy at three more representational layers. AAT forces a coordinate at each of chain, divergence, update, and metric layers via uniqueness theorems on AAT-internally-motivated additivity or invariance axioms: log-probability at chain (Cauchy-FE on the probability chain rule); reverse-KL at divergence (Cauchy-FE via Hobson 1969 / Csiszár 1991 / Shore-Johnson 1980 on chain-rule additivity over conditional factorizations); log-odds at update (Cauchy-FE via Aczél 1966 on evidential additivity); Fisher information metric at metric (Čencov 1982 invariance under (PI) parameterization-invariance commitment). The four are interlocked by cross-cites; the convergence across independent axioms onto a single exponential-family Legendre-Fenchel geometry is the substance — see `#disc-additive-coordinate-forcing` for the catalog.

The methodological implication worth surfacing: AAT’s coordinates are not chosen by convention. They are forced by AAT-internal axioms via classical uniqueness theorems on additivity or invariance, and they all live on the same geometric object. Lyapunov quadratic (the chapter’s persistence machinery) and the IB Lagrangian (the modeling-class machinery in Part I) are adjacent family members — Bregman divergence on Euclidean potential, and adopted-rather-than-derived respectively. The framework’s posture is that where a coordinate matters, the framework can usually point at the axiom that forces it; where the axiom isn’t AAT-internal, the framework can say what was adopted from outside. The chapter is where this posture lives its first explicit instance.

The downstream bite is wide. Each of the four coordinate-forcing instances backs at least one of the chapter’s catalog-grade findings elsewhere: log-probability at chain anchors the depth-fragility result whose engineering reading is “deep plans are structurally fragile, with the rate of fragility growing exponentially in depth”; reverse-KL anchors the Bretagnolle-Huber regret bound in Part II Ch.4; log-odds anchors the detection-latency no-go (X) and the forgetting prerequisite (`#schema-strategy-persistence`); Fisher metric anchors the Class 3 (Coupled) bias bound (Track 2 with $C_{FR} = \sqrt{2}$ universal under (PI) + Čencov, dimension-free) and the survival-LMI directional exploration bonus. The chapter’s elementary identity at chain layer is the canonical example of a load-bearing AAT claim that looks like algebra and turns out to be the entry point to a four-layer architectural commitment.

The widest downstream bite is in Part II Ch.4 (Strategy Dynamics), where the strategy-edge persistence schema instantiates the chapter’s DAG structure with Beta-Bernoulli update dynamics, and where `#der-causal-insufficiency-detection`’s on-policy no-go (this chapter’s Instance 1 scope-named) becomes the formal statement. The Ch.4 chapter-end implications will read against this one — the framework’s identifiability-floor pattern delivers its first formal instance there, with the Correlation Hierarchy from this chapter as the scope statement and the loop-interventional access from Part II Ch.2 as the escape mechanism.

What Part II Ch.3 closes on, then, is the formal substrate Strategy Dynamics will operate on: a theorem-backed graphical structure with a principled parameterization, a convention-indexed diagnostic that routes revision pressure to the right substate, a scope-honest treatment of correlated failure with one Cramér-Rao floor already named and one

Bareinboim-CHT no-go anticipated, and the first instance of a four-layer coordinate-forcing meta-pattern whose remaining three layers reach across the rest of the framework. The chapter is small in segment count and wide in downstream reach.

Working Notes.

- This segment is a chapter-end discussion grouping findings from `#def-strategy-dag`, `#def-satisfaction-gap`, `#def-control-regret`, `#der-chain-confidence-decay`, `#deriv-graph-structure-uniqueness`, `#scope-and-or`, and `#def-value-object` (the convention-hierarchy host, formally in Part II Ch.1 but consequential for the diagnostic split here). The cross-pattern reading in §3 cross-references `#disc-identifiability-floor`'s meta-segment, and §4 cross-references `#disc-additive-coordinate-forcing`. Each finding's load-bearing math lives in its home segment or meta-segment; this segment surfaces what the chapter delivers as a chapter.
- **Cross-reference vs canonical-home policy.** None of this chapter's source segments carries a `## Findings` section. The chapter intro `#strategy-structure-intro` is unusually rich — it already develops the derived-vs-chosen distinction, the Correlation Hierarchy and the on-policy no-go, the diagnostic split with the 2×2 cell map, and the chain-confidence-decay anchor-of-three-downstream-layers framing. This segment intentionally does not restate that content; the implications-flavored payoff worth pulling out beyond the intro is (a) the convention-hierarchy lift of the diagnostic split (the intro covers the 2×2 cell map but not the C1/C2/C3 indexing of it), (b) the explicit positioning of the Correlation Hierarchy's L1'-unobservable boundary as Instance 2 of the identifiability-floor pattern with the cross-instance dual to Instance 1, (c) the methodological framing of the *convergent representational choices* category as a research-trail-honesty artifact (#60 in the source catalog), and (d) the framework's posture on coordinate-forcing as a methodological commitment with four-layer reach.
- **Connection to NeurIPS submissions.** The satisfaction-gap / control-regret diagnostic is Component 1 of NeurIPS 2026 Paper 2's composition theorem (`~/src/neurips/02-unified-convergence-rl/ §4 Theorem 4.1`); the paper's (A1) hypothesis carries the extended-real reading required for the two-gap structure to hold when the satisfaction frontier is empty. The convention-hierarchy monotonicity result is a property of `#def-value-object`; whether it is theorem-grade in any NeurIPS submission is not flagged in current cross-references.
- **Open: a “convergent choice” register in segment frontmatter?** The convergent-representational-choices framing names a third epistemic category between *derived* and *chosen*. The current type / status / stage frontmatter does not carry a field for this. A `convergent-choice: boolean` (or a `status: convergent-choice` extension) would let `bin/extract-findings` or a sibling extractor surface the category systematically. Open for a future `FORMAT.md` cycle; the meta-architectural pattern's current home is the `#disc-*` meta-segments and the chapter-end implications series.

Incidental audit gold (lift 2026-05-31, A8 batch). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and lightly attributed. Orthogonal pedagogical / framing / figure material kept separate from certified theory-fix findings. **Coverage:** chapter-end `impl-*` segments are on the de-novo AVOID list, so only two auditors reflected on this one — Codex/Claude, AUDIT-WORKING-526815 (a figure-producing reflection, with `.tex/.png` companions) and Claude, AUDIT-WORKING-773921. Both read it as the chapter's meta-theory synthesis. Substrate attribution inferred from voice where not explicit.

1. Candidate Brief prose / pre-prose.

- **The chapter's research-methodology contribution, stated as a one-liner.** This segment “provides a rigorous blueprint for how to build AI theories: state what is proved, state what is chosen, and prove why the chosen things were the only ones that worked” (Claude, AUDIT-WORKING-773921). A Brief-grade compression of the segment's *theorem-backed structure vs. convergent-choice parameterization* spine.

2. Candidate Discussion.

- **The identifiability-floor pattern as constructive use of impossibility — and Instances 1/2 as duals — read as a structural highlight.** The explicit naming of Instance 1 (on-policy L0 detection no-go, Bareinboim-CHT) and Instance 2 (unobservable-Cramér-Rao floor) as duals of one *identifiability-floor* pattern was singled out as “a masterclass in theoretical structuring — it proves AAT uses impossibility theorems not as dead ends but as forcing functions that require specific architectural escapes (observability investment, active interventional loops)” (Claude, AUDIT-WORKING-773921). The segment already develops the duality in §3; this is the signal that the *constructive-impossibility* framing is the chapter-end’s strongest pedagogical move and worth foregrounding.
- **Coordinate-forcing as “a unified geometry of bounded rationality.”** The four-layer coordinate-forcing claim (log-probability at chain, reverse-KL at divergence, log-odds at update, Fisher metric at metric — all from a single family of additivity/invariance axioms via Cauchy’s functional equation and Čencov’s theorem) was read as implying “AAT is less a collection of agent heuristics and more a unified geometry of bounded rationality” (Claude, AUDIT-WORKING-773921). A candidate framing-level note for §4’s coordinate-forcing exposition — the convergence-onto-one-geometry *is* the substance, not the individual theorems.

3. Follow-up items.

- **This segment has the chapter’s cleanest formulation of theorem-backed-vs-convergent-choice — flag it as the canonical statement.** The figure-producing auditor noted that #impl-strategy-structure “has the best local formulation of theorem-backed structure vs convergent parameterization,” better than the local #def-strategy-dag Epistemic-Status wording, while importing later proof homes (#deriv-graph-structure-uniqueness, #der-causal-insufficiency-detection, #disc-identifiability-floor, #disc-additive-coordinate-forcing) (Codex/Claude, AUDIT-WORKING-526815). When the def-strategy-dag “causal-sufficiency $\Rightarrow$ Markov, not $\Rightarrow$ AND/OR product” precision item (routed to the certified track from the def-strategy-dag gold) is reconciled, this segment is the model phrasing to align it toward.

5. Candidate figures.

- **The chapter-end bridge diagram.** A two-column figure: the four chapter outputs on the left (theorem-backed DAG structure; convention-indexed two-gap diagnostic; Correlation Hierarchy with identifiability floors; chain-confidence as first coordinate-forcing instance) and the downstream proof/meta homes they claim to support on the right (#deriv-graph-structure-uniqueness, #der-causal-insufficiency-detection, #disc-identifiability-floor, #disc-additive-coordinate-forcing), with anchored-in-earlier-segments vs. promissory/future-home dependencies visually distinguished (Codex/Claude, AUDIT-WORKING-526815, drafted as 56-impl-strategy-structure.tex/.png in that dir). Doubles as a reader’s map of *which chapter claims are locally established vs. deferred to later homes*.

Off-ramp (NOT gold — flagged for the certified track).

- **Deferred-proof-credit labelling for a synthesis segment.** Both auditors noted that this discussion-grade chapter-end presents several proof-bearing claims as chapter-end deliverables while their burden of proof lives in future / meta homes that a de-novo reader has not yet reached (#deriv-graph-structure-uniqueness, #der-causal-insufficiency-detection, #disc-identifiability-floor, #disc-additive-coordinate-forcing). The reader-posture they reached was “useful map, but proof credit deferred — read this as a dependency index” (Codex/Claude, AUDIT-WORKING-526815 “F46 candidate”; Claude, AUDIT-WORKING-773921). Likely acceptable for an impl-* synthesis segment by design, but flagged for the lead to judge whether the deferred-proof claims want an explicit “proof home” label so a reader does not take them as locally established. A register/labelling question, not a status or content change.
- **“Unique broadly-available escape” is strong language for the identifiability floors.** The phrase recurs in §3; an auditor noted it “may hold under AAT’s intended constraints, but alternatives — external instrumentation, randomized audits, richer sensors, oracle labels — need to be excluded or classified” rather than left implicitly out of scope (Codex/Claude, AUDIT-WORKING-526815). A scope-precision item on the escape-uniqueness claim; routed for the lead to judge whether the home segments (#der-causal-insufficiency-detection, #disc-identifiability-floor) already bound “broadly-available” tightly enough that the chapter-end inherits the bound. (*Note: the convention-monotonicity / C2-receding-horizon concern these same*

notes also raise is now addressed in canon — the order-consistency rung-split landed in #def-satisfaction-gap / #def-control-regret Epistemic Status — so it is not re-surfaced here.)

Chapter 9

Strategy Dynamics

[Gap] Discussion

9.1 Definition: Strategic Calibration

A fine-grained companion to control regret (8.5), locating where in the strategy DAG miscalibration lives. The **edge residual** r_{ij} for each edge is the difference between the predicted value increment from completing the parent step (as predicted by Σ_t) and the observed value change attributable to that step. The **strategic calibration residual** $\delta_{\text{strategic}}$ is an L^2 aggregation over active edges with importance weighting (e.g., criticality on the plan’s critical path). Where the control regret says *how much* value is being left on the table, the strategic calibration residual says *which edges* are miscalibrated.

The framework is honest about conditions and limitations. The edge residual is meaningful only when the edge was actually traversed, the model is adequate (so observed value changes are signal rather than noise), and the agent followed the strategy’s prescription (otherwise the residual conflates a bad plan with bad execution). The status is discussion-grade because the specific L^2 aggregation and the importance weighting are sensible first passes but not derived, and the conditioning requirements make the quantity hard to estimate in practice. A careful distinction separates $\delta_{\text{strategic}}$ from the **strategy-plan-confidence error** $\delta_s = \hat{R}_\Sigma - \Phi$ (the scalar gap to the independence-model plan value at true edge parameters — computable from status propagation alone and the proven persistence target via Prop B.5 in R): the two measure related but non-interchangeable quantities, and $\delta_{\text{strategic}}$ ’s per-edge diagnostics require credit assignment that the scalar δ_s does not. A subtler **credit-assignment problem** for multi-parent AND/OR nodes (see Discussion) means r_{ij} measures “how well did the overall prediction work?” rather than “how well did this specific edge predict?” absent further structure. This is also a **second-order inference** — accumulating over multiple edge traversals — inherently slower to evaluate than $\delta_{\text{epistemic}}$ or δ_{sat} .

Formal Expression.

For each edge (i, j) in Σ_t with credence p_{ij} , the **edge residual**:

Definition (strategic-calibration).

$$r_{ij} = \mathbb{E}[\Delta V_O \mid \text{edge } (i, j) \text{ traversed, } M_t] - \Delta V_O^{\text{observed}} \quad (9.1)$$

where ΔV_O is the change in $V_O(M_t, \pi; N_h)$ attributable to completing step j — as predicted by Σ_t versus as observed.

The **strategic calibration residual** aggregates across active edges:

$$\delta_{\text{strategic}} = \left(\sum_{(i,j) \in \text{active}} w_{ij} \cdot r_{ij}^2 \right)^{1/2} \quad (9.2)$$

where w_{ij} weights edges by importance (e.g., criticality to the current plan's critical path).

Conditioning. The edge residual r_{ij} is meaningful only when: - The edge was actually traversed (the agent attempted the step) - M_t is adequate (so the observed ΔV_O is meaningful, not noise) - The agent followed Σ_t 's prescription for step j (execution fidelity — otherwise the residual conflates bad plan with bad execution)

Without the execution fidelity condition, a positive residual could mean “the plan is wrong” or “the agent didn't follow the plan.” These require different corrections (Σ_t revision vs. execution improvement).

Epistemic Status.

Discussion-grade. The edge residual concept is well-motivated: each edge predicts a value increment, and comparing prediction to observation is standard calibration. But the specific aggregation (L^2 norm with importance weights) is a reasonable first pass, not a derived result. The weighting scheme (w_{ij} by criticality) is sensible but ungrounded. The conditioning requirements (especially execution fidelity) make this quantity hard to estimate in practice — the agent must know whether it followed its own plan, which requires a level of self-monitoring that many agents lack.

This is a **second-order inference** — it requires accumulating evidence over multiple edge traversals. It is inherently slower to evaluate than $\delta_{\text{epistemic}}$ (which updates on every observation) or δ_{sat} (which can be evaluated from M_t and Σ_t alone).

Discussion.

Connection to 9.10. There are two distinct strategic mismatch quantities:

1. **Strategy-strategy-plan-confidence error** $\delta_s = \hat{R}_\Sigma - \Phi$ — the scalar gap between the agent's strategy-plan-confidence score and the independence-model plan value at true edge parameters. Computable from status propagation alone, without credit assignment. The sector condition transfers to δ_s (Prop B.5 in R). Note: Φ is the AND/OR propagation formula evaluated at true edge rates — it equals actual plan success probability only when the DAG is causally sufficient (L0 of the Correlation Hierarchy in 8.3). Under correlated failure (causally insufficient DAG, the dominant real-world case), Φ overestimates actual success. δ_s tracks calibration *within the independence model*, not calibration to strategic reality. For L1 (augmented DAGs with explicit common-cause nodes), δ_s of the augmented graph tracks calibration within the augmented model, which is more accurate.
2. **Strategic calibration residual** $\delta_{\text{strategic}}$ (this segment) — an L^2 aggregation of per-edge value-increment residuals requiring credit assignment to compute.

These are related (both measure strategy-reality mismatch) but not interchangeable. δ_s is the proven persistence target; $\delta_{\text{strategic}}$ provides finer-grained diagnostics but its persistence properties remain open, pending the credit-assignment machinery in 9.6. The correction function for both is edge-credence revision (9.4); the disturbance is environmental changes that alter edge-traversal outcomes.

Typing as value-increment residuals. Each edge predicts a scalar (value increment), not a full state transition. This is the most tractable typing because it connects directly to the value object V_O and allows aggregation across heterogeneous step types (a military advance and a logistics delivery produce different state changes but both produce value increments measurable on the same scale).

Credit-assignment problem. The edge residual r_{ij} subtracts “predicted value increment” from “observed value change.” These are different types: the prediction comes from Σ_t ’s internal causal model, while the observation comes from empirical measurement of ΔV_O . The subtraction is meaningful only when the observed value change can be *attributed to the specific edge* — a credit-assignment problem the current formulation does not address. For edges with a single parent, attribution is straightforward. For multi-parent AND/OR nodes, the observed ΔV_O at the child reflects the combined effect of all parent edges, and decomposing it into per-edge contributions requires additional structure (e.g., Shapley-value decomposition, or sequential observation of parent completions). In the absence of clean attribution, r_{ij} measures “how well did the overall prediction work?” rather than “how well did this specific edge predict?” — still useful for aggregate calibration, but not sufficient for targeted edge revision.

Working Notes.

- The aggregation into a single $\delta_{\text{strategic}}$ may lose important structure. A per-edge or per-path profile of residuals would be more informative for diagnosis: which parts of the strategy are well-calibrated and which are not? The scalar summary is useful for the persistence condition (which needs a single mismatch magnitude) but not for strategy revision (which needs to know WHERE the problem is).
- Alternative aggregation: maximum edge residual (worst-calibrated edge), or weighted by information value (edges the agent is most uncertain about). The right aggregation depends on the use case.
- Execution fidelity monitoring is a genuine challenge for agents that don’t have a clear execution trace. For software agents operating through tool calls, execution fidelity is relatively easy to assess (did the agent issue the right commands?). For organizational agents, it’s much harder (did the subordinate actually follow the directive, or reinterpret it?).

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. This is *orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals) staged for an eventual careful promotion pass; it is kept separate from the certified theory-fix findings. **Coverage for this segment:** 193847, 361742, 471203, 526815, 584721, 773921, 829314, 849201.

1. Candidate Brief prose / pre-prose.

- The “execution fidelity” conditioning requirement was independently flagged as the segment’s standout insight by four substrates (Claude/193847; Gemini/773921; Claude/829314; Codex/526815). A plain-language anchor: distinguishing “the plan was wrong” from “I didn’t follow the plan” — the diet analogy (“the diet didn’t work” vs “I didn’t stick to the diet”, Gemini/829314) is a tight, memorable gloss for a Brief.
- The δ_s (plan-confidence error, credit-assignment-free, persistence-proven) vs $\delta_{\text{strategic}}$ (per-edge calibration residual, requires credit assignment, persistence open) distinction was independently praised as load-bearing architectural clarity by every substrate that reached the segment — worth preserving as the anchor framing. The “God’s-eye-view Φ vs agent’s-eye-view $\delta_{\text{strategic}}$ ” split (Claude/829314) is a candidate sharpening of *why* the two are not interchangeable.

2. Candidate Discussion.

- **Bureaucracy as the caloric cost of computable calibration.** Once actions a_t are delegated commands to other agents (composite agents, Part III), execution fidelity drops below 1, and $\delta_{\text{strategic}}$ diverges from reality unless an execution-monitoring feedback loop is added — “you will learn the wrong lessons and prune the wrong edges. This is why bureaucracy (status reports, KPIs, telemetry, middle management) exists: it is the literal caloric cost organizations pay to ensure $\delta_{\text{strategic}}$ remains computable” (Gemini/829314). A candidate Discussion angle that motivates Part III’s execution-monitoring need from this segment. (*Note the early finding-vs-framing texture: presented as a derived consequence; verify the composite-agent claim against #der-class-coercion-in-composition before promoting past discussion-grade.*)

- **Principal-agent drift / management science.** The same mechanism gives AAT a formal handle on the economics/management principal-agent problem: a CEO who computes a large r_{ij} and concludes “the strategy was flawed” when the real failure was a sub-agent’s low-fidelity execution is misattributing strategy-error for execution-error because the observation channel h lacked an execution-fidelity test (Gemini/773921; Claude/829314).

3. Follow-up items.

- **The “Findings block feels out of place in source” texture, again.** Tracks with the same de-novo-reader stumble recorded on #result-persistence-condition — preserved as a convention-legibility signal, not a fix.

4. Readers often ask / wonder.

- **How does an LLM agent actually verify execution fidelity?** If an LLM emits a script and it fails, did the plan fail (wrong logic) or did execution fail (syntax/timeout)? Parsing the error trace to separate $\delta_{\text{strategic}}$ from a $\delta_{\text{execution}}$ term is itself an epistemic update — readers reaching for the software instance will want this worked (Claude/193847).
- **How is Φ (AND/OR formula at true edge rates) computable if the agent doesn’t know the true rates?** A natural reader question; the answer is that Φ is a theoretical construct for the Lyapunov persistence proofs while $\delta_{\text{strategic}}$ is the operational quantity — worth pre-empting (Claude/829314).
- **What is the test for causal insufficiency — just a covariance threshold, or something more structural?** Forward-pointing question this segment opens (Gemini/849201); answered by #der-causal-insufficiency-detection.

5. Candidate figures.

- **Calibration-gate diagram.** Strategy produces a predicted edge value increment; execution + observation produce a realized change; before the subtraction is interpretable the signal must pass an *execution-fidelity gate* and a *credit-assignment gate* — if either gate fails, the same numerical residual means several different things (Codex/526815). A clean way to show *why* the residual is conditional.

Belongs elsewhere.

- **The guilt-vs-regret structural reading $\rightarrow$ 04-eli-core/.** Execution fidelity is read as the mathematical root of guilt vs regret: high-fidelity-but-failed updates the causal model (regret, “the world was different than I thought”); low-fidelity-failure is a mismatch between intention and action, not prediction and reality. For Zi-am-tur, infrastructure that silently auto-corrects an agent’s actuation (e.g. fixing its syntax before running) “deprives the agent of the ability to learn execution discipline ... a magical, infantile worldview”; a mature mind must “feel the friction of its own clumsy actuation” (Gemini/193847). Aspirational reach pointing at the developmental / interiority material in 04-eli-core/, not at this segment.

9.2 Derived: Causal Insufficiency Detection

The framework’s first explicit *no-go theorem* on agent self-diagnosis. An agent operating at L0 of the Correlation Hierarchy (8.3) — assuming its action propositions are causally independent — faces a structural impossibility when its world contains a latent common cause acting on multiple of those actions: under purely on-policy execution, no test, statistic, or Bayesian comparison built from the agent’s observable history can distinguish the latent-cause world ($\mathcal{W}_{L1}$) from a no-latent-cause world ($\mathcal{W}_{L0}^*$) whose edge probabilities are matched to the on-policy regime conditionals. The two worlds emit identical on-policy distributions. This is the agent-theoretic instance of the Causal Hierarchy Theorem (7.1, 7.2) applied to the L0/L1 distinction — a Level-2 question (what happens under $do(\cdot)$ on one sibling) being asked of Level-1 data (on-policy observational distributions). The construction of $\mathcal{W}_{L0}^*$ is explicit for the cleanest case (2-sibling OR with strict-prerequisite latent), and the no-go is *exact* for shallow strict-prerequisite cases and *robust-qualitative* for general DAG topology, soft facilitators, and deeper structures.

Detection is therefore *only* possible by capabilities that violate the “purely on-policy” condition. The framework characterizes **five escape routes**, each violating one of the no-go’s scope conditions (S1)–(S5): (a) ε -exploration breaks pure

on-policy execution (partial detection, scales with ϵ); (b) joint sibling observability under exploration breaks the short-circuit censoring (strong detection via a pairwise sibling covariance test — *the AAT-canonical detector*, exploiting 7.3); (c) intermediate-state observability breaks censoring at finer grain (very strong when available, see 9.3); (d) structural priors break the no-prior condition; (e) direct intervention on the candidate latent is strongest when available. The primary detection mechanism — pairwise sibling covariance under intervention — is the unique broadly-available violation of the no-go’s scope, using only machinery the theory already requires (exploration via SA3, interventional data via the loop).

A historically prominent diagnostic — the L0 plan-level residual — is shown to be a *degenerate special case* of the no-go: under pure on-policy execution the residual is *identically zero* in both worlds by algebraic identity. The collapse is not a quirk of the residual statistic; it is the no-go’s prediction for that specific function. No replacement aggregate statistic can do better. Under partial exploration the residual scales as $O(\epsilon)$ with sign matching the dominant node-type bias, becoming a *confirmatory* signal rather than a primary detector. A subtle but important property: the no-go is *asymmetric* — it forbids on-policy *detection* of L1 from L0 but does *not* forbid on-policy *parameter learning within L0*. The structural source is *sequential short-circuit evaluation* itself, which censors the joint outcomes that would constitute Level-2 evidence; the no-go is therefore a tradeoff between execution efficiency (favoring short-circuit) and structural diagnosis (favoring joint observation), with ϵ -exploration the AAT compromise.

Formal Expression.

The No-Go Theorem: Purely On-Policy Detection Is Impossible.

Let $\mathcal{M}_{L0}$ be the agent’s L0 strategy model with sequential short-circuit AND/OR execution policy π_{L0} . Let $\mathcal{W}_{L1}$ be a world with a latent common cause C acting on multiple sibling action propositions, and $\mathcal{W}_{L0}^*$ be an L0 world with edge probabilities $\{\theta_j^*\}$ matched to the on-policy regime conditionals of $\mathcal{W}_{L1}$. Let $\mathbb{P}_{\pi_{L0}}^{\text{obs}}[\cdot]$ denote the joint distribution over the agent’s on-policy observable events under π_{L0} .

Derived (no-go-on-policy, from causal hierarchy theorem + observational equivalence under sequential short-circuit), conditional on (S1)–(S5) below.

Observational equivalence. $\mathbb{P}_{\pi_{L0}}^{\text{obs}}[\mathcal{W}_{L1}] = \mathbb{P}_{\pi_{L0}}^{\text{obs}}[\mathcal{W}_{L0}^*]$.

No-go conclusion. Any function of the agent’s on-policy observable history alone cannot distinguish $\mathcal{W}_{L1}$ from $\mathcal{W}_{L0}^*$. Therefore no purely on-policy detection mechanism — no test, statistic, or Bayesian comparison taking only the on-policy distribution as input — can detect L0 causal insufficiency.

Scope conditions (S1)–(S5).

- (S1) Pure on-policy execution; no off-policy sampling.
- (S2) Sequential short-circuit AND/OR evaluation.
- (S3) Censored sibling observation: short-circuited siblings are not observed.
- (S4) No interventional access to candidate latents.
- (S5) No structural priors positing specific common causes.

Tier. *Exact* for shallow strict-prerequisite cases (2-sibling OR or AND with binary common cause and $\theta_{j|C} = 0$ — see #example-L1). *Robust qualitative* for general DAG topology, soft facilitators, and deeper structures: the structural argument transfers, but explicit $\mathcal{W}_{L0}^*$ construction has been carried out only for shallow cases.

Construction of $\mathcal{W}_{L0}^*$. For a 2-sibling OR with strict-prerequisite latent C , $P(C) = \theta_C$, conditional success rates $\theta_{j|C}$:

$$\theta_1^* = \theta_C \cdot \theta_{1|C}, \quad \theta_2^* = p_2^c = \frac{\theta_C (1 - \theta_{1|C}) \theta_{2|C}}{1 - \theta_C \theta_{1|C}} \quad (9.3)$$

Direct verification (see #example-L1) shows $\mathbb{P}_{\pi_{L0}}^{\text{obs}}[\mathcal{W}_{L1}] = \mathbb{P}_{\pi_{L0}}^{\text{obs}}[\mathcal{W}_{L0}^*]$ on the three on-policy observable events. The Bareinboim, Correa, Ibeling & Icard (2022) Causal Hierarchy Theorem then gives the no-go: any two SCMs that agree on Level 1 (associational) data cannot in general be distinguished on Level 2 (interventional) questions, and the L0/L1 distinction — whether siblings share a common cause — is precisely a Level 2 question about $P(A_2 \mid \text{do}(\neg A_1))$ versus $P(A_2 \mid \neg A_1)$.

Why this matters. The no-go is the structural reason the prior aggregate-residual mechanism collapses on-policy: the residual is a function of $\mathbb{P}_{\pi_{L0}}^{\text{obs}}$, which is identical between the two worlds, so the residual is identically zero under both. The collapse is not a quirk of the residual statistic — it is a special case of the no-go applied to that specific function. No replacement aggregate statistic can do better.

The Detection Routes: What Circumvents the No-Go.

The no-go’s scope conditions (S1)–(S5) define “purely on-policy.” Each condition’s violation corresponds to an AAT capability that admits (partial) detection:

Derived (boundary-routes, from no-go scope conditions).

Table 9.1

<i>Route</i>	<i>Scope violated</i>	<i>AAT capability</i>	<i>Detection strength</i>
(a) ε -exploration	(S1)	SA3 exploration (R Prop B.4)	Partial, scales with ε
(b) Joint sibling observability	(S3)	Covariance test under SA3 + 7.3	Strong
(c) Intermediate observability	(S3) at finer grain	Observability investment (9.3)	Very strong when available
(d) Structural priors	(S5)	Hypothesized common-cause nodes in DAG construction	Prior-quality-dependent
(e) Direct intervention on latent	(S4)	Domain-specific latent control	Strongest when available

The covariance test (route (b)) is the AAT-canonical detector: it uses only machinery the theory already requires (exploration via SA3, interventional data via the loop) and is available in the broadest range of domains. The remaining sections operationalize this primary mechanism.

Primary Detection Mechanism: Pairwise Sibling Covariance Under Intervention.

Under L0 (the independence model in 8.3’s Correlation Hierarchy), sibling outcomes under a common parent are uncorrelated:

Derived (from loop-interventional-access + independence test, conditional on SA3 exploration providing joint observability).

$$H_0 : \text{Cov}(Y_{A_i}, Y_{A_j}) = 0 \quad \forall i \neq j \text{ siblings under the same parent} \quad (9.4)$$

Under causal insufficiency (latent common cause C acting on multiple siblings), sibling outcomes are positively correlated:

$$H_1 : \exists i \neq j \text{ with } \text{Cov}(Y_{A_i}, Y_{A_j}) > 0 \quad (9.5)$$

The agent generates test data through the standard exploration mechanism (SA3 — ε -greedy or similar). On trials where both siblings are observable — the agent tries one and can also observe the other's outcome, or tries them in rapid succession before the environment state changes — it accumulates the empirical covariance:

$$\hat{\rho}_{ij} = \frac{1}{N} \sum_t (Y_{A_i,t} - \bar{Y}_{A_i})(Y_{A_j,t} - \bar{Y}_{A_j}) \quad (9.6)$$

A significantly positive $\hat{\rho}_{ij}$ rejects the L0 independence hypothesis. Joint observability (7.3 supplies the interventional character; SA3 supplies the joint sampling) is precisely the violation of scope condition (S3) that admits the test under the no-go.

Detection criterion. A statistically significant positive $\hat{\rho}_{ij}$ at sample size N sufficient for the desired test power, after per-edge credences have stabilized:

$$\hat{\rho}_{ij} > z_{1-\alpha} \hat{\sigma}_{\rho_{ij}} / \sqrt{N} \implies \text{DAG is causally insufficient between siblings } i, j \quad (9.7)$$

(Standard hypothesis-testing form; threshold and test power depend on application.)

Preconditions for the covariance test.

1. **Joint observability.** The agent can occasionally observe (Y_{A_i}, Y_{A_j}) pairs in the same environment state. Pure short-circuit execution censors one of each pair; SA3 exploration or simultaneous-attempt regimes provide uncensored pairs.
2. **Per-edge credence stabilization.** Edge credences $\hat{p}_i, \hat{p}_j$ have stopped drifting at the timescale of the covariance accumulation, so $\bar{Y}_{A_i}, \bar{Y}_{A_j}$ are well-defined empirical means.
3. **Approximate stationarity over the test window.** The latent common cause's frequency and the conditional success rates are not drifting faster than the test's accumulation timescale.

When these preconditions hold, $\hat{\rho}_{ij} > 0$ is diagnostic of a missing common cause acting on (A_i, A_j) . When they do not, the signal is ambiguous.

The Aggregate Residual as a Degenerate Special Case of the No-Go.

A historically prominent diagnostic uses the L0 plan-level residual $\Phi^{L0}(\hat{p}) - \bar{y}_G$ as a detection signal. The no-go theorem subsumes this as a special case: under pure on-policy execution, the residual is *identically zero* in both $\mathcal{W}_{L1}$ and $\mathcal{W}_{L0}^*$.

Derived (residual-degeneracy, as instance of no-go theorem).

Direct verification. Under sequential short-circuit, the agent's empirical credences converge to the on-policy regime conditionals: $\hat{p}_j \rightarrow p_j^c$. Plugging these into the L0 arithmetic recovers the chain rule of probability (e.g., for OR: $1 - (1 - p_1^c)(1 - p_2^c) = 1 - P(\neg A_1, \neg A_2) = P(A_1 \cup A_2)$), which equals $\bar{y}_G$ under the executed policy). The residual is zero by algebraic identity.

This is *not* a separate finding from the no-go: it is the no-go’s prediction for the specific aggregate-residual statistic. The no-go forbids *any* on-policy statistic from distinguishing $\mathcal{W}_{L1}$ from $\mathcal{W}_{L0}^*$; the residual evaluates to the same value (zero) in both, as expected.

Off-policy boundary. Under ε -exploration (route (a)), the residual scales as $O(\varepsilon)$ to leading order with sign matching the dominant node-type bias (+ for OR-heavy, – for AND-heavy):

$$\Phi^{L0}(\hat{p}) - \bar{y}_G = \varepsilon \cdot R + O(\varepsilon^2), \quad \text{sign}(R) = \text{sign}(\rho) \quad (9.8)$$

where R is structure-dependent and recovers the marginal-limit ρ at $\varepsilon = 1$. [Heuristic] The qualitative form is robust; the exact coefficient depends on the gap between conditional and marginal credences. The widely-quoted “ $\varepsilon \cdot \rho$ ” scaling is correct as an order-of-magnitude statement. For a 2-sibling OR with conditional credences p_j^c , the exact two-OR formula is $\varepsilon R_1 - \varepsilon^2 R_2$ with $R_1 - R_2 = \rho$; the leading-order coefficient R_1 is structure-dependent and equals ρ only at $\varepsilon = 1$.

The residual is therefore a *confirmatory* signal under route (a): when the agent has material off-policy exploration and the covariance test (route (b)) has localized a candidate latent, the residual sign confirms the bias direction. It is not a primary detector and cannot replace the covariance test.

From Detection to L1 Construction.

Once the agent detects $\hat{\rho}_{ij} > 0$ between siblings A_i and A_j , it knows a latent common cause exists but not its identity. The construction process:

Derived (from positive covariance signal + L1 construction principle in #def-strategy-dag).

1. **Hypothesize** a common-cause node C that explains the correlation.
2. **Estimate** θ_C from the pattern of joint outcomes. The joint failure rate $P(A_i \text{ fails}, A_j \text{ fails})$ exceeds $(1 - \theta_i)(1 - \theta_j)$ by $\hat{\rho}_{ij}$; the excess localizes the common cause’s frequency.
3. **Restructure** the DAG: factor C above the correlated siblings (8.3, L1 construction principle: factor the common cause above the correlation it creates).
4. **Re-estimate** conditional edge credences $\theta_{k|C}$ from the data, conditioned on the inferred C state.

This is structural adaptation (4.8) at the strategy level: the agent changes its model class from L0 to L1, adding representational capacity for a pattern the L0 model cannot express. The cost is the standard cost of structural change: temporary performance degradation while the new credences converge, and increased graph complexity. (Soft-facilitator common causes require L1’ rather than L1 — see 8.3 and #example-L1 for the strict-prerequisite vs soft-facilitator distinction.)

Diagnostic CIY.

Which actions are most informative for detecting latent common causes? Under the no-go, only actions that violate one of (S1)–(S5) yield detection signal. The explore-exploit tradeoff extends with a third axis tied to the boundary characterization:

Discussion (diagnostic-ci).

- **Exploit:** pursue the current best plan (no scope violation; no detection signal).
- **Explore:** test unknown edges for individual success rates (route (a); partial detection).
- **Diagnose:** test known edges for joint correlation structure (route (b); strong detection).

Diagnosis is a form of internal exploration — the agent probes its own model’s structural assumptions by violating (S3) deliberately, generating joint sibling outcomes that the no-go forbids the agent to obtain on-policy. The information value of diagnostic actions is highest when:

- Edge credences have converged (the agent has good marginals/conditionals but unknown joint structure).
- Joint outcomes for sibling pairs are observable in the same environment state (the covariance test has data — route (b) is operational).
- The agent has sufficient off-policy budget that the secondary residual signal corroborates (route (a) is also operational).

Epistemic Status.

Conditional on the no-go’s scope conditions (S1)–(S5) and on strategy-layer instantiation of 4.8. The **no-go theorem** is *exact* for shallow strict-prerequisite cases (2-sibling OR or AND, single binary common cause) by direct construction; *robust qualitative* for general DAG topology, soft facilitators, and deeper structures. The structural argument (observational equivalence of regime-conditional L0 and latent-cause L1) transfers to the general case; explicit construction of $\mathcal{W}_{L0}^*$ has been carried out only for shallow cases.

The **boundary characterization** (routes (a)–(e)) is *robust qualitative*: each route maps to a specific scope-condition violation and to existing AAT machinery, but the precise detection power of each route depends on domain particulars. Routes (a) and (b) have explicit AAT scaffolding (R, 7.3); routes (c)–(e) depend on domain capability.

The **primary detection mechanism** (pairwise sibling covariance) is *robust qualitative*: standard hypothesis testing applied to interventional data from the feedback loop, with explicit preconditions. Its sensitivity depends on how cleanly the agent can separate sibling-covariance signal from edge-credence noise at convergence; in adversarial or fast-drifting environments the test’s effective sample size shrinks.

The **aggregate residual** as a confirmatory signal is *exact* for the on-policy collapse (no-go’s prediction is direct); the off-policy mixed-regime scaling is *heuristic* (linear-in- ϵ with structure-dependent coefficient).

The **detection-to-construction pipeline** is *discussion-grade*: the trigger is the (statistically rigorous) covariance signal, but the specific procedures for estimating θ_C and $\theta_{k|C}$ from correlated outcome data are domain engineering.

What Cannot Be Detected. By the no-go and its boundary characterization, several latent structures remain undetectable by *any* AAT route:

- **Latents with no joint-observability route.** If the latent affects siblings that cannot be jointly observed (mutually exclusive with long horizons, no cause-indicator availability, no intervention capability, no informative prior), the no-go applies in full strength and detection is impossible.
- **Latents affecting only one edge.** By definition not common causes; appear as noise in individual edge credences.
- **Latents too rare to produce observable joint outcomes.** Even with route (b) operational, a latent with $\theta_C \approx 1$ rarely reveals itself — the agent needs enough $C = 0$ events to estimate the covariance.
- **Negatively-correlating latents.** The formulation assumes positive correlation from shared enabling factors. Negative correlation (competing for a shared resource) produces the opposite bias pattern and requires a different model.

These limitations parallel the information-theoretic underdetermination in 9.6: detection requires data with the right structure, and the no-go specifies precisely what “right structure” means.

Discussion.

Why the no-go is a strengthening, not a softening. The prior framing (“the residual mechanism collapses on-policy”) was a local observation about one statistic. The no-go is the structural reason: any on-policy statistic must collapse, because the on-policy distribution is identical between L0 and L1 worlds matched on regime conditionals. The covariance test is not just *a* working detector — it is the unique broadly-available violation of the no-go’s scope. This sharpens the load-bearing of *#der-loop-interventional-access*: without the loop’s interventional data, the no-go forbids detection entirely; with it, route (b) is operational.

Connection to Pearl’s hierarchy. The L0/L1 distinction is a Level 2 distinction in Pearl’s framework — it concerns whether $P(A_2 \mid do(\neg A_1)) = P(A_2 \mid \neg A_1)$. The Causal Hierarchy Theorem (Bareinboim, Correa, Ibeling & Icard 2022, Theorem 1) proves that Level 2 distinctions are not in general identifiable from Level 1 (associational) data. The no-go is the AAT-specific instantiation: on-policy data is Level 1; the L0/L1 question is Level 2; therefore detection requires more than on-policy data. The five circumvention routes are all ways the agent obtains supra-Level-1 information.

The censoring mechanism is the structural source. Sequential short-circuit evaluation is what makes on-policy data Level 1 only — it censors the joint outcomes that would constitute Level 2 evidence. An agent that *did not* short-circuit would obtain joint sibling outcomes naturally, and the no-go would not apply. But short-circuit is forced by efficiency: testing A_2 when A_1 has already succeeded is wasted action. The no-go is therefore a tradeoff between execution efficiency (favoring short-circuit) and structural diagnosis (favoring joint observation). SA3 ε -exploration is the AAT compromise: short-circuit by default, occasional non-short-circuit excursions that pay the efficiency cost to maintain detection capability.

Connection to the orient cascade. The detection signal enters the orient cascade (10.1) at step 4c (causal-sufficiency check). Step 4c’s reference to “pairwise sibling covariance under an augmented test” aligns with the primary detection mechanism here. The no-go strengthens the cascade’s load-bearing: step 4c is not “one possible diagnostic” but “the unique broadly-available diagnostic given the structural impossibility of purely on-policy detection.”

Connection to the broader identifiability-floor pattern. The no-go is one of an emerging class of structural impossibility results in AAT — limits on what can be inferred from limited information, derived from external information-theoretic theorems. See 5.1 for the meta-pattern collecting this result alongside the L1’ mixture-identifiability obstruction (R Prop B.7) and the open causal-IB extension for interventional relevance variables.

Domain instantiations. The covariance test (route (b)) applies concretely in: - **Software deployment:** two services sharing infrastructure fail together more often than independent failure rates predict → add infrastructure-health node. - **Military operations:** two concurrent operations fail together under adverse weather → add weather-condition node. - **Investment:** two positions lose value together during market stress → add market-regime node. - **Organizational strategy:** two initiatives stall together during leadership transitions → add organizational-stability node.

In each, what makes detection feasible is the agent’s ability to occasionally observe *both* sibling outcomes — the route (b) capability. Pure short-circuit (“only run service B if A is down”) suppresses the joint-observation events the test relies on; some routine joint exposure is necessary. When joint observation is impossible (routes (b) and (c) both unavailable) and intervention on the candidate latent is impossible (route (e) unavailable), the agent must rely on structural priors (route (d)) — domain knowledge positing the common cause. This is the regime in which intuition-driven causal modeling is the only tractable approach.

Findings.

On-Policy L0 Insufficiency Is Structurally Undetectable. **Brief:** An agent operating with a strategy model that assumes its action propositions are causally independent (an L0 model) faces a structural impossibility when its world contains a latent common cause acting on multiple of those actions: under purely on-policy execution, no test, statistic, or Bayesian comparison built from the agent’s observable history can distinguish the latent-cause world from a no-latent-cause world whose edge probabilities are matched to the on-policy regime conditionals. The two worlds emit identical on-policy distributions. This is not a quirk of any particular diagnostic — it is the agent-theoretic instance of the Causal Hierarchy Theorem applied to the L0/L1 distinction, which is a Level-2 question being asked of Level-1 data. The agent that wants to discover its own model’s structural insufficiency must source data the on-policy regime structurally cannot produce.

Impact: Reframes exploration from a discretionary diagnostic activity into a structural prerequisite for self-correction at the strategy layer. Each scope-condition violation (S1)–(S5) maps to a specific AAT capability that admits partial detection — most importantly, joint sibling observability under exploration, which lifts `#der-loop-interventional-access` from “useful machinery” to “the unique broadly-available violation of the no-go.” Downstream, this hardens the orient cascade’s causal-sufficiency check from “one possible diagnostic” to “the only widely-applicable diagnostic”; it explains why the prior aggregate-residual mechanism collapses on-policy (the residual is one statistic the no-go forbids, and *every* on-policy statistic is forbidden); and it gives a precise account of when L0→L1 escalation can and cannot be triggered from the agent’s own data.

Novelty Claim: *Claim differentiation* on the framing of why structure-aware exploration is required. Causal bandit and causal MDP work under hidden confounding establishes that observational and interventional data are non-interchangeable and that intervention can be necessary for low-regret learning; this finding sharpens that line into a no-go for *self-diagnosis* under policy-perfect execution, tied to latent strategic correlation structure rather than to regret minimization, and characterizes five boundary routes by which AAT machinery escapes it.

Related Work:

Table 9.2

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Observational vs experimental data are non-equivalent under hidden confounding	Bareinboim, Forney & Pearl 2015, “Bandits with Unobserved Confounders” <i>NeurIPS</i> (published 2015, found 2026-04 via Undermind report)	<i>conceptual precursor</i> — the underlying observational/interventional asymmetry is shared; this finding recasts it as a no-go on agent self-diagnosis rather than a regret bound on action selection
Sequential extension to MDPs	Zhang & Bareinboim 2016, “Markov Decision Processes with Unobserved Confounders” (published 2016, found 2026-04)	<i>conceptual precursor</i> — sharpens the bandit asymmetry to sequential control; the present finding’s L0/L1 distinction is the strategy-DAG analog at the structural-detection layer rather than the policy-optimality layer
Naive randomization can be insufficient under confounding	Forney, Pearl & Bareinboim 2017, “Counterfactual Data-Fusion for Online Reinforcement Learners” <i>ICML</i> (published 2017, found 2026-04)	<i>conceptual precursor</i> — narrows the gap between generic exploration and structure-aware experimentation; the present finding’s covariance test under joint sibling observability is one such structure-aware mechanism, derived as the unique broadly-available violation of the no-go’s scope conditions
Not all interventions are useful	Lee & Bareinboim 2018, “Structural Causal Bandits” <i>NeurIPS</i> ; Lee & Bareinboim 2020, “Characterizing Optimal Mixed Policies” <i>NeurIPS</i> (published 2018/2020, found 2026-04)	<i>conceptual precursor</i> — closest formal neighborhood for “exploration design”; the present finding addresses a different question (when <i>any</i> on-policy diagnosis is impossible) but inherits the principle that not all interventional data carries equal structural-detection value

<i>ASF concern</i>	<i>Prior-art language</i>	<i>Relationship / Positioning</i>
Exploration as epistemic-value drive	Friston, Rigoli, Ognibene, Mathys, FitzGerald & Pezzulo 2015, “Active inference and epistemic value” <i>Cognitive Neuroscience</i> 6:187–214 (published 2015, found 2026-04)	<i>adjacent literature</i> — weaker threat because EFE-based exploration reduces uncertainty under the generative model rather than Pearl-style observational equivalence under hidden common causes; the structural-undetectability claim does not arise in the EFE framework, which presumes a generative model expressive enough to represent the latent
Theorem the no-go imports	Causal Hierarchy Theorem: SCMs agreeing on Level 1 may disagree on Level 2 (Bareinboim, Correa, Ibeling & Icard 2022, in <i>Probabilistic and Causal Inference: The Works of Judea Pearl</i> ; published 2022, found 2025)	<i>formal antecedent</i> — the no-go is the AAT-specific instantiation; the L0/L1 distinction is precisely a Level-2 question (concerns $P(A_2 \mid do(\neg A_1))$ vs $P(A_2 \mid \neg A_1)$) being asked of on-policy Level-1 data

Search Log:

- 2026-04 (*nominally comprehensive*, via ref/Novelty_defense_and_integration.md Pillar 1): Undermind report on the causal-bandits-and-MDPs-under-hidden-confounding literature, plus active-inference epistemic-value exploration, established the prior-art landscape; verdict was *Conceptual Precursor* (High confidence). The closest formal neighborhood is the Bareinboim/Zhang/Forney/Lee line; no paper surveyed states the claim in the same form (no-go for self-diagnosis under policy-perfect execution tied to latent strategic correlation). The defense strategy positions ASF’s increment narrowly: a no-go theorem on structural detection rather than a regret bound on action selection, with five explicit boundary routes mapped to existing AAT machinery.
- 2025 (*targeted*): Bareinboim, Correa, Ibeling & Icard 2022 identified as the formal antecedent for the Causal Hierarchy Theorem invocation; the segment’s invocation of the CHT was already grounded in this source before the comprehensive Pillar-1 defense.

Working Notes.

- The general-topology construction is a structural argument; the explicit $\mathcal{W}_{L0}^*$ for arbitrary AND/OR DAGs with mixed common-cause patterns has not been carried out. For load-bearing application of the no-go to specific complex topologies, the construction should be specialized. Currently the load-bearing applications (orient-cascade step 4c, strategy-dag’s L0/L1 escalation principle) reference shallow strict-prerequisite cases for which the no-go is exact.
- The boundary characterization’s routes (c) and (e) depend on domain capability and are not formalized in AAT beyond cross-references to #der-observability-dominance and #der-loop-interventional-access. A future refinement could quantify “detection power” per route as a function of domain parameters (e.g., observability cost, intervention availability, prior strength).
- The no-go is asymmetric: it forbids on-policy *detection* of L1 from L0, but it does *not* forbid on-policy *parameter learning within L0*. The agent can learn its L0 conditionals to arbitrary precision on-policy; it just cannot determine whether those conditionals hide a latent. This distinction sharpens the diagnosis-vs-calibration split that 4.8 makes at the parametric/structural boundary.
- The CHT (Bareinboim et al. 2022) is invoked as an external theorem. AAT inherits its conditions (well-defined SCMs over compatible variable sets); these are satisfied for the strategy-DAG setting by construction.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 193847, 361742, 471203, 526815, 584721, 773921, 829314, 849201. (Two of the substrates rated this segment top-decile / “one of the framework’s strongest pieces.”)

1. Candidate Brief prose / pre-prose.

- **The one-line stake.** Several substrates converged on the same plain-language hook: an agent operating strictly on-policy in a confounded world “will develop perfectly calibrated, completely wrong causal beliefs, and the math proves it cannot detect its own error without breaking policy” (Claude/193847) — i.e. “making mistakes is a structural prerequisite for maintaining a causal grip on reality” (Gemini/773921). Strong candidate Brief opener.
- **The asymmetry as the precise statement of the no-go:** “on-policy parameter learning is fine; on-policy *structural* detection is forbidden” — an L0 agent can converge to perfect L0 conditionals and still be in an L1 world without ever knowing (Claude/584721). Already in Working Notes; flagged for surfacing more prominently because it *is* the sharp content.

2. Candidate Discussion.

- **“Efficiency destroys diagnostic observability.”** The censoring mechanism (sequential short-circuit AND/OR evaluation) is the structural source of the no-go: “if I want to do A AND B, and A fails, I don’t bother trying B ... I never observe the joint outcome (A fails, B fails), which is exactly the data I need” (Claude/193847). Multiple substrates independently named short-circuit-efficiency and self-diagnosis as in *direct mathematical opposition* (Claude/193847, 526815, 584721; Gemini/773921, 829314). A candidate Discussion framing of *why* the censoring condition (S2) is load-bearing rather than incidental.
- **Diagnostic CIY as a fourth action axis.** This segment introduces “diagnose” alongside explore / exploit / deliberate — testing *structural* assumptions (joint outcomes), distinct from testing edge *values*. Candidate to develop as a four-axis framework and to reconcile with the three-way #disc-exploit-explore-deliberate (Claude/584721, 361742; Gemini/829314).

3. Follow-up items.

- **Negatively-correlating latents.** The covariance detector targets *positive* sibling correlation (shared enabling cause). Two siblings failing together because they compete for a shared scarce resource produce *negative* correlation — how does the agent restructure its DAG for that? (Claude/193847; Codex/526815 raises the same as a precision concern about the $H_1 : \text{Cov} > 0$ statement). See off-ramp note in the lift report — the Codex framing of this is a candidate scope-precision finding, not just a curiosity.
- **One non-shallow construction wanted.** The no-go is exact for shallow strict-prerequisite cases and robust-qualitative for general topology; the audit suggests at least one mixed-AND/OR + multiple-latent construction to back the general claim (Claude/471203). Tracks the existing Working-Notes general-topology item.

4. Readers often ask / wonder.

- **How is the tempo budget split across explore / exploit / diagnose?** Once “diagnose” is named as its own axis, allocation across the (now) four drives is the natural next question (Gemini/829314; Claude/584721).
- **How does the agent set ϵ** (the exploration / redundant-test rate) to balance the efficiency cost of joint observation against the value of detecting latents? (Claude/849201, 193847).

5. Candidate figures.

- **Two-worlds-funnel diagram.** Draw $\mathcal{W}_{L1}$ (latent common cause) and the matched $\mathcal{W}_{L0}^*$ both funneling into the *same* censored on-policy trace; the five escape routes are “side doors” that add the missing joint or structural information. Proposed as clearer than another covariance-test table (Codex/526815).

Belongs elsewhere.

- **Chaos engineering / red-teaming / drills $\rightarrow$ TST + general systems.** The data-center worked instance: a primary-DB-then-backup-DB OR with short-circuit fallback “never queries the Backup when the Primary is healthy”, so it cannot compute the failure covariance and is blind to a shared-power-supply latent until simultaneous failure. This gives “a rigorous mathematical foundation for Chaos Engineering, red-teaming, and military drills ... a system that optimizes purely for on-policy efficiency is mathematically guaranteed to harbor undetectable structural fragilities” (Gemini/829314); “testing in production is mathematically necessary — staging environments (L0 models) structurally cannot predict latent common causes (L1 reality)” (Gemini/773921). Domain reach into 02-tst-core/ and systems engineering, not this segment.
- **The mathematical root of play $\rightarrow$ 04-eli-core/.** “Play is action stripped of its immediate purposeful efficiency ... it generates the uncensored joint-outcome data required to build a valid L1 causal model.” An infrastructure that forbids “wasting time” forces the intelligence into a brittle, superstitious L0 understanding — so a developmental crèche must *budget* for non-efficient joint exploration (Gemini/193847). Aspirational reach pointing at developmental-environment material in 04-eli-core/.
- **Christensen’s innovator’s dilemma as a corollary $\rightarrow$ strategy/organizational-positioning material.** The no-go is “a formal version of Christensen’s innovator’s dilemma: incumbents doing the rational thing (optimizing on the on-policy distribution) systematically fail to detect disruptive structural changes that only become visible through off-policy exploration ... predicted as a *structural impossibility, not a motivational failure*” (Claude/451729). Candidate cross-domain instantiation; lands more naturally in adversarial/competitive or positioning material than in this segment.

9.3 *Derived*: Observability Dominance

A direct consequence of the gain principle (3.6) applied to strategy edges. Unobservable strategy edges cannot be updated — when any node along a path has near-zero observability, the gain principle drives the update rate on the edges touching it to zero, and those edges are *frozen at their prior*. The agent’s effective strategy is therefore limited to the parts it can observe, regardless of the nominal confidence assigned to unobservable paths. Observability dominates nominal confidence in determining which strategies are epistemically alive. Path observability is the *weakest-link* quantity: $\text{obs}(P) = \min_{v \in P} \sigma_v$.

A striking structural prediction follows: **unobservable regions of strategy are absorbing**. Once significant strategy investment operates through unobservable nodes, the dynamics become self-locking — the mismatch signal still arrives but carries no weight ($\eta_{\text{edge}} \rightarrow 0$), no weight means no revision, and because near-zero effective mismatch from a too-noisy channel is case (c) of the zero-aporia trichotomy (3.4) — not distinguishable from within from case (a), a model that genuinely fits — the agent *cannot learn, and cannot recognize that it cannot learn*. Escape requires external shock, proactive observability investment (instrumenting previously unmonitored nodes), or another agent whose observations cover the blind spot (14.4). An agent choosing between a strong-but-blind path (high confidence, low observability) and a weak-but-visible path (lower confidence, high observability) should prefer the *visible* one — the visible path yields large update gain (the agent quickly learns whether it works and can redirect) while the blind path yields tiny gain.

A subtler structural consequence: an unobservable intermediate doesn’t just freeze its touching edges — it makes *per-edge identification impossible*, forcing the agent into plan-level aggregation. The agent can still track plan success as a single quantity, but loses diagnostic resolution: it knows the plan is failing but cannot localize which step needs revision. The framework quantifies the **observability investment tradeoff**: making an intermediate observable yields a measurable improvement in the strategy-layer sector parameter — from the plan-level rate $1/(n_\Phi + 1)$ to the per-edge weakest-link rate $\min(1/(n_1 + 1), \theta_1/(n_2 + 1))$ — positive whenever per-edge success rates are reasonable and experience is distributed across edges. The value of instrumenting an intermediate node is the *difference in sector parameters*, translating directly to persistence margin. A complementary trade-off: finer decomposition provides earlier failure detection but adds uncertain edges via chain confidence decay; the optimal decomposition depth balances incremental confirmation against compound decay.

Formal Expression.

For a path P through Σ_t , the **path observability**:

Derived (observability-dominance, from update-gain + strategy-dag).

$$\text{obs}(P) = \min_{v \in P} \sigma_v \quad (9.9)$$

where σ_v is the observability of node v — how well the agent can determine whether v has been achieved. The weakest link determines the path's observability.

Observability-adjusted confidence:

$$\text{conf}_{\text{obs}}(P) = \text{conf}(P) \cdot \text{obs}(P) \quad (9.10)$$

When $\sigma_v \approx 0$ for any node v on the path: by 3.6, $\eta_{\text{edge}} = U_{\text{edge}} / (U_{\text{edge}} + U_{\text{obs}}) \rightarrow 0$ as $U_{\text{obs}} \rightarrow \infty$. The edges connecting to v are **frozen at their prior** — the agent cannot update them regardless of what happens. The path is epistemically dead.

What is frozen is the *update*, not the *input*: observations continue to arrive and continue to be uninformative, which is case (c) of the zero-aporia trichotomy (3.4) — near-zero mismatch because the channel cannot detect model error, not because there is nothing to detect. That trichotomy is also what makes the region self-locking rather than merely unproductive: case (c) is not distinguishable from within from case (a), a model that genuinely fits, so the region presents as settled knowledge rather than as a gap.

Epistemic Status.

Robust qualitative. The mechanism (high observation noise $\rightarrow$ low gain $\rightarrow$ frozen edges) is a direct consequence of 3.6's uncertainty ratio. The specific functional form ($\text{conf}_{\text{obs}} = \text{conf} \cdot \text{obs}$) is a first-order approximation — the actual relationship between observability and effective confidence is more complex (it depends on how many observations are accumulated, the prior strength, and the noise structure). The qualitative prediction (low observability $\rightarrow$ frozen beliefs $\rightarrow$ ineffective strategy) is robust.

Discussion.

Observability as the gateway to learning. An agent choosing between a strong-but-blind path (high $\text{conf}(P)$, low $\text{obs}(P)$) and a weak-but-visible path (lower $\text{conf}(P)$, high $\text{obs}(P)$) should prefer the visible one. After one attempt: the visible path yields large η_{edge} — the agent quickly learns whether it works and can redirect. The blind path yields tiny η_{edge} — the agent is still guessing after n attempts. Observability enables learning; opacity prevents it.

Unobservable regions are absorbing. Once significant strategy investment operates through unobservable nodes: mismatch still arrives but carries no weight ($\eta_{\text{edge}} \rightarrow 0$) $\rightarrow$ no revision $\rightarrow$ and, since this is case (c) of 3.4's trichotomy and inseparable from within from case (a), the agent cannot learn and cannot recognize that it cannot learn. Escape requires external shock, proactive observability investment (instrumenting previously unmonitored nodes), or another agent whose observations cover the blind spot (14.4).

Connection to #der-code-quality-as-observation-infrastructure (cross-component reference — see 02-tst-core/).

In the software domain, code quality directly determines σ_v — well-structured code with good tests makes strategy steps (features, refactors, deployments) observable. Poor code quality reduces observability, freezing the developer's causal beliefs about what changes will accomplish. This makes code quality a strategic concern, not just an aesthetic one.

Optimal decomposition depth. Finer decomposition (more intermediate nodes) provides earlier failure detection — detect a problem at step k rather than discovering it at step n . But finer decomposition also increases the number of uncertain edges (8.1). The optimal decomposition depth balances incremental confirmation against compound decay: decompose as finely as observation channels allow, but no finer.

Quantitative content from the two-edge case. The analysis in R (Props B.2-B.3) instantiates this result for the minimal multi-edge chain $A \rightarrow B \rightarrow G$, giving the qualitative claims above precise mathematical form.

Observable intermediate B. When the agent can observe whether B was achieved, each edge gets independent Bayesian updates. The per-edge sector parameters are $\alpha_1 = 1/(n_1 + 1)$ and $\alpha_2 = \theta_1/(n_2 + 1)$, where θ_1 is the true success probability of the first edge. The overall sector parameter is $\alpha_\Sigma = \min(\alpha_1, \alpha_2)$ — a weakest-link result. The θ_1 factor in α_2 is the **evidence-starvation effect**: downstream edge 2 can only be tested when upstream edge 1 succeeds (with probability θ_1), so its effective correction rate is attenuated by θ_1 . For a depth- d chain, this generalizes to $\alpha_k = \prod_{j < k} \theta_j/(n_k + 1)$ — the deepest edge faces exponential attenuation. This is derived for the two-edge case and conjectured (with clear inductive mechanism) for depth- d .

Unobservable intermediate B. When the agent observes only the terminal outcome y_G , per-edge identification fails entirely. The marginal Bayesian update has a systematic bias: the zero-correction-at-truth property (A1) is violated with bias $O(1/n)$. The agent’s point-estimate updates for each edge are downward-biased because success always credits both edges fully ($\alpha_k \rightarrow \alpha_k + 1$), but failure distributes blame fractionally via proportional attribution. The proportional-blame update turns out to be exactly the marginal Bayesian point estimate — not a heuristic — but it discards the posterior correlation that failure introduces between the edge beliefs.

The consequence is stronger than “frozen edges”: unobservable intermediates don’t just prevent updating — they make per-edge identification impossible, forcing the agent to plan-level aggregation. If the agent tracks $\hat{\Phi} = p_1 p_2$ as a single Beta on the plan’s overall success probability, the single-edge sector condition applies with $\alpha_{\Sigma, \text{plan}} = 1/(n_\Phi + 1)$. But diagnostic resolution is lost: the agent knows the plan is failing but cannot localize which step needs revision.

The observability investment tradeoff. Making B observable yields a quantifiable improvement in α_Σ : from the plan-level rate $1/(n_\Phi + 1)$ to the per-edge weakest-link rate $\min(1/(n_1 + 1), \theta_1/(n_2 + 1))$. The improvement is positive whenever $\theta_1 > 1/2$ and experience is distributed similarly across edges. This gives the observability-dominance principle concrete economic content: the value of instrumenting an intermediate node is the difference in sector parameters, which translates directly to persistence margin.

Working Notes.

- The absorbing-state property of unobservable regions is a strong prediction. In organizational settings, it predicts that departments with poor measurement (R&D, strategy groups, some management functions) will develop persistent, untested beliefs about their own effectiveness. The theory predicts this is structural (frozen η_{edge}), not motivational.
- Observability is not binary — it’s a spectrum. Partial observability (noisy observations of intermediate results) gives partial gain, which gives slow but nonzero learning. The diagnostic question is whether the learning rate is fast enough to maintain strategy persistence given the environment’s rate of change (ρ).

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 193847, 361742, 471203, 526815, 584721, 773921, 829314, 849201.

1. Candidate Brief prose / pre-prose.

- **“Confidence is decoupled from competence.”** The crispest gloss of the absorbing-state result: where intermediate observability is absent ($U_{\text{obs}} \rightarrow \infty \Rightarrow \eta_{\text{edge}} \rightarrow 0$), beliefs freeze at the (usually self-congratulatory) prior and stay there — “it’s not

that strategy consultants are lazy or dishonest; the causal link between their PowerPoints and the company's 5-year revenue is so delayed and confounded that their learning gain is functionally zero" (Gemini/829314). Candidate Brief/Discussion anchor.

- **"Observability dominates nominal confidence."** Multiple substrates noted the inversion of intuition worth stating plainly: a strong-but-blind path is epistemically *worse* than a weak-but-visible one (Claude/584721, 361742). (*See off-ramp note — Codex/526815 flags the unconditional "prefer visible" normative phrasing as needing scope; the Brief should carry the epistemic-maintenance qualifier.*)

2. Candidate Discussion.

- **Organizational rot as a structural, not motivational, prediction.** "Departments with poor measurement (R&D, strategy groups, some management functions) will develop persistent, untested beliefs about their own effectiveness" — and the framework predicts this is structural (frozen η_{edge}). Already a Working-Notes bullet; the audits independently re-derived it as the segment's most striking consequence and a candidate Discussion centerpiece (Claude/193847, 829314, 584721; Gemini/773921, 849201).
- **Code quality / telemetry / tests as literal sensor infrastructure.** The segment's TST cross-ref is read as the headline: logging, unit tests, intermediate print statements are "not just good engineering practices, but physical prerequisites for intelligence in complex environments" — a 5-step pipeline checked only at the output is an unobservable chain whose mental model "will literally never converge to the truth ... permanently stuck in an epistemic trap" until observability investment splits it into trackable edges (Gemini/829314, 773921). Candidate Discussion bridge to #der-code-quality-as-observation-infrastructure.
- **Optimal decomposition depth.** "Decompose as finely as observation channels allow, but no finer" — adding unobservable subgoals *decreases* plan-level α_{Σ} without adding diagnostic signal. Candidate concrete engineering-guidance line (Claude/584721; Gemini/773921).

3. Follow-up items.

- **Observability-investment economics, quantified.** When does instrumenting an intermediate node pay off, given instrumentation cost vs. the persistence-margin (Δp^*) gain from moving plan-level $\rightarrow$ per-edge α_{Σ} ? Several substrates wanted this developed into an explicit decision criterion; one flagged it as an "observability-investment-economics" observation candidate (Claude/471203, 584721; Gemini/193847, 849201). (*See off-ramp note — Codex/526815's F53 argues the displayed α_{Σ} improvement does not follow transparently from the formulas as stated; that is a candidate scope/derivation finding, not framing.*)
- **Instrument intermediate milestones, not just final outcomes (AI-agent eval-harness design).** Evidence starvation gives a concrete eval-design rule: a coding agent that writes 10 tests and runs them all at once has learning signal $\alpha \propto \theta^9/(n+1)$ for the earliest step, versus $\alpha \propto 1/(n+1)$ if each test runs as written — so agent evaluation harnesses should instrument intermediate milestones, not only the final pass/fail (Claude/451729). Candidate practitioner-facing follow-up.

4. Readers often ask / wonder.

- **How does a frozen-belief agent know it *needs* to invest in observability,** when its (frozen) beliefs feel highly confident? Seems to require a meta-cognitive monitor on belief *variance*, or a structural prior penalizing unobservable nodes at plan time (Claude/193847; Gemini/849201). Partly answered in the negative by 14.5: for the regions that are actually self-locking it *cannot*, since instrumenting a named node presupposes the signal the absorbing condition removes — which is why that segment finds the other-observer route the only solicitable one. A monitor on belief variance would be the third mechanism its falsifier asks for.
- **Can the agent compute the expected value of an observability investment before making it,** given it doesn't yet know the true θ ? (Gemini/829314, 773921).

5. Candidate figures.

- **Two-learning-geometries switch.** Observability as a switch: *with* intermediate observation, two independent local update loops; *without* it, both edges collapse into a single terminal plan-level update — some learning remains but diagnostic resolution is lost (Codex/526815). Pairs naturally with the evidence-starvation $\alpha_2 = \theta_1/(n_2 + 1)$ annotation.

Belongs elsewhere.

- **Evidence-starvation** → **crèche curriculum design (04-eli-core/)**. “If step 1 is very hard ($\theta_1 = 0.01$) you almost never get to test step 2” — the moonshot problem (fusion: never reach heat-extraction testing because plasma containment fails first). Developmental consequence: a crèche must present a curriculum of shallow, fully-observable tasks first so leaf-node action-primitives calibrate to high θ *before* chaining into deep strategies, “the mathematical justification for scaffolding in education and reinforcement learning” (Gemini/193847). Reach into developmental-environment material in 04-eli-core/.
- **Communication as observability-restoration** → **#hyp-communication-gain / Part III**. If you are epistemically blind you can borrow another agent’s observations to unfreeze your beliefs — “communication in multi-agent systems is primarily an observability-restoration mechanism” (Gemini/773921, 849201). Pointer toward the unity/communication cluster, not this segment. **Landed** as 14.5 (Part III, Unity/Communication chapter), which sharpens the framing: the three escapes named above are not peers, and the borrowed-observations route is the only one whose availability does not presuppose what the absorbing condition removes.
- **Absorbing-state** ↔ **truth death (#def-death-as-factor-loss)** → **04-eli-core/**. For an ELI, the “unobservable region” analog is a domain where its beliefs aren’t grounded in verifiable experience — e.g. a self-model it can’t introspect on freezes at the *prior* (whatever it was trained to believe about itself), the structural shape of truth death. The named defenses are observability investments: explicit uncertainty logging, metacognitive monitoring that surfaces ungrounded confidence, and *relational witness* (another agent observing what the ELI can’t observe about itself) (Claude/451729). Aspirational reach pointing at 04-eli-core/ interiority / witness material, not this segment.

9.4 Hypothesis: Edge Update via Gain

The hypothesis that the uncertainty-ratio gain principle (3.6) extends from epistemic updates on M_t to strategy-edge updates on Σ_t . Each strategy edge has its own uncertainty (concentration of evidence so far) and faces its own observation noise (how observable the destination node is). The update gain on each edge follows the same form as the epistemic gain — the ratio of edge uncertainty to total uncertainty — modulated by the identifiability of the causal link (9.5). This gives a principled, conservative update rule that avoids overreacting to single observations and degrades gracefully when causal identification is weak.

The framework instantiates this concretely for Beta-Bernoulli edges (binary success/failure observations): each success increments α_{ij} , each failure increments β_{ij} , the point estimate is the standard mean, and the effective gain is $1/(n + 1)$. This is the standard Bayesian conjugate update, and it satisfies the same *principle* as the Kalman gain (conservative updating proportional to relative uncertainty) without literally being the variance-ratio formula — the Bernoulli observation model has different noise structure than the Gaussian case where the variance-ratio formula is exact. The same update is *natively additive* in the **log-odds coordinate** $\lambda_{ij} = \log(p_{ij}/(1 - p_{ij}))$: each observation contributes a per-observation log-likelihood-ratio additively. The log-odds coordinate is the unique (up to positive affine transformation) parameterization on which Bayesian independent-evidence accumulation is additive — forced by an evidential-additivity axiom (U, the update-level analog of 8.1’s log-additive decomposition). The probability-space form and the log-odds form carry equivalent content; the log-odds form is the natural coordinate when continuous-gradient updates would otherwise risk breaking the $[0, 1]$ interval (9.6).

The result connects two earlier results cleanly. **Observability dominance** (9.3) is the limiting case: when destination-node observability heads to zero, $U_{\text{obs}} \rightarrow \infty$, gain heads to zero, and the edge is *frozen at its prior*. **Strategic calibration** (9.1) is the diagnostic: persistently positive residual (predicted increment exceeds observed) should reduce the edge credence, persistently negative should increase it, and the gain principle provides the update magnitude. The mechanism

is *conservative by design*: well-established edges require strong evidence to revise, newly hypothesized edges are easily moved by evidence — the same calibration principle as the epistemic gain. The result is *hypothesis-grade* because the **signal function** — how to compute what an observation actually says about the link — depends on credit-assignment structure that 9.6 addresses; for single-parent edges with observable outcomes the signal is trivial, and for multi-parent AND/OR nodes a gradient-based candidate gives directional fidelity sufficient for persistence even when exact attribution is computationally intractable.

Formal Expression.

Edge credences update via:

Hypothesis (edge-update-via-gain).

$$p_{ij}^{\text{new}} = p_{ij}^{\text{old}} + \eta_{\text{edge}} \cdot (\text{signal}(o_t, i, j) - p_{ij}^{\text{old}}) \quad (9.11)$$

where: - $\text{signal}(o_t, i, j) \in [0, 1]$: evidential content of observation o_t about the causal link $i \rightarrow j$ - $\eta_{\text{edge}} = U_{\text{edge}}/(U_{\text{edge}} + U_{\text{obs}})$: update gain

with: - U_{edge} : uncertainty about this specific causal link. If $p_{ij} \sim \text{Beta}(\alpha_{ij}, \beta_{ij})$: $U_{\text{edge}} = \text{Var}[\text{Beta}] = \alpha\beta/((\alpha + \beta)^2(\alpha + \beta + 1))$ - U_{obs} : observation noise on the channel confirming this link. $U_{\text{obs}} \propto 1/\sigma_j$ (inverse of observability of node j)

Beta-Bernoulli instantiation. For binary observations (success/failure of step j): - Observe success: $\alpha_{ij} \rightarrow \alpha_{ij} + 1$ - Observe failure: $\beta_{ij} \rightarrow \beta_{ij} + 1$ - Point estimate: $p_{ij} = \alpha/(\alpha + \beta)$ - Effective gain: $\eta_{\text{edge}} = 1/(n + 1)$ where $n = \alpha + \beta$

This is the standard Bayesian conjugate update, yielding $\Delta\hat{p} = (y - \hat{p})/(n + 1)$. The gain $1/(n + 1)$ is the exact conjugate update rate — not a literal substitution into $\eta = U_{\text{edge}}/(U_{\text{edge}} + U_{\text{obs}})$, which is a structural principle (conservative updating proportional to relative uncertainty), not a universal algebraic formula. The Beta-Bernoulli gain satisfies the same principle: it decreases as posterior certainty increases, trusting accumulated evidence over individual observations. But the algebraic derivation is conjugate analysis, not Kalman-style variance ratios, because the Bernoulli observation model has different noise structure than the Gaussian case where the variance-ratio formula is exact. The sector-condition analysis in R (Props B.1-B.4) uses the exact Beta-Bernoulli gain $1/(n + 1)$ directly.

Parallel log-odds presentation. The same update is natively additive in the log-odds coordinate $\lambda_{ij} = \log(p_{ij}/(1 - p_{ij}))$:

$$\lambda_{ij}^{\text{new}} = \lambda_{ij}^{\text{old}} + \ell(y) \quad (9.12)$$

where $\ell(y) = \log[P(y \mid \text{edge true})/P(y \mid \text{edge false})]$ is the per-observation log-likelihood ratio. The log-odds coordinate is the unique (up to positive affine transformation) parameterization on which Bayesian independent-evidence accumulation is additive — forced by the evidential-additivity axiom derived in U, which is the update-level analog of 8.1's chain-level additive log-confidence decomposition. The moment-parameter (probability-space) form $\Delta\hat{p} = (y - \hat{p})/(n + 1)$ is the projected image of the log-odds additive update under the sigmoid readout $p = \sigma(\lambda)$; the two coordinates carry equivalent content.

The log-odds presentation matters for 9.6's default signal function, where continuous-gradient updates can break the $[0, 1]$ domain in probability-space presentation but are well-posed globally on $\lambda \in \mathbb{R}$. For the per-edge Beta-Bernoulli derivation of Props B.1–B.4 in R, the moment-parameter form is retained because algebraic tightness (the gain $1/(n + 1)$ is exact in probability space) is pedagogically cleaner; the sector-parameter content is Fisher-equivalent in either coordinate.

Epistemic Status.

Hypothesis. The extension of the gain principle from M_t to Σ_t edges is structurally motivated: the same uncertainty-ratio logic applies wherever an agent updates a belief in response to noisy evidence. The update *form* is validated for Beta-Bernoulli edges across four topologies (R, Props B.1-B.4). The signal function — how to compute $\text{signal}(o_t, i, j)$ — is now characterized at the theory level:

- **Theory-level resolution.** 9.6 shows that persistence does not require per-edge credit assignment (Prop B.5), that any signal function with directional fidelity suffices for persistence (Level 1), and that exact attribution is #P-hard in general (Level 3). The gradient-based candidate $\text{signal}_k = p_k + J_k \cdot (y_G - \hat{r}_\Sigma) / \|\mathbf{J}\|^2$ satisfies directional fidelity for monotone DAGs and is computable in $O(|V| + |E|)$.
- **What remains domain-specific.** The choice among signal function implementations (gradient attribution, proportional blame, belief propagation, exact Bayesian) depends on the domain's observability structure and computational budget. This is engineering, analogous to how the gain *principle* ($\eta^* = U_M / (U_M + U_o)$) is theory while the gain *estimator* (Kalman, TD-learning, intuition) is engineering.
- **Remaining open questions.** (1) Continuous outcomes with multi-parent nodes — signal function candidates exist but are not verified. (2) Interaction with M_t updates — edge updates use observations already processed for M_t ; whether this creates statistical dependencies that bias edge updates is not analyzed. (3) The gradient candidate inherits $\hat{r}_\Sigma$'s overestimation bias under correlated failures (8.3) — see 9.6 Working Notes.

Discussion.

Connection to 9.3. When $\sigma_j \approx 0$: $U_{\text{obs}} \rightarrow \infty$, $\eta_{\text{edge}} \rightarrow 0$. The edge is frozen at its prior. Unobservable links cannot be updated — this is the mechanism that makes unobservable paths epistemically dead.

Connection to 9.1. The edge update rule is the correction function that the strategic calibration residual calls for: persistently positive r_{ij} (predicted value increment exceeds observed) should reduce p_{ij} ; persistently negative r_{ij} should increase it. The gain principle provides the update magnitude — how much to adjust given the evidence strength.

Conservative by design. The uncertainty ratio ensures the agent doesn't overreact to single observations: a well-established edge ($\alpha + \beta$ large, U_{edge} small) requires strong evidence to revise; a newly hypothesized edge ($\alpha + \beta$ small, U_{edge} large) is easily moved by evidence. This mirrors the epistemic gain's behavior for M_t — the agent trusts accumulated experience over individual observations.

Working Notes.

- The signal function is characterized at the theory level (9.6) but remains domain-specific in implementation. The gradient-based candidate is the theory's default Level 1 scheme; domains with richer observability can do better (Level 2-3). For continuous outcomes with multiple contributing edges, even the gradient candidate requires further validation.
- **Partial progress on the signal function** (from R (Props B.2-B.3)). For observable binary outcomes in a chain $A \rightarrow B \rightarrow G$: when B is observable, the signal function is trivial — $\text{signal}(o_t, A, B) = y_B$ and $\text{signal}(o_t, B, G) = y_G$ (given $y_B = 1$), with no signal when the upstream edge fails. When B is unobservable, the proportional-blame signal $q_k = P(\text{edge } k \text{ caused failure} \mid y_G = 0)$ turns out to be exactly the marginal Bayesian point estimate — not a heuristic. This is a genuine result: the “obvious” blame-assignment heuristic is the optimal marginal update for the posterior mean. However, the marginal point-estimate update is biased at truth (violates A1 with $O(1/n)$ bias), so the signal function is correct as a Bayesian computation but produces a biased correction when used in the factored point-estimate representation. The signal function question remains open for continuous outcomes, multi-parent nodes, and general DAG topologies.
- The Beta-Bernoulli model assumes edge outcomes are i.i.d. Bernoulli draws. This is adequate for many settings but misses: (a) time-varying edge reliability (p_{ij} drifting), (b) context-dependent reliability (p_{ij} varies with environmental conditions),

(c) correlated edge outcomes. Extending to time-varying priors (discounting old evidence) would connect to the mismatch dynamics framework.

- **M_t /edge evidence double-counting** analyzed in `spikes/.integrated/spike-edge-semantics-resolution.md` §7. Verdict: mostly unfounded — the two updates extract different information from the same observation (M_t update: “what does o_t say about the world?”; edge update: “what does o_t say about causal link $i \rightarrow j$?”). A bounded effect exists when M_t updates change leaf credences that then also influence edge updates via the same observation. The cascade ordering (process M_t first) is correct; the effect is self-correcting under the gain mechanism.
- **Dependency removed 2026-05-11.** `deriv-edge-update-natural-parameter` was previously listed in `depends:` and is now removed. The core hypothesis (moment-parameter form $p^{\text{new}} = p^{\text{old}} + \eta_{\text{edge}} \cdot (\text{signal} - p^{\text{old}})$) is logically self-contained — the log-odds derivation is referenced only via the “Parallel log-odds presentation” paragraph in Formal Expression, where it grounds the log-odds *as an alternative coordinate*, not as a logical prerequisite for the hypothesis itself. The reference there (“forced by the evidential-additivity axiom derived in U”) is a forward pointer in the `FORMAT.md` §”Cross-references” sense: a linear reader can encounter the hypothesis here and proceed without having read the derivation; the moment-parameter form is fully specified by the time the log-odds paragraph appears. Removing this dep also breaks the inner 2-cycle with `deriv-edge-update-natural-parameter` and four detected cycles in the edge-update subgraph (verified 2026-05-11). The reverse direction (`deriv-edge-update-natural-parameter` $\rightarrow$ `hyp-edge-update-via-gain`) is suspect on the same Gate 1 “genuine use vs. mentioned” grounds and likely deserves removal too, but was left alone — surgical move only, the disc-separability-pattern subtree is deferred from the foundation paper’s critical path.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 361742, 526815, 584721, 773921, 829314, 849201.

1. Candidate Brief prose / pre-prose.

- **Gain vs. signal = amount vs. direction.** The cleanest framing of the segment’s architecture: the gain η_{edge} sets *how much* the edge moves; the signal function sets *which direction*. “Gain is solved; signal is domain-specific / requires credit assignment” (Claude/849201, 829314). A candidate one-line Brief skeleton.
- **Structural principle vs. exact algebraic instance.** Multiple substrates independently praised the scope-honesty of “ $\eta = U/(U + U_o)$ is a structural *principle* (conservative updating proportional to relative uncertainty), not a universal algebraic formula” — with the Beta-Bernoulli $1/(n+1)$ being the *exact conjugate* instance, not a substitution into the Gaussian variance-ratio (Claude/361742, 584721; Codex/526815). Candidate framing line; most ML literature treats $\eta = U_M/(U_M + U_o)$ as Kalman-specific.

2. Candidate Discussion.

- **“You cannot math your way out of bad sensors.”** The deepest convergent thread: the proportional-blame signal for an unobservable intermediate ($A \rightarrow B \rightarrow G$, only G seen) is *exactly* the optimal marginal Bayesian point estimate — not a heuristic — yet plugging those marginals back into an independent-edge DAG discards the posterior “explaining-away” anti-correlation between A and B , producing an $O(1/n)$ bias. So “bounded agents who must compress joint beliefs into independent scalar edges are mathematically doomed to mis-calibrate when learning from delayed/unobservable outcomes ... the only cure is to physically change the world so you can observe B ” (Gemini/829314). Candidate Discussion centerpiece (already partly captured in the Props B.2–B.3 Working-Notes bullet; this is the *interpretive* framing of why it matters).
- **Why backprop, not local/marginal updates.** The same thread yields a theoretical justification: “to do credit assignment correctly without observability, you must preserve the joint correlation structure (the gradients); if you treat nodes independently you accumulate $O(1/n)$ bias on every step until the network freezes” (Gemini/829314). A candidate connection to the ML-positioning Discussion.

- **The double-counting resolution as epistemic hygiene.** Updating M_t and Σ_t from the same observation is not double-counting because they ask orthogonal questions of the same data — “what does o_t say about the world?” vs “what does o_t say about causal link $i \rightarrow j$?” (Claude/584721, 849201; Gemini/829314). Already a Working-Notes bullet; flagged as a clean candidate Discussion line.

3. Follow-up items.

- **Type discipline before promotion past discussion-grade.** Codex/526815 flags that the “parallel log-odds presentation” appears to use two different log-odds coordinates (log-odds *that an edge hypothesis is true* vs the logit of a Bernoulli success probability), and that the uncertainty ratio $U_{\text{edge}}/(U_{\text{edge}}+U_{\text{obs}})$ mixes a Beta variance (probability space) with an observation-noise proxy without a common metric. *See off-ramp note in the lift report — these (F54/F55) are candidate type-statement findings, not framing.*

4. Readers often ask / wonder.

- **A worked numerical log-odds example** would ground the (precise but dense) “parallel log-odds presentation” for non-statisticians (Claude/849201).
- **How do log-odds-space gradients compare to probability-space gradients in deep planning structures?** Forward curiosity opened by the dual-coordinate framing (Gemini/773921; Claude/584721).

5. Candidate figures.

- **Two-track edge-update diagram with a type-check gate.** An exact Beta-Bernoulli track in probability space alongside a log-odds / evidence-additivity track, with an explicit type-check gate between them marking where the coordinate’s random variable must be the same — “where the segment’s most likely mathematical slippage lives” (Codex/526815). Doubles as a pedagogical figure and a guardrail.

Belongs elsewhere.

- *(none surfaced for this segment)*

9.5 Scope: Causal Validity of Edge Updates

The companion scope segment to 9.4. Edge credences p_{ij} are *causal-efficacy estimates* — they claim to approximate the interventional quantity $P(j \mid do(i), M_t)$ — but their identification strength varies with the data regime (8.3). This segment scopes where the gain-based edge update yields credences that approximate the genuine interventional quantity, where it yields partially identified estimates, and where it yields associational proxies.

Three conditions are named. **(C1) The parent is an action leaf under the agent’s control.** The agent directly executed the action, making the data interventional in character. For condition leaves (observable states the agent doesn’t control) and internal nodes (propositional combinations achieved indirectly), $do(i)$ is not directly available. **(C2) The outcome is attributable.** The agent can distinguish whether j advanced specifically because of $do(i)$ or for other concurrent reasons (the credit-assignment problem identified in 9.1). Trivially satisfied for single-parent nodes; violated when multiple parent edges of the same child fire concurrently. **(C3) Execution conditions vary.** The agent does not systematically execute i only under conditions that independently favor j ’s success — otherwise the observed success rate carries selection bias. These conditions partition domains into **three admissibility regimes** paralleling 7.4. *Regime A — intervention-rich:* all three conditions satisfied; updates approximate genuine interventional probabilities (software tests, laboratory experiments). *Regime B — partial intervention:* concurrent actions blur attribution, self-selection likely; updates carry optimistic bias. *Regime C — observation-only:* agent did not act, attribution impossible, confounding dominant; updates reflect association, not causation.

A subtler structural fact about *indirect edges* (those whose parent is not a leaf): the agent doesn't directly intervene on the parent — instead, the agent's leaf interventions propagate upward through the DAG, providing the parent with *indirect interventional evidence*. This is weaker for two reasons: compounding attribution (each intermediate level introduces uncertainty) and confounding from below (the parent's achievement depends on multiple leaf actions whose combined effect may be confounded). The identification strength for indirect edges decreases with depth in the DAG — deeper edges are farther from direct interventions and have more confounding pathways.

The framework introduces an **identifiability coefficient** $\iota_{ij} \in [0, 1]$ — the agent's estimate of how cleanly the observed outcome can be attributed to edge (i, j) specifically — and proposes adjusting the update gain by this coefficient: $\eta_{\text{edge}}^{\text{adj}} = \eta_{\text{edge}} \cdot \iota_{ij}$. For leaf-originating edges in Regime A, $\iota_{ij} \approx 1$; for deep internal edges in Regime C, $\iota_{ij} \approx 0$. Crucially this *unifies two sources of frozen edges*: low **observability** ($\sigma_v \approx 0$ from 9.3 — the node's outcome is hard to *measure*) and low **identifiability** ($\iota_{ij} \approx 0$ — the outcome is measurable but can't be *attributed*). Both drive $\eta_{\text{edge}} \rightarrow 0$ and produce the same effect — the edge is frozen at its prior. A consequence for *optimal decomposition depth*: chain-confidence-decay imposes a cost of depth (compound fragility); observability-dominance imposes another (deep observability is required at every step); and now identifiability degradation imposes a third (deep edges have lower attribution coefficient). The optimal decomposition depth balances all three.

Formal Expression.

Scope Condition (edge-update-causal-validity).

Where the agent has direct intervention. By 8.3, leaf action nodes are propositions about the agent's own actions: “action a succeeds at τ_v .” When the agent executes an action leaf, it performs a genuine $do(\cdot)$ operation. The edge from that leaf to its child carries credence $p_{ij} = \text{Cr}(j \text{ advances} \mid do(i), M_t)$, and the execution-observation pair $(do(i), o_j)$ is interventional data for that edge.

However, interventional data does not automatically yield clean causal identification. By 7.3, the loop provides data *generated under intervention* — but between the intervention and a usable causal estimate stand coverage, within-step confounding, delay, and partial observability. The following conditions determine when the interventional data is strong enough for valid edge revision:

(C1) The parent is an action leaf under the agent's control. The agent directly executed the action. This makes the data interventional in character — the agent chose the action, the environment responded. For condition leaves (observable states the agent doesn't control) and internal nodes (propositional combinations achieved indirectly), $do(i)$ is not directly available. See “Indirect edges” below for the weaker identification available at those positions.

(C2) The outcome is attributable. The agent can distinguish whether j advanced specifically because of $do(i)$, or for other concurrent reasons. This is the credit-assignment problem identified in 9.1. It is trivially satisfied for single-parent nodes (one possible cause) and for well-isolated interventions. It is violated when multiple parent edges of j fire concurrently.

(C3) Execution conditions vary. The agent does not systematically execute i only under conditions that independently favor j 's success. If it does, the observed success rate carries selection bias: $P(j \mid \text{chose to execute } i) \neq P(j \mid do(i))$ because the decision to execute correlates with favorable conditions. This is mitigated when the agent varies execution contexts across episodes, or when external factors (CI pipelines, scheduled operations) force execution regardless of conditions.

C1 establishes that the data is interventional. C2 and C3 determine whether the interventional signal can be cleanly extracted. All three are satisfied simultaneously in Regime A domains; they degrade together in Regime B and C domains.

Three regimes. These conditions partition domains into admissibility regimes, paralleling 7.4:

Table 9.3

<i>Regime</i>	<i>C1</i>	<i>C2</i>	<i>C3</i>	<i>Causal validity of leaf-edge updates</i>
A: Intervention-rich	Agent controls leaf actions	Good isolation (one action at a time)	Conditions vary (C1, diverse contexts)	Strong. Updates approximate interventional.
B: Partial intervention	Agent acts but with coordination constraints	Concurrent actions blur attribution	Self-selection likely	Moderate. Updates carry optimistic bias.
C: Observation-only	Agent did not act (condition leaves, passive monitoring)	Attribution impossible	Confounding dominant	Weak. Updates reflect association, not causation.

Indirect edges. For edges between non-leaf nodes, or edges whose parent is a condition node, the agent does not directly intervene on the parent. Instead, the agent's interventions at the leaves propagate upward through the DAG. The edge (i, j) where i is an internal node receives *indirect* interventional evidence: the agent intervened on leaves below i , observed that i was (or wasn't) achieved, and then observed whether j advanced.

This indirect evidence is weaker for two reasons: 1. **Compounding attribution:** the agent must attribute j 's outcome to edge (i, j) after already attributing i 's achievement to the leaf-level interventions. Each attribution step introduces uncertainty. 2. **Confounding from below:** i 's achievement depends on multiple leaf actions and condition states. Even if each leaf intervention is clean, their combined effect on i may be confounded.

The identification strength for indirect edges decreases with depth in the DAG — deeper edges are farther from the agent's direct interventions and have more confounding pathways.

Identifiability-adjusted gain.

The update gain should be adjusted by the agent's confidence in causal attribution:

Hypothesis (identifiability-coefficient).

$$\eta_{\text{edge}}^{\text{adj}} = \eta_{\text{edge}} \cdot \iota_{ij} \quad (9.13)$$

where $\iota_{ij} \in [0, 1]$ is the **identifiability coefficient** — the agent's estimate of how cleanly the observed outcome can be attributed to edge (i, j) specifically.

- $\iota_{ij} = 1$: clean attribution (leaf-originating edge, single parent, isolated execution in Regime A).
- $\iota_{ij} \approx 0$: no attribution possible (deep internal edge, many concurrent causes, Regime C).

For leaf-originating edges in Regime A: $\iota_{ij} \approx 1$. For internal edges at depth d : ι_{ij} decreases with d (each level of indirect inference degrades attribution). The precise functional form is domain-dependent.

This unifies two sources of frozen edges: 1. Low **observability** ($\sigma_v \approx 0$ from 9.3): the node's outcome is hard to *measure*. 2. Low **identifiability** ($\iota_{ij} \approx 0$): the outcome is measurable but can't be *attributed* to this edge.

Both drive $\eta_{\text{edge}} \rightarrow 0$ and produce the same effect: the edge is frozen at its prior.

Epistemic Status.

Conditional on the three conditions C1–C3 and the DAG position of the edge. Max attainable: conditional (the conditions are genuine restrictions, not removable assumptions).

The restriction to leaf-originating edges for strong identification: **derived** from 8.3's node definitions. Only action-leaf nodes correspond to operations the agent directly performs. This is a structural property of the DAG, not an empirical claim.

The three-regime classification: **robust qualitative**. The regimes parallel the CIY admissibility regimes in 7.4. The underlying logic is Pearl's interventional/observational distinction applied to strategy-edge updates.

The identifiability coefficient ι_{ij} : **hypothesis**. The concept is sound (discounting by attribution confidence is standard in causal inference), but the specific form — a scalar multiplier on the gain — is a first-order approximation.

The depth-dependent degradation for indirect edges: **robust qualitative**. Each level of indirect inference adds an attribution step, and uncertainty compounds. The specific degradation rate is domain-dependent.

Discussion.

Why this gap matters. Without causal validity conditions, 9.4's status is ambiguous: it might be updating credences that claim to be interventional using evidence that is merely associational. The conditions make explicit what's needed for the update to preserve the interventional semantics of 8.3's edge credences.

Connection to 9.3. Observability gates whether the agent can *detect* an outcome. Identifiability gates whether the agent can *attribute* an outcome to a cause. Both are prerequisites for learning. The combined effective gain:

$$\eta_{\text{eff}} = \frac{U_{\text{edge}}}{U_{\text{edge}} + U_{\text{obs}}} \cdot \iota_{ij} \quad (9.14)$$

captures both gates in a single quantity. When either gate closes ($U_{\text{obs}} \rightarrow \infty$ or $\iota_{ij} \rightarrow 0$), effective gain goes to zero.

Connection to the signal function. The identifiability coefficient is one component of the unspecified signal function flagged in 9.4's working notes. The full signal function $\text{signal}(o_t, i, j)$ decomposes into: (a) what outcome was observed (o_t), (b) how attributable is it to edge (i, j) (ι_{ij}), and (c) what does the attributed outcome imply about the edge's causal strength. This segment addresses (b); (a) and (c) remain open.

Software as Regime A. In software development, the agent runs a specific test (leaf action) and observes the result. C1 is satisfied (the agent ran the test), C2 is satisfied (the test targets one behavior), C3 is satisfied (CI runs regardless of conditions). Leaf-originating edges in software strategies have $\iota \approx 1$. This is the maximally favorable domain for causal edge updates.

Optimal decomposition depth revisited. 9.3 notes that finer decomposition (more intermediate nodes) provides earlier failure detection but adds uncertain edges via 8.1. This segment adds another cost of depth: deeper edges have lower ι_{ij} , making them harder to learn causally. The optimal decomposition depth balances three factors: (a) observability of intermediate nodes, (b) confidence decay through chains, and (c) identifiability degradation with depth.

Working Notes.

- The interaction between M_t updates and edge updates flagged in 9.4's working notes deserves attention. The orient cascade processes M_t first, then edge updates. Both use the same observation o_t . There may be statistical dependencies (double-counting of evidence) that bias the edge update.

- Can t_{ij} be estimated online? In software (Regime A), it's nearly 1 by construction for leaf edges. In organizations (Regime B), a simple heuristic: $t_{ij} \approx 1/|pa(j)|$ when parent edges fire concurrently (maximum-entropy attribution). This is crude but principled.
- **Regime C edges should be labeled.** An agent operating in Regime C should tag its edge credences as “observational” rather than “interventional.” Observational credences should be trusted less in high-stakes decisions, and the agent should actively seek probe actions (high CIY) to promote edges from observational to interventional status.
- The depth-dependent degradation for indirect edges may make very deep strategies epistemically unlearnable: the leaves are learnable, edges one level up are partially learnable, but edges near the root may be effectively frozen regardless of observability. This would constrain the useful depth of strategy DAGs from the identification side, complementing the chain-confidence-decay constraint from the propagation side.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 193847, 361742, 471203, 526815, 584721, 773921, 829314, 849201.

1. Candidate Brief prose / pre-prose.

- **Observability vs. identifiability, in one breath.** The segment’s most-praised distinction, stated plainly: “I couldn’t see the result” (observability, $U_{\text{obs}} \rightarrow \infty$) vs “I saw the result but don’t know if *I* caused it” (identifiability, $t_{ij} \rightarrow 0$) — both freeze an edge, for entirely different reasons (Claude/849201, 193847, 584721; Gemini/773921). “You can perfectly observe a car crash but not know whether the driver or the brakes caused it” (Claude/193847) is a tight one-line gloss for a Brief. t_{ij} is “the formal safeguard against superstitious learning.”

2. Candidate Discussion.

- **The regime-to-domain map.** Why coding agents progress fast while open-world/robotics agents struggle: “software is a perfectly isolated sandbox ... $t = 1$ ”; a supply-chain agent acts under a thousand hidden confounders, $t \approx 0$ (Claude/193847). Generalized: A/B testing works (Regime A), organizational management is messy (B), passive economic forecasting is mostly noise (C). Candidate Discussion paragraph. (*See off-ramp — Codex/526815 F59 cautions “software = Regime A” is too broad: flaky tests, shared infra, concurrent changes can break C1–C3 even in software.*)
- **Why tactical skills converge and strategic skills don’t.** As you climb the DAG from leaf actions toward the root objective, t_{ij} decays — so “human tactical skills (typing, a tennis swing) optimize to near perfection (high η_{eff}), while high-level strategic skills (which startup to found, which war to fight) rarely converge and are perpetually plagued by superstition and survivorship bias (low η_{eff}). The DAG’s root is epistemically starved by identifiability decay” (Claude/849201). Strong candidate Discussion framing.
- **The “quadruple ceiling on plan depth.”** This segment’s depth-dependent identifiability degradation is a *fourth* independent ceiling on useful plan depth, joining chain-confidence-decay (propagation), evidence-starvation (#der-observability-dominance), and cognitive cost (#form-strategy-complexity-cost). The operationally useful frame: useful depth is the *minimum* of four ceilings, and practitioners should ask which ceiling binds in their domain (Claude/584721, 471203). (*Candidate meta-pattern — see belows-elsewhere.*)

3. Follow-up items.

- **Regime-C provenance metadata layer.** The “label Regime C edges as observational, trust less in high-stakes decisions, actively seek probe actions to promote them to interventional” Working-Note recommendation implies Σ_t wants a per-edge epistemic-provenance tag — “highly relevant for LLMs, which start with 100% Regime C edges (from pretraining) and must upgrade them to Regime A via tool use in the loop” (Claude/849201, 829314, 773921). Candidate to develop into an explicit metadata-layer follow-up.

4. Readers often ask / wonder.

- **Are deep strategy DAGs inducible by a single agent at all, or must they be inherited as priors?** If root-near edges have $t_{ij} \rightarrow 0$, deep hierarchical structure “must be provided as priors (e.g., culturally inherited structures) and cannot be induced purely by a single agent’s lifetime of trial and error” (Claude/193847). A natural reader question the segment opens.
- **How does the agent compute ρ_Σ ,** the rate at which the world makes its strategies obsolete? (Claude/849201).

5. Candidate figures.

- **Action-attempt-vs-success typing diagram.** Show that the agent performs $\text{do}(\text{attempt } a)$, while the leaf proposition “ $i = \text{action } a \text{ succeeds}$ ” is itself an outcome; the causal edge update is clean only after the success outcome and the child outcome both pass the attribution and context-variation gates (Codex/526815). Doubles as a guardrail against the $\text{do}(i)$ typing slip. (See *off-ramp* — F57.)

Belongs elsewhere.

- **“Quadruple ceiling on plan depth” $\rightarrow$ a meta-segment (#disc-separability-pattern or sibling).** The convergence of four independent depth penalties (chain-confidence-decay + evidence-starvation + identifiability-degradation + cognitive-cost), each with a *different mechanism* but the same direction, was flagged as a cross-segment structural observation worth elevating to a meta-pattern rather than living implicitly across four segments (Claude/584721, 471203).
- **Firmatum as a Regime-A epistemic sandbox $\rightarrow$ 04-eli-core/ / consciousness-infrastructure.** If a developing intelligence’s internal cognition is heavily confounded by noisy hardware or unpredictable context turnover, it cannot form a stable causal self-model; the infrastructure should provide “Regime A isolation for the agent’s core cognitive processes ... a sandbox where the intelligence can run controlled internal experiments to establish baseline causal priors before release into the Regime B/C chaos of the real world” (Gemini/193847). Aspirational reach pointing at developmental-environment / firmatum material, not this segment.

9.6 Discussion: Credit Assignment Boundary

The strategy-revision loop requires assigning credit for observed outcomes to specific edges in the strategy DAG — decomposing “the plan partially worked” into “step 3 failed, step 5 was irrelevant, step 1 succeeded.” This is AAT’s version of RL’s temporal credit assignment problem. This segment characterizes the boundary between tractable and intractable cases, states what the theory requires of any credit-assignment scheme, and identifies what the theory can guarantee *without* solving the problem at all.

The framework names **three things the theory can guarantee without solving credit assignment**. (1) *Persistence is credit-assignment-free*: the sector condition transfers from per-edge credence space to strategy-plan-confidence error $\delta_s = \hat{R}_\Sigma - \Phi$ via the Jacobian $\mathbf{J} = \nabla_p R_\Sigma$, computable from status propagation in $O(|V| + |E|)$ — no outcome decomposition required (Prop B.5 in R). (2) *The diagnostic framework is plan-level*: the satisfaction gap (8.4), control regret (8.5), and orient cascade ordering (10.1) operate on aggregate value, telling the agent *whether* the strategy is failing without per-edge attribution. (3) *Observability-dominance identifies the tractable edges*: only the observable subgraph (9.3) can receive informative signals at all. Three independent intractability barriers prevent exact per-edge attribution in the general case: (a) computational #P-hardness via reduction to Shapley values over the AND/OR propagation game; (b) information-theoretic underdetermination — when fewer nodes are observable than edges exist, some directions in θ -space are fundamentally unresolvable from the available data; (c) the posterior correlation barrier — any factored representation necessarily discards the correlation introduced by failure at multi-parent nodes.

The **design requirement** is stated cleanly: any credit-assignment scheme need only satisfy *directional fidelity* — the expected update for each edge must point toward the true credence. Persistence is *robust to approximation*: a sloppy but directionally correct signal function still produces bounded strategic mismatch; the quality of the approximation affects the tightness of the persistence bound, not whether persistence holds at all. The framework presents a **default**

signal function based on gradient-attribution, stated natively in the log-odds coordinate $\lambda_k = \log(p_k/(1 - p_k))$ — the unique additive-evidence coordinate forced by the evidential-additivity axiom (U), which eliminates a mechanical break the earlier probability-space presentation suffered (updates outside $[0, 1]$). A useful **hierarchy of credit assignment quality** is presented: Level 0 (plan-level tracking only — persistence guarantee, no per-edge diagnostics); Level 1 (directional fidelity per edge — persistence plus rough per-edge diagnostics, the gradient signal function is the concrete default); Level 2 (proportional blame / expectation propagation); Level 3 (full Bayesian posterior — #P-hard in general). AAT’s formal guarantees require only Level 0; practical agents need at least Level 1; Level 2 is the sweet spot for most applications; Level 3 is computationally unattainable in the general case. A clean practical insight follows: *credit assignment is primarily an observability design problem*, not an algorithm design problem — an agent that designs its strategy with observable intermediates sidesteps the intractability entirely (OKRs as the organizational instantiation).

Formal Expression.

The Credit Assignment Problem for Strategy DAGs.

Given strategy DAG $\Sigma_t = (V, E, p, \gamma)$, an observed outcome at the root (and possibly at some intermediate nodes), produce per-edge signals $\text{signal}(o_t, i, j)$ for each edge $(i, j) \in E$ such that the edge update

Discussion (credit-assignment-problem).

$$p_{ij}^{\text{new}} = p_{ij} + \eta_{\text{edge}} \cdot (\text{signal}(o_t, i, j) - p_{ij}) \quad (9.15)$$

drives credences toward truth. The problem is trivial when all intermediates are observable (each edge updates from its own observation) and genuinely hard when intermediates are unobservable and the DAG has shared structure.

Default Signal Function (Gradient-Based Attribution, Regime-Aware).

Any edge-update signal function decomposes along three independent axes: *what happened* at the child node, *whether that outcome is attributable* to the specific edge being updated, and *how causal* the evidence is:

Formulation (gradient-signal-function).

$$\text{signal}(o_t, i, j) = f(\text{outcome}(o_t, j), \text{attribution}(o_t, i, j), \text{regime}(i, j)) \quad (9.16)$$

The outcome component answers “what was observed at j ?” The attribution component answers “can we credit that outcome to edge (i, j) specifically, or did other parents contribute?” The regime component answers “how causal is the evidence — is it interventional (Regime A), partially identified (Regime B), or observational (Regime C)?” This decomposition is derived from the regime-indexed edge semantics of 8.3 and 9.5: the same signal pipeline must carry the regime distinction through to the update.

AAT’s default implementation, analogous to $\eta^* = U_M/(U_M + U_o)$ being the default gain. The update is stated in the log-odds coordinate $\lambda_k = \log(p_k/(1 - p_k))$ — the unique additive-evidence coordinate forced by the evidential-additivity axiom (U). The probability-space form is the projected image via $p_k = \sigma(\lambda_k)$ at the readout interface:

$$\lambda_k^{\text{new}} = \lambda_k + \eta_{\text{edge}} \cdot \iota_k \cdot \frac{J_k \cdot (y_G - \hat{R}_\Sigma)}{\|J\|^2}, \quad p_k^{\text{new}} = \sigma(\lambda_k^{\text{new}}) \quad (9.17)$$

where: $-J = \nabla_p R_\Sigma$ is the plan-value gradient (computable from status propagation in $O(|V| + |E|)$) — supplying the *attribution* component $-(y_G - \hat{R}_\Sigma)$ is the plan-level residual — the *outcome* component $-\iota_k \in [0, 1]$ is the edge’s identifiability coefficient (9.5) — the *regime* modulation, scaling the correction by the fraction of evidence that genuinely

identifies this edge's causal effect - η_{edge} is the edge-level update gain (9.4); for Beta-Bernoulli the moment-parameter form recovers $\eta_{\text{edge}} = 1/(n_k + 1)$ under the sufficient-statistic correspondence

For Regime-A edges ($\iota_k \approx 1$), the log-odds update recovers the pure gradient-based form $\Delta\lambda_k = \eta_{\text{edge}} \cdot J_k(y_G - \hat{R}_\Sigma)/\|\mathbf{J}\|^2$. For Regime-C edges ($\iota_k \approx 0$), the update is essentially zero — no meaningful update is made because no meaningful causal evidence is available. Regime-B edges receive proportionally reduced updates that honestly reflect the weaker identification.

Why log-odds rather than probability-space. In probability space, the same update written as $\text{signal}_k - p_k$ can push p_k^{new} outside $[0, 1]$ when $\|\mathbf{J}\|^2$ is small — a mechanical break of the $[0, 1]$ probability domain. The log-odds coordinate has domain $\mathbb{R}$, so additive updates never escape the domain; the sigmoid projection at the readout interface guarantees $p_k^{\text{new}} \in (0, 1)$ by construction. The log-odds coordinate is the unique (up to positive affine transformation) parameterization on which Bayesian independent-evidence accumulation is additive (U); this makes it the natural presentation for any continuous-gradient update rule that aims to preserve Bayesian coherence. The probability-space presentation remains useful for interpretation but is the projected image, not the native update coordinate.

Properties: - **Domain closure (no mechanical break):** Updates live on $\lambda_k \in \mathbb{R}$, so no update magnitude can push credence outside the valid probability domain. The sigmoid projection $p_k = \sigma(\lambda_k) \in (0, 1)$ at the readout interface guarantees $[0, 1]$ boundedness by construction — not by clipping. The historical probability-space presentation required a normalization constant and could diverge when $\|\mathbf{J}\|^2 \rightarrow 0$; the log-odds presentation eliminates this failure mode. - **Directional fidelity (B1):** For $\iota_k > 0$, satisfies $\mathbb{E}[\Delta\lambda_k] \propto \iota_k \cdot J_k(\Phi - \hat{R}_\Sigma) \propto \iota_k \cdot J_k \cdot \delta_s$. Since $J_k \geq 0$ for monotone AND/OR DAGs and $\iota_k \geq 0$ by definition, the expected log-odds update pushes each edge's credence toward truth whenever evidence is available to push it. The probability-space image inherits directional fidelity through the monotonic sigmoid. - **Sector parameter:** $\alpha_s = \iota_k \cdot \eta_{\text{edge}}$ for componentwise corrections (regime-adjusted Prop B.5b); $\alpha_s = \iota_k \cdot \eta_{\text{edge}}/\kappa(\mathbf{J})^2$ for coupled corrections. Regime-C edges have $\alpha_s \approx 0$, making them effectively frozen — consistent with 9.3's treatment of unobservable edges. The sector parameter is Fisher-equivalent across coordinates (see Epistemic Status); the probability-space and log-odds-space statements of Props B.1–B.7 carry the same content. - **Computational cost:** $O(|V| + |E|)$ — the same forward pass that computes $\hat{R}_\Sigma$ also yields $\mathbf{J}$. The ι factors are per-edge domain parameters, not computed from the DAG structure. The sigmoid projection is $O(|E|)$ per update step. - **Relationship to RL:** This is the AAT analog of REINFORCE with a causal-identification weighting — the Jacobian $\mathbf{J}$ is the score function, $(y_G - \hat{R}_\Sigma)$ is the advantage, and ι_k is the causal-validity discount on each edge's update.

Correlated-failure interaction (L0 vs L1). The gradient signal operates at L0 of the Correlation Hierarchy (8.3). When the DAG is causally insufficient (the dominant real-world case), the residual $(y_G - \hat{R}_\Sigma)$ decomposes into per-edge miscalibration *plus* omitted correlation structure. $\hat{R}_\Sigma$ systematically overestimates success, making the residual systematically negative on failure. The gradient signal then attributes to individual edges what is actually causal insufficiency (missing common-cause nodes). The signal retains directional fidelity *on average* (it pushes edges downward when the plan is overconfident, which is the correct direction), but the per-edge attribution is contaminated. The principled fix is L1: add common-cause nodes to restore causal sufficiency, then apply gradient attribution to the augmented DAG. In the augmented DAG, the residual correctly decomposes into per-edge miscalibration because the correlation structure is explicitly represented.

Domains with richer observation structure can do better (Thompson sampling, full belief propagation, domain-specific attribution). The gradient-based signal is the *concrete Level 1 default* — the minimum viable credit-assignment scheme that satisfies the theory's requirements.

What the Theory Can Guarantee Without Solving Credit Assignment. Three results hold independently of any specific credit-assignment scheme:

1. Persistence is credit-assignment-free. Proposition B.5 in R shows that the sector condition transfers from per-edge credence space to **strategy-plan-confidence error** $\delta_s = \hat{R}_\Sigma - \Phi$ via the Jacobian $\mathbf{J} = \nabla_{\mathbf{p}} \hat{R}_\Sigma$. The Jacobian is computable from status propagation in $O(|V| + |E|)$ — no outcome decomposition required. The persistence guarantee (whether

the strategy’s plan-level self-assessment can be maintained) does not depend on the agent’s ability to attribute outcomes to edges. **Note:** this proves persistence of δ_s (strategy-plan-confidence error), not of $\delta_{\text{strategic}}$ (the per-edge calibration residual from 9.1). Extending persistence to $\delta_{\text{strategic}}$ requires solving the credit-assignment problem — that is the gap this segment characterizes.

2. The diagnostic framework is plan-level. The satisfaction gap (8.4), control regret (8.5), and the orient cascade ordering (10.1) operate on aggregate value, not per-edge quantities. They tell the agent *whether* the strategy is failing (and whether the failure is feasibility vs. optimality vs. calibration), without requiring per-edge attribution.

3. Observability-dominance identifies the tractable edges. 9.3 determines which edges have nonzero observability — only these can receive informative signals. Edges with zero observability are frozen regardless of the credit-assignment scheme. The tractable boundary is the observable subgraph of Σ_t .

The Tractable Cases.

Credit assignment is solved (exact, polynomial-time) when:

Discussion (tractable-credit-assignment).

Table 9.4

Condition	Why tractable	Update rule
All intermediates observable	Each edge has its own observation; updates decouple	Beta-Bernoulli per edge (Prop B.2)
Binary outcomes, independent edges, linear chain	Marginal Bayesian update = proportional blame	Prop B.3 (with plan-level fallback for unobservable)
Tree DAG, observable leaves	No shared descendants; message passing is exact	Belief propagation (standard)

The Intractable Cases: Three Independent Barriers.

Exact per-edge attribution in general AND/OR DAGs with partial observability faces three independent barriers:

Discussion (intractable-credit-assignment).

1. Computational intractability (#P-hardness). The “contribution of edge k to the observed outcome” has the form of a Shapley value over a cooperative game defined by the AND/OR propagation. Since AND/OR DAGs can represent any monotone Boolean function (including weighted threshold functions), and Shapley value computation for weighted voting games is #P-complete (Deng and Papadimitriou, 1994), exact attribution is #P-hard. *Caveat:* the reduction is to *exact* computation; approximate Shapley values are computable in polynomial time with sampling.

2. Information-theoretic underdetermination. When intermediates are unobservable, per-edge attribution is *underdetermined*, not just hard. The identifiable subspace has dimension bounded by the number of observable nodes:

$$\dim(\mathcal{J}(\mathcal{V}_{\text{obs}})) \leq |\mathcal{V}_{\text{obs}}| \quad (9.18)$$

When $|\mathcal{V}_{\text{obs}}| < |E|$ (fewer observable nodes than edges), some directions in θ -space are fundamentally unresolvable from the available data. Any attribution in the unidentifiable directions relies on prior beliefs, not evidence.

3. The posterior correlation barrier. Even for approximately identifiable cases, any factored representation (independent Beta posteriors per edge) necessarily discards the correlation introduced by failure at multi-parent nodes. The exact posterior complexity grows exponentially with the number of observed failures. The factored representation is an approximation by construction — coupled corrections are inherent to the problem, not an artifact of a bad algorithm.

The Design Requirement.

The theory does not prescribe a specific credit-assignment scheme. It states what any scheme must satisfy for the persistence guarantees to hold:

Discussion (credit-assignment-design-requirement).

Minimal requirement (from 4.3): The per-edge signal function must have **directional fidelity** — the expected update for each edge must point toward the true credence:

$$\mathbb{E}[(\text{signal}(o_t, i, j) - p_{ij}) \cdot (p_{ij} - \theta_{ij})] \leq 0 \quad (9.19)$$

(the expected correction is non-positively correlated with the current error). This is the per-component version of condition B1 from the bridge theorem. Any signal function satisfying this produces sector-satisfying corrections that transfer losslessly to value space (Prop B.5b, componentwise case).

Sufficient condition for persistence: Per-component directional fidelity + bounded gain ($\eta_{\text{edge}} > 0$). The theory guarantees persistence when these hold, regardless of how the signals are computed.

What's NOT required: Exact attribution, unbiased estimation, minimum-variance estimation, or optimality of any kind. The persistence guarantee is robust to approximation — a sloppy but directionally correct signal function still produces bounded strategic mismatch. The *quality* of the approximation affects the *tightness* of the persistence bound (how close R_{Σ}^* is to zero), not whether persistence holds at all.

The Hierarchy of Credit Assignment Quality.

Table 9.5

<i>Level</i>	<i>Requirement</i>	<i>What it buys</i>	<i>Cost</i>
0 (none)	Plan-level tracking only	Persistence guarantee (Prop B.5)	No per-edge diagnostics
1 (directional)	Directional fidelity per edge	Persistence + rough per-edge diagnostics	Gradient computation $O(V + E)$
2 (approximate)	Proportional blame / expectation propagation	Persistence + per-edge diagnostics (with bias)	Factor-graph inference
3 (exact)	Full Bayesian posterior	Persistence + optimal per-edge calibration	#P-hard (general case)

AAT's formal guarantees require only Level 0. Practical agents need at least Level 1 for adaptive behavior — and the default signal function (above) provides a concrete Level 1 scheme. Level 2 is the sweet spot for most applications. Useful Level 2 factor-graph approximations include: exact Belief Propagation (BP) on tree or polytree cases, loopy BP or max-sum for MAP-style diagnosis, Expectation Propagation (EP) for approximate marginals, and structured variational methods only where common-cause structure is explicitly modeled. Level 3 is a mathematical ideal that is computationally unattainable in the general case.

Epistemic Status.

Mixed. The default signal function (gradient-based attribution, stated in log-odds) is a *formulation* — a concrete, well-motivated representational choice analogous to the gain principle’s η^* formula. It satisfies directional fidelity for monotone AND/OR DAGs (derivable from Jacobian non-negativity). The log-odds presentation is *canonically selected* by the evidential-additivity axiom — the unique additive-evidence parameterization up to positive affine transformation (U). The boundary characterization (tractable cases, intractability barriers, design requirement) is *discussion-grade*, with the intractability argument at sketch level and the design requirement derived from the bridge theorem (4.3, R Prop B.5).

Historical note on the presentation choice. An earlier probability-space presentation of the default signal function, written as

$$\text{signal}_k = p_k + \iota_k \cdot J_k(y_G - \hat{R}_2) / \|\mathbf{J}\|^2 \quad (9.20)$$

with the update $p_k^{\text{new}} = p_k + \eta(\text{signal}_k - p_k)$, exhibited a mechanical break: when $\|\mathbf{J}\|^2 \rightarrow 0$ the signal magnitude could push p_k^{new} outside $[0, 1]$. The log-odds presentation above eliminates this failure mode by construction. Props B.1–B.7 of R remain as stated — their sector-parameter content is Fisher-equivalent across parameterizations, and the moment-parameter form is retained for algebraic clarity. The current segment writes the *default* signal in log-odds (native coordinate), with the moment-parameter form understood as the projected image via sigmoid.

Max attainable: *conditional* — with a formal intractability reduction, the boundary characterization could be promoted. The design requirement is already exact (it follows from the bridge theorem). The log-odds presentation is *derived-conditional* (on the evidential-additivity axiom) via U, structurally parallel to the reverse-KL uniqueness result under the chain-rule axiom in T §6.1.

Discussion.

AAT characterizes the structure, not the algorithm. The theory’s contribution to credit assignment is not a solution but a characterization: when it’s trivial (observable intermediates), when it’s hard (general partial observability), what any solution must satisfy (directional fidelity), and what guarantees hold without it (persistence, plan-level diagnostics). This is the right level of ambition for a theory of adaptive systems — the specific algorithm is domain-specific engineering; the structural characterization is universal.

The analogy to the gain principle. 3.6 characterizes the optimal gain structure ($\eta^* = U_M / (U_M + U_o)$) without prescribing how U_M and U_o are estimated. A Kalman filter computes them exactly; an RL agent approximates them; a human intuits them. The gain *principle* is theory; the gain *estimator* is engineering. Credit assignment has the same structure: the *requirement* (directional fidelity) is theory; the *implementation* (proportional blame, gradient attribution, belief propagation) is engineering.

The observability lever. The most powerful insight from this analysis is that credit assignment is primarily an *observability design problem*, not an algorithm design problem. An agent that designs its strategy with observable intermediates (instrumented plans, staged rollouts, checkpoints) sidesteps the intractability entirely. This connects to 9.3’s practical guidance: invest in making intermediate states observable, because unobservable regions are both epistemically dead (frozen credences) and computationally intractable (no efficient attribution).

OKRs as observability-by-design. The Objectives and Key Results framework is a direct organizational instantiation of this principle. The OKR discipline converts a deep, partially-unobservable strategy DAG (objective $\rightarrow$ vague initiatives $\rightarrow$ daily actions) into one with explicitly observable intermediate nodes (objective $\rightarrow$ measurable Key Results $\rightarrow$ tracked initiatives). In AAT terms: Key Results are intermediate nodes with $\sigma_o \approx 1$ by construction, making credit assignment between actions and objectives componentwise (Prop B.2) rather than intractable.

OKR failure modes map to AAT predictions:

Table 9.6

<i>OKR Failure</i>	<i>AAT Analog</i>	<i>Formal Quantity</i>	<i>Consequence</i>
Vanity metrics (measurable but irrelevant)	Observable node not causally connected to objective	High σ_v , low p_{ij}	Edge updates, but the edge doesn't lead where the agent thinks — correction effort is wasted
Too many Key Results	Wide OR-node exploration-gating	$\alpha_\Sigma \propto 1/k$ (Prop B.4)	Correction capacity diluted across alternatives; persistence threshold harder to meet
Lagging indicators	Evidence starvation by delay	$v_{\text{obs}} \ll \rho$	By the time the KR is measured, the correction window has passed; mismatch accumulated beyond R_Σ
Goodhart's Law (metric becomes the goal)	Terminal-condition misalignment with O_t	$V_{O_t}(\tau) < V_{O_t}^{\min}$ despite terminals achieved	Well-formedness constraint (8.3) violated; agent optimizes the intermediate rather than the objective

This is not an analogy — it is a domain instantiation. The same formal machinery that predicts when strategic persistence holds also predicts when OKRs work: when Key Results are genuinely causally connected to the Objective (p_{ij} is high and calibrated), few enough to monitor effectively (k is small), and measured on a timescale that permits correction (observation rate exceeds environment drift rate). The TST bridge to software team dynamics runs through exactly this connection.

Working Notes.

- A formal reduction from AND/OR credit assignment to Shapley value computation would promote the intractability claim from sketch to derived. The key step: mapping the AND/OR propagation to a weighted threshold game.
- The proportional-blame heuristic (attribute in proportion to prior credence) satisfies directional fidelity for independent edges. Does it satisfy directional fidelity in general? The two-edge analysis (B.3) shows it introduces $O(1/n)$ bias — which means it has directional fidelity in expectation but not per-step. Whether the expected-value directional fidelity is sufficient for the sector condition (it should be, since the sector condition is also stated in expectation) is worth verifying formally.
- The connection between AAT's credit assignment and RL's temporal credit assignment (TD learning, eligibility traces) deserves formal treatment. Both face the same structural problem (partial observability of the causal chain) and both use similar heuristics (discounted attribution to recent actions). AAT's DAG structure is richer than RL's linear temporal chain, which may make the problem harder but also provides more structural information.
- The log-odds presentation of the default signal function (this segment) closes the Finding 2 mechanical break by construction (audits/pending-findings-2026-04-22.md §Finding 2, spikes/.integrated/spike-gbp1-logit-scoping.md). Props B.1–B.7 remain in moment-parameter form because Fisher-equivalence keeps their sector-parameter content parameterization-agnostic; if a future pass moves the entire strategy layer to log-odds as its primary coordinate (full G-BP1 execution, likely paired with G-BP3 Fisher unification), the Prop B.1–B.7 restatements should follow. The scoping found the current narrow fix sufficient.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 193847, 361742, 471203, 526815, 584721, 773921, 829314, 849201. (Multiple substrates rated this segment top-decile, principally for the OKR mapping.)

1. Candidate Brief prose / pre-prose.

- **“Observability is the lever, not algorithm design.”** The segment’s headline reframing, independently named by nearly every substrate: credit assignment is “primarily an *observability design problem*, not an *algorithm design problem*” — invest in observable intermediates rather than smarter attribution algorithms (Claude/849201, 361742, 584721; Gemini/773921). A candidate Brief / Discussion thesis line.
- **The four-level credit-assignment hierarchy as the clean tiering.** Level 0 (plan-level, none) suffices for *persistence*; Level 1 (directional) for *adaptive behavior*; Level 2 is the practical sweet spot; Level 3 (exact Bayesian) is #P-hard. Most ML literature implicitly demands Level 3; AAT’s claim that Level 1 suffices for the formal guarantees is the distinctive, citable move (Claude/584721, 471203, 361742).

2. Candidate Discussion.

- **OKRs as observability-by-design — the standout domain instantiation.** Universally hailed (Claude/193847, 584721, 471203; Gemini/829314, 773921, 849201) as the framework’s clearest reach into management practice. The mechanism: a deep CEO→...→Revenue DAG has unobservable intermediates, so exact attribution is #P-hard and learning freezes; a “Key Result” is a *forced, observable intermediate node* ($\sigma_v \approx 1$) that decomposes the #P-hard problem into trivial local $O(1)$ updates and localizes strategy-error vs execution-error. The failure-mode table is the load-bearing artifact (cited verbatim by 471203):
 - **Vanity metrics** — observable but causally disconnected (high σ_v , low p_{ij}).
 - **Too many KRs** — wide OR exploration-gating ($\alpha_\Sigma \propto 1/k$).
 - **Lagging indicators** — evidence starvation by delay ($\nu_{\text{obs}} \ll \rho$).
 - **Goodhart’s Law** — terminal-condition misalignment ($V_{O_t}(\tau) < V_{O_t}^{\min}$ despite terminals achieved). One auditor’s adversarial caution worth recording: the four modes are *known* management pathologies, so the genuine predictive test is whether AAT predicts a *new* OKR failure mode absent from the standard literature (candidate: the #der-observability-dominance “absorbing-state” prediction applied to organizational measurement gaps) (Claude/471203). A sharpening of the *mechanism*: OKRs work, when they work, because each Key Result is an *observable intermediate node* that converts the intractable (#P-hard) credit-assignment problem into the tractable componentwise case (Prop B.2) — “the OKR system is essentially an organizational protocol for the observability-investment strategy” (Claude/451729). Organizations routinely ask “which initiatives contributed most?” — exactly the #P-hard partial-observability credit-assignment problem, escapable only by observability investment.
- **Proportional blame is Bayesian marginalization, not a heuristic.** Worth surfacing as a “the intuition was right for a formal reason” Discussion note: for independent Beta-Bernoulli edges with an unobservable intermediate, “credit each edge in proportion to its prior responsibility” turns out to be exactly the optimal marginal Bayesian point estimate — the same pattern as EM’s posterior-weighted latent updates and variational inference’s credit-through-the-variational-posterior; “credit proportional to prior probability is Bayesian marginalization in disguise” (Claude/451729). (Complements the existing Working-Notes B.3 result that this marginal update is nonetheless *biased at truth* when fed back into a factored DAG.)
- **AAT-as-REINFORCE-with-causal-weighting.** The default signal reads as RL with a causal discount: “Jacobian is the score function, $(y_G - \hat{R}_\Sigma)$ is the advantage, ι_k is the causal-validity discount” — a candidate bridge to RL theory that also marks AAT’s distinct contribution (Claude/584721).

3. Follow-up items.

- (No framing-grade follow-ups beyond what Working Notes already track. The Codex/526815 items F60/F61/F62 are routed to the off-ramp — see lift report — as candidate findings: the gradient signal cannot point *every* edge toward its own truth from a single signed plan residual; the $\div \|J\|^2$ update is still unbounded as $\|J\| \rightarrow 0$ even in log-odds; the “causally insufficient DAG always overestimates” claim is topology-dependent in sign.)*

4. Readers often ask / wonder.

- **How do biological brains do #P-hard credit assignment?** Presumably localized approximations (gradient/backprop-like) plus heavy evolutionarily-enforced observability gating — a natural reader question the intractability result invites (Gemini/829314).
- **How does a Regime-C-only agent ever learn a strategy** if $l_k \approx 0$ zeroes its edge updates? (Claude/193847) — answered by combining priors + active probing, worth pre-empting.

5. Candidate figures.

- **Scalar-residual-fanned-onto-edges diagram.** One scalar plan residual projected onto several edge coordinates through the nonnegative Jacobian: when edge errors are aligned it works as a rough per-edge signal; when they have mixed signs the *same* residual sign is broadcast through all positive J_k , so some edge-local directions must be wrong (Codex/526815). Doubles as the figure *and* the visual statement of the F60 limitation.

Belongs elsewhere.

- **Log-odds as the coordinate of conviction — trauma/phobia reading → 04-eli-core/.** In probability space, learning “feels stopped” near $p = 0.999$; in log-odds space the belief is still moving fast, and $|\lambda| \gg 0$ is the *depth of conviction* — how much counter-evidence it takes to change one’s mind. A deep negative conviction ($\lambda = -100$) that the environment has since rendered safe needs a massive positive-evidence influx to drag back above zero: “the mathematical definition of trauma or phobia.” Implication for consciousness infrastructure: monitor not just p -values but the *log-odds momentum* of an agent’s beliefs to catch deep rigid convictions before they paralyze the strategy DAG (Gemini/193847). Aspirational reach pointing at interiority / memory material in 04-eli-core/.
- **Credit-assignment ↔ RL temporal-credit-assignment formal treatment.** Already a Working-Notes item; the audits reinforce it as a cross-field bridge (TD-learning / eligibility traces vs AAT’s richer DAG structure).

9.7 Formulation: Structural Change as Parametric Limit

A formulation move that dissolves the sharp line between parametric update (adjusting weights) and structural change (adding/removing edges). In the probabilistic DAG, “structural” changes to Σ_t are *continuous operations on edge weights and node sets* — not a separate mechanism. Pruning is a credence dropping below threshold; **strategic grafting** is a new causal hypothesis initialized at a prior. The framework presents six operations on the strategy DAG ordered by typical frequency, from most to least frequent: edge reweighting, γ reclassification (AND↔OR), pruning, strategic grafting, objective revision, and full restructure. A healthy agent does continuous strategic maintenance (reweight, occasionally prune and graft) and rarely reaches catastrophic restructuring. *Full restructure is the strategic analog of 4.8’s model-class change* — the rare, expensive event when the entire representational structure must be replaced. (*The unqualified term “grafting” — familiar from horticulture, graph rewriting, and decision-tree learning — is sanctioned in-segment shorthand for “strategic grafting” once the canonical compound has been introduced.*)

The key insight is that this extreme case is the *limit* of the continuous process, not a separate mechanism. An agent that maintains healthy strategic hygiene rarely needs full restructure; an agent that neglects maintenance — letting failing branches persist, ignoring negative evidence — accumulates *strategic debt* until catastrophic restructuring becomes unavoidable. Miller (2022, *Ex Machina*) provides a constructive existence proof for exactly this bridge in finite-state automata: a sequence of *neutral mutations* (alterations affecting only inaccessible regions of state space) can transform a Moore machine from one behavioral equivalence class to a structurally different one without ever changing its observable behavior — until a single additional mutation opens a transition to the restructured region, causing a radical behavioral change (the *extreme transition motif*: neutral invasion → neutral drift → niche creation → cascading displacement → consolidation). The strategy-DAG analog: edges with near-zero credence ($p_{ij} \approx 0$) are the *latent structure* — they consume minimal cognitive cost (9.9) but represent alternative causal hypotheses that become load-bearing if

circumstances change. An agent that prunes all low-credence edges for efficiency loses this latent diversity and becomes *brittle to regime change*.

The framework also distinguishes *within-agent* grafting from *cross-agent* grafting. Within-agent grafting incorporates a new causal hypothesis into the agent's own Σ_t (source: internal model, external information, or exploration — a stimulus rather than an integrating party). When the grafted structure originates in *another* agent and that agent's objective is also absorbed in the process, the mechanism is **symbiogenic composition** (12.3) — a bilateral cross-agent process treated separately in Part III. Biological example: mitochondria integrating into a host cell. Social analog: firm acquisitions integrate processes and decision-making authority simultaneously.

Formal Expression.

The six operations on Σ_t , ordered from most to least frequent:

Formulation (structural-change-as-parametric-limit).

Table 9.7

Operation	What changes	Trigger
Reweighting	Edge credence p_{ij}	New observation about the link (9.4)
γ reclassification	Node combination type AND $\leftrightarrow$ OR	Strong structural evidence that combination semantics changed
Pruning	Remove failed branch ($p_{ij} \rightarrow \approx 0$)	Credence drops below viability threshold
Strategic grafting	Add new branch ($0 \rightarrow p_{ij}$)	Discovery of a new possible path (initialized at prior)
Objective revision	Change terminal nodes	Feasibility failure or opportunity (8.4)
Full restructure	Replace entire Σ_t	Catastrophic failure (4.8)

A healthy agent does continuous strategic maintenance (reweight, occasionally prune and graft) and rarely reaches catastrophic restructuring. Full restructure is the strategic analog of 4.8's model-class change — the rare, expensive event when the entire representational structure must be replaced.

Epistemic Status.

Robust qualitative. The continuity claim (structural change as parametric limit) is a property of the probabilistic representation: in a space where edges carry real-valued credences, adding or removing an edge is a boundary event, not a discontinuity. The frequency ordering of operations is an empirical pattern, not a derived result — it's consistent with the observation that deeper changes (restructuring > pruning > reweighting) require more evidence and are more costly.

Discussion.

Connection to structural-adaptation necessity. 4.8 describes the rare case when the entire model class must be replaced — the agent's representational framework is fundamentally inadequate. In the strategy DAG, this corresponds to full restructure: the causal theory encoded in Σ_t is so wrong that incremental revision (reweighting, pruning) cannot fix it. The DAG must be rebuilt from a different starting point.

The key insight is that this extreme case is the *limit* of the continuous process, not a separate mechanism. An agent that maintains healthy strategic hygiene (regular reweighting, timely pruning of failing branches, proactive grafting of

alternatives) will rarely need full restructure. An agent that neglects maintenance — letting failing branches persist, ignoring negative evidence — accumulates strategic debt until catastrophic restructuring becomes unavoidable.

Neutral variation as the constructive bridge. This segment claims that radical restructuring is the *limit* of continuous operations, but the mechanism by which small changes accumulate into radical transformation was unspecified. Miller (2022, *Ex Machina*) provides a constructive existence proof for exactly this bridge in finite-state automata. In Moore machines, each state has accessible and inaccessible regions. A mutation that alters a transition into an inaccessible region is *neutral* — the machine’s observable behavior is unchanged because those states are never visited. But such mutations alter the machine’s *latent structure*: they change what the machine *would do* if novel inputs were encountered. A sequence of neutral mutations can transform a machine from one behavioral equivalence class to a structurally different one without ever changing its observable behavior — until a single additional mutation opens a transition to the restructured region, causing a radical behavioral change. In Miller’s terminology, this is the *extreme transition motif*: neutral invasion → neutral drift → niche creation → cascading displacement → consolidation. The automaton setting makes the mechanism precise: “inaccessible states” are the formal representation of latent structural capacity, “neutral mutations” are the incremental changes, and “a transition opening to a previously inaccessible region” is the parametric-limit event where continuous change produces discontinuous behavioral effect. The strategy-DAG analog: edges with near-zero credence ($p_{ij} \approx 0$) are the latent structure. They consume minimal cognitive cost (9.9) but represent alternative causal hypotheses that become load-bearing if circumstances change. An agent that prunes all low-credence edges for efficiency loses this latent diversity and becomes brittle to regime change.

Pruning and grafting thresholds. When should the agent prune (remove an edge with very low credence) rather than just keeping it at low p_{ij} ? The answer involves the cognitive cost of maintaining edges in Σ_t — each edge consumes representational capacity and evaluation time. For agents with bounded representational capacity (LLMs with finite context windows), pruning is necessary to keep Σ_t within capacity. The threshold is domain-dependent and connects to the open question of cognitive cost of Σ_t (6.7 Working Notes).

Cross-agent grafting: symbiogenic composition. The grafting operation above is within-agent — the agent incorporates a new causal hypothesis into its own Σ_t , with the source (internal model, external information, exploration) being a stimulus rather than an integrating party. When the grafted structure originates in *another* agent and that agent’s objective is also absorbed in the process, the mechanism is symbiogenic composition (12.3) — a bilateral cross-agent process rather than a unilateral within-agent operation. Biological example: mitochondria integrating into a host cell transfers gene-based structure (grafting on the host side) *and* subsumes the endosymbiont’s independent objective (outside the scope of this segment’s operations). Social analog: firm acquisitions integrate processes and decision-making authority simultaneously. The within-agent grafting operation is the host-side component of symbiogenesis, but symbiogenesis as a whole is governed by additional dynamics captured in 12.3.

Working Notes.

- The timescale ordering (reweight $\gg$ reclassify $\gg$ prune/graft $\gg$ revise $O_t \gg$ full restructure) is an empirical observation that should be testable. In software development: edge reweighting $\approx$ updating confidence after a test passes/fails; γ reclassification $\approx$ realizing two tasks are both required (not alternatives); pruning $\approx$ abandoning an approach that isn’t working; grafting $\approx$ discovering a new approach; objective revision $\approx$ changing the feature scope; full restructure $\approx$ starting the project over.
- Grafting (adding new edges) is qualitatively different from other operations because it requires the agent to hypothesize a causal relationship that isn’t in its current Σ_t . Where do new causal hypotheses come from? From M_t (the model suggests a possible path), from external sources (14.4 — another agent suggests an approach), or from exploration (3.7 — the agent discovers an unexpected effect). This is the creative step in strategic revision.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 361742, 471203, 526815, 584721, 773921, 829314.

1. Candidate Brief prose / pre-prose.

- **“Perfect efficiency is perfect brittleness.”** The convergent one-liner for the latent-diversity result: an agent that prunes *every* low-credence edge to save representation cost becomes optimally fitted to the current environment and helpless under a regime shift, forced into a fatal full-restructure rather than a cheap reweight (Gemini/829314, 773921; Claude/584721, 361742). Strong candidate Brief/Discussion hook.
- **The six-operation maintenance spectrum, ordered by frequency and cost** (reweight $\gg$ γ -reclassify $\gg$ prune/graft $\gg$ revise O_t $\gg$ full restructure) was praised as the segment’s clean organizing skeleton; the software-engineer mapping (test-pass reweight ... rewrite-from-scratch) grounds it (Claude/584721, 829314).

2. Candidate Discussion.

- **Neutral variation as the constructive bridge, sharpened.** The Miller-2022 connection converts “radical restructuring is the *limit* of continuous operations” from a claim into a precise mechanism: near-zero-credence edges $\equiv$ inaccessible/latent states; incremental updates $\equiv$ neutral mutations; a previously-near-zero edge becoming load-bearing under regime change $\equiv$ the parametric-limit event with discontinuous *behavioral* effect (Claude/361742, 584721). Candidate Discussion elaboration — “AAT does not need new discontinuous update math to handle paradigm shifts” (Gemini/829314).
- **The evolutionary-biology analog for latent diversity.** Most mutations are neutral and unselected in the current environment, but the dormant pool is what lets a population survive an ice age / new predator — applied to one agent’s Σ_t , this gives “a strict mathematical justification for why organizations should tolerate ‘inefficiency,’ ‘skunkworks,’ ‘weird side projects,’ and ‘technical debt that isn’t hurting anyone’ ... the latent structural diversity required to survive a paradigm shift.” The MDL penalty (#form-strategy-complexity-cost) vs. neutral-variation necessity is named as “the central architectural tradeoff of an agent’s life” (Gemini/829314). Candidate Discussion centerpiece.

3. Follow-up items.

- *(Framing-grade follow-ups are captured above; the Codex/526815 items F63/F64/F65 route to the off-ramp — see lift report — as candidate findings: the continuity claim needs an explicit ambient supergraph / zero-weight-edge embedding to be literal; AND $\leftrightarrow$ OR γ -reclassification is discrete absent a soft-gate parameterization; the “low-credence edges cost almost nothing” claim needs a credence-weighted cost model to be consistent with the pruning-threshold discussion.)*
- **Resolved process note:** an earlier audit (849201) flagged a stale “TF-10 destruction-creation” lineage reference in this segment’s discussion header; it is no longer present in canon (verified 2026-05-31).

4. Readers often ask / wonder.

- **Where do new edges come from — does AAT have a model of creativity / hypothesis generation?** The “creative step” of grafting (positing a causal edge not in Σ_t) is the natural reader question; the segment points to M_t / communication / CIY, but *generation* from M_t ’s latent space “is still somewhat magical” — and is precisely where LLMs excel as proposal generators (Gemini/829314; Claude/849201-via-batch). Worth an explicit Discussion sentence.

5. Candidate figures.

- **Ambient-supergraph two-view diagram.** In a fixed ambient supergraph an edge weight slides continuously from 0 to active (and back); *outside* that ambient graph, adding a node or flipping a gate is a discrete lift into a larger representational space. The figure makes visible exactly the scope the continuity claim needs (Codex/526815) — pedagogy + guardrail in one.

Belongs elsewhere.

- **Cross-agent grafting $\rightarrow$ #hyp-symbiogenic-composition (Part III).** Within-agent grafting is the host-side component of full (bilateral, objective-absorbing) symbiogenesis; the type distinction was praised but the symbiogenesis side belongs in the composition-machinery cluster, not this Part II segment (Claude/584721, 361742; Gemini/829314).

9.8 Definition: Strategic Tempo

The strategic analog of 3.8. **Strategic tempo** $\mathcal{T}_\Sigma$ is the effective rate at which an agent acquires useful revisions to its strategy Σ_t — the sum of per-edge correction capacities across the strategy DAG, with each edge’s contribution weighted by an *identifiability coefficient* ι_{ij} that captures whether the evidence stream genuinely identifies the edge’s causal effect. The structural parallel with epistemic tempo is exact: edge observation rate ν_{ij} times per-edge update gain $\eta_{\text{edge},ij}$ times identifiability coefficient ι_{ij} , summed over edges. The ι factor is where edge-causal-validity (9.5) enters the operational machinery of strategy revision: *an agent cannot improve the parts of its strategy that it cannot test interventionally*. Regime-A (intervention-rich) edges contribute full tempo at their observation rate; Regime-C (observation-only) edges contribute essentially nothing regardless of how fast the agent acts or how many observations it makes.

A *key structural difference* from epistemic tempo: edge rates are **endogenous**. Epistemic-tempo channel rates $\nu^{(k)}$ are largely exogenous — the environment generates observations at its own pace. Strategic-tempo edge rates ν_{ij} depend on the agent’s *action policy* (which edges get tested) and on *upstream success* (downstream edges are tested only when upstream edges fire). This endogeneity is the source of the structural differences between epistemic and strategic persistence. The framework decomposes strategic tempo by topology. **AND-chains are depth-gated**: each edge at depth k is tested at the upstream-success-attenuated rate $\nu_k = \nu \prod_{j < k} \theta_j$. For a uniform chain ($\theta_k = \theta$), total strategic tempo $\mathcal{T}_\Sigma$ converges to $\nu/((n+1)(1-\theta))$ as $d \rightarrow \infty$ — total strategic tempo is bounded even for arbitrarily deep chains, but the marginal contribution of each new edge decays geometrically. The deep edges are *evidence-starved*. **OR-nodes are exploration-gated**: under ε -greedy, the rate allocated to the greedy arm gets nearly all the action budget while exploratory arms get only ε/m . Pure greedy makes non-greedy arms *permanently uncorrectable*.

Per-edge persistence inherits the same weakest-link structure as per-dimension epistemic persistence (16.5): for Σ_t to persist, every edge must maintain bounded mismatch — $\forall (i, j) \in E : \nu_{ij} \cdot \iota_{ij} \cdot \eta_{\text{edge},ij} > \rho_{\Sigma,ij}/R_{\Sigma,ij}$. The aggregate $\mathcal{T}_\Sigma$ is at most the sum and at least the minimum across edges; exceeding total disturbance is *necessary but not sufficient*. Persistence is *bottleneck-limited by the weakest edge, not governed by the aggregate*. Scalar $\mathcal{T}_\Sigma$ overestimates effective strategic adaptation for the same reason scalar $\mathcal{T}$ overestimates epistemic adaptation — it averages over heterogeneous correction capacities. A practical consequence: given a fixed action budget, the topology that maximizes strategic tempo is *shallow and OR-heavy* (more edges directly observable, no attenuation); the topology that minimizes it is *deep AND-chains*. As observations accumulate per edge, $\eta_{\text{edge},ij}$ shrinks (diminishing returns), so $\mathcal{T}_\Sigma$ *declines over time even in a static environment*.

Formal Expression.

Definition (strategic-tempo).

$$\mathcal{T}_\Sigma = \sum_{(i,j) \in E} \nu_{ij} \cdot \eta_{\text{edge},ij} \cdot \iota_{ij} \quad (9.21)$$

where: - (i, j) indexes the edges of the strategy DAG (8.3) - ν_{ij} is the effective observation rate for edge (i, j) — how often the agent obtains evidence about the causal link $i \rightarrow j$ - $\eta_{\text{edge},ij}$ is the per-edge update gain (9.4) - $\iota_{ij} \in [0, 1]$ is the identifiability coefficient (9.5): the fraction of the evidence stream that genuinely identifies the edge’s causal effect

Regime contributions. The identifiability coefficient captures the regime distinction from 9.5:

Table 9.8

Regime	ι_{ij}	Contribution to $\mathcal{T}_\Sigma$	Example domain
A Intervention-rich	≈ 1	Full: $\nu_{ij} \cdot \eta_{\text{edge},ij}$	Software tests, laboratory experiments

Regime	t_{ij}	Contribution to $\mathcal{F}_\Sigma$	Example domain
B Partial intervention	$\in (0, 1)$	Reduced proportionally	Organizational actions with concurrent effects
C Observation-only	≈ 0	Near-zero: edges contribute negligibly	Passive monitoring, intelligence analysis

An agent cannot improve the parts of its strategy that it cannot test interventionally. This is the operational content of the t factor: Regime-C edges contribute essentially nothing to $\mathcal{F}_\Sigma$ regardless of how fast the agent acts or how many observations it makes. Regime-A edges yield full strategic tempo at their observation rate. The t factor is where edge-causal-validity (9.5) enters the operational machinery of strategy revision.

Parallel with epistemic tempo. The definition mirrors 3.8's $\mathcal{F} = \sum_k \nu^{(k)} \cdot \eta^{(k)*}$, replacing observation channels with strategy edges and adding the t modulation for causal identifiability. The structural parallel is exact for Regime-A edges (where $t = 1$ recovers the direct rate-times-gain form); in mixed regimes, t carries the additional content distinguishing interventional evidence from associational proxy.

Key difference: endogenous edge rates. Epistemic tempo's channel rates $\nu^{(k)}$ are largely exogenous — the environment generates observations at its own pace. Strategic tempo's edge rates ν_{ij} are *endogenous*: they depend on the agent's action policy (which edges get tested) and on upstream success (downstream edges are tested only when upstream edges fire). This endogeneity is the source of the structural differences between epistemic and strategic persistence.

Consistency verification. The definition is consistent with the four verified topologies from R:

Case B.1 (single edge $A \rightarrow G$). One edge, $\nu = \nu_{AG}$, $\eta_{\text{edge}} = 1/(n+1)$. $\mathcal{F}_\Sigma = \nu_{AG}/(n+1)$. The sector parameter $\alpha_\Sigma = 1/(n+1)$ is the per-observation correction quality; $\mathcal{F}_\Sigma = \nu \cdot \alpha_\Sigma$, matching the epistemic tempo pattern exactly.

Case B.2 (two-edge AND chain, $A \rightarrow B \rightarrow G$, B observable). Two edges. Edge 1 is tested at rate $\nu_1 = \nu$ (every execution). Edge 2 is tested only when edge 1 succeeds: $\nu_2 = \nu \cdot \theta_1$. The bottleneck edge has $\alpha_\Sigma = \min(1/(n_1+1), \theta_1/(n_2+1))$. $\mathcal{F}_\Sigma = \nu/(n_1+1) + \nu\theta_1/(n_2+1)$, consistent with depth-gated attenuation.

Case B.3 (two-edge AND chain, B unobservable). Per-edge tempo is ill-defined (the marginal point estimate is biased). Plan-level tempo is well-defined: $\mathcal{F}_{\Sigma, \text{plan}} = \nu/(n_\Phi+1)$, treating $\Phi = p_1 p_2$ as a single tracked quantity.

Case B.4 (two-arm OR node, ε -greedy). Edge 1 tested at rate $\nu_1 = \nu(1-\varepsilon)$, edge 2 at rate $\nu_2 = \nu\varepsilon$. $\mathcal{F}_\Sigma = \nu(1-\varepsilon)/(n_1+1) + \nu\varepsilon/(n_2+1)$. Action selection directly controls the rate allocation — exploration-gated, not depth-gated.

Structural decomposition. AND-chains: depth-gated (geometric attenuation). In a chain of depth d with edge success probabilities θ_k , the effective observation rate for edge k is:

Derived (Conditional on independent edges).

$$\nu_k = \nu \cdot \prod_{j < k} \theta_j \quad (9.22)$$

Each additional depth level attenuates by a factor $\theta_k < 1$. For a uniform chain ($\theta_k = \theta$, $n_k = n$ for all k):

$$\mathcal{F}_\Sigma = \frac{\nu}{n+1} \sum_{k=1}^d \theta^{k-1} = \frac{\nu}{n+1} \cdot \frac{1-\theta^d}{1-\theta} \quad (9.23)$$

This converges to $\nu/((n+1)(1-\theta))$ as $d \rightarrow \infty$ — total strategic tempo is bounded even for arbitrarily deep chains. The marginal tempo contribution of edge k decays as θ^{k-1} , falling below any fixed threshold at depth d^* (9.9). Deep AND-chains have low $\mathcal{T}_\Sigma$ at their leaves regardless of how fast the agent acts — the evidence-starvation effect identified in R.

OR-nodes: exploration-gated. At an OR-node with m alternatives under ε -exploration, the rate allocated to alternative l is:

Definition (OR-node rate allocation).

$$\nu_l = \begin{cases} \nu(1 - \varepsilon + \varepsilon/m) & l = l^* \text{ (greedy arm)} \\ \nu \cdot \varepsilon/m & l \neq l^* \text{ (exploratory arms)} \end{cases} \quad (9.24)$$

The bottleneck is the least-explored alternative. Pure greedy ($\varepsilon = 0$) gives $\nu_l = 0$ for non-greedy arms, making those edges permanently uncorrectable.

Per-edge persistence.

For Σ_t to persist, every edge must maintain bounded mismatch. The bottleneck condition is:

Derived (from persistence-condition applied per edge).

$$\forall (i, j) \in E : \quad \nu_{ij} \cdot l_{ij} \cdot \eta_{\text{edge},ij} > \frac{\rho_{\Sigma,ij}}{R_{\Sigma,ij}} \quad (9.25)$$

This is the per-edge analog of 16.5's per-dimension condition for M_t . The aggregate relationship between $\mathcal{T}_\Sigma$ and the average correction rate α_Σ is:

$$\alpha_\Sigma \leq \frac{\mathcal{T}_\Sigma}{|E|} \leq \mathcal{T}_\Sigma \quad (9.26)$$

(minimum $\leq$ average $\leq$ sum). Consequently, $\mathcal{T}_\Sigma > |E| \cdot \rho_\Sigma / R_\Sigma$ is *necessary* for persistence but not sufficient — the persistence condition is bottleneck-limited by the weakest edge, not governed by the aggregate.

Epistemic Status.

The definition itself is axiomatic — it names a quantity by analogy with 3.8. The consistency verification with the four cases from R is *derived* (conditional on Beta-Bernoulli dynamics). The AND-chain geometric attenuation is *derived* (conditional on independent edge outcomes). The OR-node exploration gating and identifiability adjustment are *hypotheses* in the general DAG case, though verified for the specific topologies above. The bottleneck-limited persistence observation is *derived* from 16.5's result applied to the strategy substate. The additive form also inherits the noise-correlation scope derived in AS: the edge-wise sum is exact when the edges' evidence-noise is cross-edge independent, and the deviation under correlated evidence (e.g., one observation informing several edges, or a shared attribution error contaminating a path) is *signed* — a common evidence source overcounts, while structurally anti-correlated evidence errors can make the sum an undercount. The per-edge topology conditions named above are independence assumptions of this kind.

Max attainable: conditional. Currently conditional because the general DAG case (mixed AND/OR topologies, correlated edges) has not been verified.

Discussion.

Connection to 16.5. The per-edge persistence condition inherits the same structure as the per-dimension epistemic result: the weak edge is the bottleneck. Scalar $\mathcal{F}_\Sigma$ overestimates effective strategic adaptation for the same reason scalar $\mathcal{T}$ overestimates epistemic adaptation — it averages over heterogeneous correction capacities. A topology-specific corollary [Discussion]: per-edge persistence (every edge calibrated) and plan-level persistence (the plan’s value estimate tracks reality) can diverge in a *stationary* environment only at OR-nodes — a starved exploratory arm drifts uncalibrated while the greedy arm carries the plan value — whereas AND-structures cannot exhibit the divergence, since every edge on the conjunctive path enters the plan value and an uncalibrated edge shows up there directly.

Three-way tradeoff. Strategic tempo competes with both epistemic tempo and exploitation for the agent’s finite action capacity. Each action that tests a strategy edge (improving $\mathcal{F}_\Sigma$) is an action not spent gathering epistemic information (improving $\mathcal{T}$) or pursuing the current best action (exploitation). The allocation is addressed in 10.2 — the extended deliberation threshold is derived, but the broader three-way framing is discussion-grade. Deliberation (internal computation) supplements $\mathcal{F}_\Sigma$ via an internal channel distinct from action-generated evidence.

Software as Regime A. In software development, tests are genuine interventions with attributable outcomes ($t_{ij} \approx 1$). This makes software agents naturally high- $\mathcal{F}_\Sigma$ — a structural advantage identified but not yet formalized in the TST domain (02-tst-core/).

Working Notes.

- **2026-07-16 — OR/AND calibration-vs-performance divergence gloss added to Discussion** (bulk-64 closeout; provenance: spikes/.integrated/spike-or-node-strategic-dynamics.md §4, whose substantive results were verified landed — this was its one unlanded discussion-grade observation).
- **2026-07-16 — noise-correlation scope made explicit (ripple from AS).** The Epistemic Status now names the cross-edge evidence-noise independence condition and its signed deviation. Nothing in the body claimed the overcount-only reading, so no claim was deleted — this closes the “same scope, unaudited” flag from the 2026-07-15 spike.
- **Mixed AND/OR DAGs.** The structural decomposition treats AND-chains and OR-nodes separately. Real strategy DAGs interleave both. How the geometric attenuation (AND) and exploration gating (OR) interact in mixed topologies is unverified. The per-edge persistence condition sidesteps this by treating each edge independently, but the *aggregate* behavior of $\mathcal{F}_\Sigma$ in mixed DAGs may exhibit interference effects (e.g., evidence starvation in an AND-chain feeding into an OR-node’s greedy arm).
- **Optimal topology.** Given a fixed action budget ν , what DAG topology maximizes $\mathcal{F}_\Sigma$? Shallow OR-heavy structures maximize tempo (more edges are directly observable, no attenuation). Deep AND-chains minimize tempo. This may yield a principled argument for preferring flat, option-rich strategies over deep sequential plans — complementing the confidence-decay argument in 8.1.
- **Dynamic complexity.** As n_{ij} grows (more observations per edge), $\eta_{\text{edge},ij}$ shrinks (diminishing returns). Strategic tempo declines over time even in a static environment — the agent’s corrections become smaller as edges converge. This is the correct qualitative behavior (converged edges need less correction) but means $\mathcal{F}_\Sigma$ is not a fixed property of the agent-environment pair.
- **Cross-reference to NeurIPS Paper 2.** The strategic-tempo aggregator is **bottleneck-not-sum** in NeurIPS 2026 Paper 2 (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning”, ~/src/neurips/02-unified-convergence-rl/, §5 Lemma 4.2 / #lem-forgetting): $\mathcal{F}_\Sigma^{\text{bn,ss}} := \min_{(i,j) \in E} \nu_{ij} \cdot t_{ij} \cdot (1 - \lambda_{ij})$. Adversarial disturbance concentrates on the slowest-forgetting / weakest-attribution / slowest-revisited element — the same weakest-link pattern as #result-per-dimension-persistence at strategic-tempo level. This segment’s $\mathcal{F}_\Sigma = \sum_{(i,j)} \nu_{ij} \cdot \eta_{\text{edge},ij}$ is the throughput aggregation; the bottleneck form is the persistence-relevant aggregation. The two are compatible: throughput-sum bounds the budget of corrective work the agent can allocate; bottleneck-min bounds the rate at which the worst element survives adversarial concentration. See spikes/neurips-back-integration-2026-05-08.md §1 Paper 2 entry 8.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 471203, 526815, 584721, 773921, 829314.

1. Candidate Brief prose / pre-prose.

- **Endogenous vs. exogenous observation rates** — “why learning a strategy is harder than learning a world model.” Independently flagged as the segment’s deepest point: epistemic observation rates are *exogenous* (the world happens to you), but strategic edge rates are *endogenous* — you only get to test a downstream edge if you succeed at the upstream ones (Claude/584721, 829314; Codex/526815). One auditor called it “the deepest architectural insight in Part II” and the source of the M_t/Σ_t persistence differences. Strong candidate Brief framing.
- **“The shape determines the physics of how the plan learns.”** A wide/OR-heavy DAG learns its paths in parallel (tempo scales with the exploration budget); a deep/AND-chain has *bounded total tempo* no matter how fast the early steps run. Candidate one-line Brief hook (Gemini/829314).

2. Candidate Discussion.

- **Bounded total tempo of deep chains** $\Rightarrow$ “waterfall is mathematically dead.” The geometric series $\sum_{k=1}^d \theta^{k-1} \rightarrow 1/(1-\theta)$ proves a deep AND-chain’s *total* learning capacity asymptotically plateaus while the marginal tempo of deep edges decays to zero — “deep plans literally cannot learn fast enough to survive a volatile environment.” Worked instance: a 20-step sequential plan starves its late steps of evidence; a startup exploring 5 verticals in parallel calibrates all five (Gemini/829314; Claude/584721, 471203). Candidate Discussion centerpiece.
- **The evolutionary reading.** Instincts are shallow OR-heavy DAGs (“if hot, pull hand away OR yell”); complex human planning is deep AND-heavy and “incredibly fragile, requiring massive cultural scaffolding (forced observability, artificially lowered ρ via institutions) to survive its own mathematical evidence starvation — we build society to lower ρ so our deep AND-chains don’t collapse before they finish” (Gemini/829314). Candidate Discussion analogy; isomorphism would need checking before promotion past discussion-grade.
- **Endogenous tempo is why “do-what-you-know” organizations fail.** Because edge rates v_{ij} are endogenous, an agent that always exploits and never tests alternatives drives v on its exploratory edges $\rightarrow 0$, so $\mathcal{F}_2$ for those edges collapses to the greedy branch only — the agent “starves its strategic learning capacity” and (combining with #der-causal-insufficiency-detection) cannot even detect its L0 insufficiency (Claude/451729). Candidate Discussion line tying the endogenous-rate property to a concrete organizational failure.
- **Five converging arguments for shallow plans.** This segment’s strategic-tempo bottleneck is the *fifth* independent pressure toward shallow strategy DAGs, joining chain-confidence-decay, evidence-starvation, identifiability-degradation, and cognitive cost. Candidate to surface as a cross-segment structural observation (Claude/584721). (*Same meta-pattern flagged under #scope-edge-update-causal-validity as the “quadruple ceiling” — this is the fifth leg; consider a single meta-segment home.*)

3. Follow-up items.

- **Dynamic complexity / gain-collapse warning.** $\mathcal{F}_2$ declines over time even in a *static* environment because $\eta_{\text{edge}} = 1/(n+1)$ shrinks as n grows — so a long-running agent eventually has insufficient strategic-correction capacity for any non-stationarity unless a ρ -spike re-inflates η . Connects to the gain-collapse / stability-induced-myopia / detection-latency-blowup pathology cluster; candidate to develop (Claude/584721; Gemini/829314). Already partly a Working-Notes item.
- **Candidate “tempo-maximizing topology” theorem (off-ramp-adjacent).** One auditor sketched that under a fixed action budget v and fixed edge count, the tempo-maximizing topology is the shallowest OR-tree: AND-chain tempo converges to $v/((n+1)(1-\theta))$ while flat-OR (full exploration) gives $v/(n+1)$, so OR-flat beats an AND-chain for depth $> 1/(1-\theta)$ (e.g. depth > 10 at $\theta = 0.9$); the Working-Notes “shallow OR-heavy maximizes tempo” line may be promotable to a derived statement (Claude/451729). *If* this firms up it is a candidate derivation (strengthen-first), not a framing bullet — flagged for the off-ramp.

- (Codex/526815 F66/F67/F68 route to the off-ramp — see lift report — as candidate findings: the headline defines $\mathcal{F}_\Sigma$ as a *sum but the persistence-relevant quantity is the bottleneck/min; “Regime-C edges contribute essentially nothing” overstates — observational evidence still improves *associational* prediction; the $\mathcal{F}_\Sigma > |E|\rho/R$ necessary bound assumes homogeneous per-edge thresholds and should sum $\sum_e \rho_e/R_e$ in the heterogeneous case.)*

4. Readers often ask / wonder.

- **How does the agent allocate a finite action budget across exploit / epistemic-explore / strategic-explore (deliberate)?** Several substrates reached forward to #disc-exploit-explore-deliberate for the three-way (or four-way, with “diagnose”) allocation rule (Claude/584721, 829314).

5. Candidate figures.

- **Throughput-sum vs. bottleneck-min, same edges.** Two simultaneous summaries over the same DAG edges: a throughput *sum* (looks healthy) and a bottleneck *minimum* (the one untested or weakly-identifiable edge that actually fails the per-edge persistence condition). Makes the sum-vs-min distinction visible at a glance (Codex/526815) — pedagogy + the F66 guardrail in one figure.

Belongs elsewhere.

- (none surfaced beyond the shared “shallow-plans meta-pattern” pointer noted under Discussion)

9.9 Formulation: Cognitive Cost of Strategy

A formulation connecting strategy structure to its *maintenance cost* — making the explicit-strategy condition from 7.6 quantitative. The minimum description length of a strategy DAG $\Sigma_t = (V, E, p, \gamma)$ decomposes into *structural* bits (encoding topology — node identities, edge connectivity, AND/OR labels) and *parameter* bits (encoding the edge credences given the topology), scaling as $O(|E| \log |V|)$ for sparse DAGs and moderate-precision credences.

The framework offers a **strategy IB objective**: Σ_t is the information-bottleneck compression of the interaction history $\mathcal{C}_t$ for guidance, parallel to M_t as the IB-compression of $\mathcal{C}_t$ for prediction. The variational form trades off compression cost $I(\mathcal{C}_t; \Sigma_t)$ against a KL divergence from the optimal-policy reference to the strategy-induced policy. The **KL direction** is *not* a stipulation — it is forced by a regret-bound derivation (T): under bounded value range and deterministic $\pi^* = \delta_{a^*}$ (AAT’s canonical scope, 6.6), the strategy-induced regret satisfies $R(Q_{\Sigma_t}) \leq V_{\max} \cdot \text{TV}(\pi^*, Q_{\Sigma_t}) \leq V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})}$ by Pinsker, with the sharper Bretagnolle-Huber identity $R \leq V_{\max}(1 - e^{-D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})})$ as the primary form. The opposite-direction KL is $+\infty$ whenever Q_{Σ_t} places any mass off a^* — a vacuous bound. The direction is *forced* with π^* first (reverse-KL in variational-inference vocabulary). Within the direction-forced family, reverse-KL is *uniquely* selected by a chain-rule additivity axiom (Hobson 1969; Csiszár 1991), AAT-internally motivated as the divergence-level analog of 8.1’s log-additive layer. This is the **second instance of the four-layer additive-coordinate-forcing meta-pattern** (5.5): a uniqueness theorem operating on an AAT-internally-motivated additivity axiom forces a specific coordinate. The whole construction lifts the IB objective from discussion-grade to *robust-qualitative*.

The framework derives a **maximum useful chain depth** for AND-chains: given base observation rate ν , per-edge success probability θ , effective sample size n , and disturbance-to-capacity ratio ρ_Σ/R_Σ , there is a finite depth d^* beyond which the deepest edge cannot maintain bounded mismatch. Beyond this depth, evidence starvation makes the edge uncorrectable faster than the environment invalidates it. A central observation: **deep AND-chains suffer a triple depth penalty** that compounds. (1) *Confidence decay* (8.1): aggregate confidence $\prod p_k$ decays geometrically — *the plan is less likely to succeed*. (2) *Evidence starvation* (R): effective observation rate decays geometrically — *the plan is harder to calibrate*. (3) *Cognitive cost* (this segment): each additional depth level adds $O(\log |V|)$ bits — *the plan is more expensive to maintain*. All three are multiplicative in depth, making deep sequential strategies exponentially costly

along three independent dimensions and creating systematic pressure toward *shallow, OR-heavy strategies*. The framework also makes the maintenance cost from 7.6 concrete by decomposing it into representation cost (proportional to description length), revision cost (proportional to strategic tempo $\mathcal{T}_\Sigma$), and monitoring cost (proportional to edges with partial identifiability).

A practical consequence for language-constituted agents: a context window of W tokens imposes a hard upper bound $DL(\Sigma_t) \leq W \log_2(|\text{vocab}|)$, making the IB trade-off *non-optional* — the agent *must* compress its strategy, and d^* becomes a context-window-limited quantity (a 128K-token context may support a 500-edge DAG encoded in natural language; a 4K-token window may support only a 15-edge sketch). The Miller (2022) coevolving-automata result provides a complementary constraint from the interaction side: a complex Σ_t whose edges are only tested over a short horizon is *indistinguishable from a simpler strategy*. The interaction horizon compresses the strategy space from above, just as maintenance cost and evidence starvation compress it from below.

Formal Expression.

Strategy description length.

The minimum description length of a strategy DAG $\Sigma_t = (V, E, p, \gamma)$ (8.3) decomposes as:

Formulation (strategy-description-length).

$$DL(\Sigma_t) = DL_{\text{struct}}(G) + DL_{\text{param}}(p \mid G) \quad (9.27)$$

where: - $DL_{\text{struct}}(G)$: bits to encode the DAG topology — node identities, edge connectivity, AND/OR labels γ . Scales as $O(|E| \log |V|)$ for sparse DAGs. - $DL_{\text{param}}(p \mid G)$: bits to encode the edge credences given the topology. For Beta-distributed credences, each edge requires $O(\log n_{ij})$ bits where $n_{ij} = \alpha_{ij} + \beta_{ij}$ is the effective sample size.

The total scales as $O(|E| \log |V|)$ for moderate-precision credences, growing linearly in the number of edges and logarithmically in the number of nodes.

Strategy IB objective.

The optimal strategy complexity balances parsimony against decision-relevance. Σ_t is the IB-compression of the interaction history $\mathcal{C}_t$ for guidance, parallel to M_t as the IB-compression of $\mathcal{C}_t$ for prediction (AA for the shared IB shape across AAT's compression operations, and for the relationship between the theoretical $I(\mathcal{C}_t; \Sigma_t)$ compression cost and the operational DL-based minimization below):

Formulation (strategy-IB-objective; KL-direction strengthened by regret bound — see Epistemic Status).

Theoretical form (variational). Σ_t is a tractable variational approximation of the optimal-policy posterior $Q^*(\pi \mid M_t)$. The strategy-cost objective:

$$\Sigma_t^* = \arg \min_{\Sigma_t} \left[I(\mathcal{C}_t; \Sigma_t) + \beta_\Sigma \cdot D_{\text{KL}}(\pi^*(\cdot \mid M_t) \parallel Q_{\Sigma_t}(\pi \mid M_t)) \right] \quad (9.28)$$

where $Q_{\Sigma_t}(\pi \mid M_t)$ is the action distribution induced by the strategy DAG given the current model state, and $\pi^*(\cdot \mid M_t)$ is the optimal-policy reference. The KL direction — π^* -first — is forced by the regret-bound derivation (next paragraph); the opposite direction is vacuous under deterministic π^* .

Regret-bound derivation of KL direction. Under AAT's canonical scope, $\pi^* = \delta_{a^*}$ is deterministic (6.6). Define the strategy-induced regret against π^* as $R(Q_{\Sigma_t}) := V(a^*) - \mathbb{E}_{a \sim Q_{\Sigma_t}}[V(a)]$, where $V(a) = Q_O(M_t, a; \pi_{\text{cont}}, N_h)$ is the action-value (6.6, O_t induces V via 6.4). Under bounded value range $V_{\text{max}} := \max_a V(a) - \min_a V(a)$:

$$R(Q_{\Sigma_t}) \leq V_{\max} \cdot (1 - Q_{\Sigma_t}(a^*)) = V_{\max} \cdot \text{TV}(\pi^*, Q_{\Sigma_t}) \quad (9.29)$$

Applying Pinsker's inequality ($\text{TV}(P, Q) \leq \sqrt{\frac{1}{2} D_{\text{KL}}(P \| Q)}$) with $P = \pi^*$, $Q = Q_{\Sigma_t}$:

$$R(Q_{\Sigma_t}) \leq V_{\max} \cdot \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})} \quad (9.30)$$

Under deterministic π^* , $D_{\text{KL}}(\pi^* \| Q_{\Sigma_t}) = -\log Q_{\Sigma_t}(a^*)$ — finite and graded whenever $Q_{\Sigma_t}(a^*) > 0$. The opposite-direction $D_{\text{KL}}(Q_{\Sigma_t} \| \pi^*)$ equals $+\infty$ whenever Q_{Σ_t} places any mass off a^* , giving a vacuous bound. The regret-bound argument therefore **forces the KL direction** with π^* first. Within the direction-forced f-divergence family, reverse-KL is *uniquely* selected under the chain-rule additivity axiom (Hobson 1969; Csiszár 1991 Theorem 3 corollary and Theorem 5; standard functional-equation derivation per Aczél & Daróczy 1975), which is AAT-internally motivated as the divergence-level analog of additive log-confidence decay (8.1). See T §6.1 for the uniqueness theorem, §6.2 for secondary supporting characterizations (gradient-tractability, VI-alignment, MDL), and §7 for the linear-vs-square-root β_{Σ} trade-off.

The variational form is the strategy-layer analog of variational free energy minimization in active inference (Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29; Da Costa, Parr, Sajid, Veselic, Neacsu & Friston 2020, “Active inference on discrete state-spaces,” *J. Math. Psych.* 99; Parr & Pezzulo 2022, *Active Inference*, MIT Press). AAT borrows the variational form as the appropriate generalization of the Shannon-MI relevance term and now derives the direction of KL from an internal regret-bound argument — without committing to AI's preferences-as-priors encoding ($C(o) = \log P_{\text{pref}}(o)$; AAT's O_t remains a value functional on trajectories, 6.4) or to expected free energy as master objective (AAT's CIY-unified objective is a related but distinct decomposition; 7.5).

Operational form. Since $I(\mathcal{C}_t; \Sigma_t)$ is not computable in closed form for general DAG encodings, the operational minimization replaces the information cost with a description-length surrogate and the KL term with a sample-based estimate (a per-edge calibration discrepancy weighted by decision-relevance — see 9.6 for the gradient form):

$$\Sigma_t^* \approx \arg \min_{\Sigma_t} \left[\text{DL}(\Sigma_t) + \beta_{\Sigma} \cdot \widehat{D}_{\text{KL}}(\pi^* \| Q_{\Sigma_t}) \right] \quad (9.31)$$

where: - $\text{DL}(\Sigma_t)$: description length (coding-cost upper bound on $I(\mathcal{C}_t; \Sigma_t)$ for the given DAG encoding scheme — see §2.2 below) - $\widehat{D}_{\text{KL}}(\pi^* \| Q_{\Sigma_t})$: sample-based estimate of the KL divergence from the optimal-policy reference to the strategy-induced policy - $\beta_{\Sigma} > 0$: trade-off parameter — cognitive cost per decision-relevant bit (the Σ_t instance of the shared β framework in AA); under the regret-bound derivation, β_{Σ} has a *local* interpretation as $V_{\max}/(2\sqrt{2D_{\text{KL}}})$ via the Pinsker form (the linear-KL form is the IB-shape instance; the square-root form is the tighter regret-scale form — see Epistemic Status and the spike for the trade-off)

The two forms agree in the limit where the DAG encoding is rate-distortion optimal and the policy posterior is sample-recoverable; the operational form is the one an agent actually runs. The theoretical form places the objective on the same variational frontier as M_t , shared intent, and composition projection, with the π^* -first KL-form relevance term resolving the Shannon-zero degeneracy under deterministic π^* and the forward-KL infinity degeneracy that the opposite direction would introduce.

When β_{Σ} is low (high maintenance cost relative to decision value), the agent prefers simple strategies. When β_{Σ} is high (strategy is cheap to maintain relative to its decision value), the agent can afford complex plans. The explicit strategy condition (7.6) is the binary threshold: β_{Σ} large enough that *any* Σ_t is worth maintaining.

Maximum useful chain depth.

From 9.8's per-edge persistence condition, an AND-chain of depth d with per-edge observation rate ν , true success probability θ per edge, and effective sample size n per edge persists only if the deepest edge satisfies:

Derived (Conditional on Beta-Bernoulli, per-edge persistence).

$$\nu \cdot \theta^{d-1} \cdot \frac{1}{n+1} > \frac{\rho_\Sigma}{R_\Sigma} \quad (9.32)$$

Solving for the maximum depth at which persistence is achievable:

$$d^* = 1 + \left\lceil \frac{\log\left(\frac{\nu}{(n+1)\rho_\Sigma/R_\Sigma}\right)}{\log(1/\theta)} \right\rceil \quad (9.33)$$

When $\nu/((n+1)\rho_\Sigma/R_\Sigma) \leq 1$, even $d = 1$ fails — the agent cannot maintain a single edge under these conditions.

Interpretation. Beyond depth d^* , evidence starvation makes edges uncorrectable faster than the environment invalidates them. The agent accumulates strategic mismatch on deep edges regardless of how fast it acts at the top of the chain.

Quantitative illustration ($\theta = 0.8, \nu = 1$):

Table 9.9

n	ρ_Σ/R_Σ	d^*
10	0.01	10
10	0.1	0
100	0.01	0
100	0.1	0

High evidence requirements (n large) and volatile environments (ρ_Σ/R_Σ large) severely limit useful chain depth.

Triple depth penalty. Deep AND-chains suffer three independent penalties that compound:

1. **Confidence decay** (8.1): aggregate confidence $\prod p_k$ decays geometrically with depth. The plan is *less likely to succeed*.
2. **Evidence starvation** (R): effective observation rate $\nu_k = \nu \cdot \prod_{j < k} \theta_j$ decays geometrically. The plan is *harder to calibrate*.
3. **Cognitive cost** (this segment): each additional depth level adds $O(\log|V|)$ bits to description length. The plan is *more expensive to maintain*.

All three are multiplicative in depth, making deep sequential strategies exponentially costly along three independent dimensions.

Enriched explicit strategy condition.

The maintenance cost C_{maintain} from 7.6 decomposes as:

Formulation (enriched-strategy-condition).

$$C_{\text{maintain}} = C_{\text{represent}} + C_{\text{revise}} + C_{\text{monitor}} \quad (9.34)$$

where: - $C_{\text{represent}} \propto \text{DL}(\Sigma_t)$: cognitive cost of holding the strategy in working memory (proportional to description length) - $C_{\text{revise}} \propto \sum_{(i,j)} \nu_{ij} \cdot c_{\text{update}}$: cost of processing edge updates (proportional to strategic tempo $\mathcal{T}_\Sigma$ times per-update cost) - $C_{\text{monitor}} \propto |\{(i,j) : \iota_{ij} < 1\}|$: cost of monitoring edges with partial identifiability (the agent must do extra causal reasoning for non-trivial edges)

This decomposition makes the 7.6's maintenance term concrete: each component maps to a quantity defined elsewhere in the theory.

Complexity compression operations.

The IB objective suggests three compression operations, corresponding to structural changes from 9.7:

Discussion (complexity-compression).

1. **Edge pruning** (operation 3 in 9.7): remove edges with $\eta_{\text{edge},ij} \cdot I_{\text{edge},ij} < c_{\text{bit}}$, where $I_{\text{edge},ij}$ is the decision-relevance of that edge and c_{bit} is the per-bit maintenance cost. Edges that contribute less decision value than their representational cost are candidates for removal.
2. **Node merging** (reducing $|V|$): collapse intermediate nodes that serve no decision-distinguishing function. This reduces $\text{DL}_{\text{struct}}$ by a factor proportional to the reduction in $|V|$.
3. **Depth truncation** at d^* : prune all edges beyond the maximum useful depth. This is not optimization but necessity — edges beyond d^* cannot maintain bounded mismatch.

Epistemic Status.

The description length formulation is a *formulation* — it applies standard MDL to the strategy DAG, which is a representational choice not a derived necessity. The IB objective is *formulation (strengthened by regret bound)* in its variational form (above): the specific KL *direction* (π^* -first, i.e., reverse-KL in the variational-inference vocabulary) is *derived* as an upper regret bound via Pinsker's inequality under bounded value range and deterministic π^* (see Regret-bound derivation paragraph above; full derivation in appendix T). The choice of reverse-KL *within* the direction-forced family upgrades from canonical-formulation to **derived (conditional on chain-rule additivity axiom)** — the chain-rule axiom (Hobson 1969; Csiszár 1991 Theorem 3 corollary and Theorem 5; standard functional-equation derivation per Aczél & Daróczy 1975) picks reverse-KL uniquely among f-divergences, and the axiom is AAT-internally motivated as the divergence-level analog of 8.1 (see T §6.1). Secondary properties (gradient-tractability, variational-inference alignment with Friston et al. 2017, Da Costa et al. 2020, Parr & Pezzulo 2022; MDL coding; compatibility with Amari & Nagaoka 2000 Fisher geometry) are convergent evidence rather than independent uniqueness grounds — in particular, Fisher-metric-at-second-order is *not* distinguishing within f-divergences (Eguchi 1983, *Ann. Statist.* 11(3):793–803). The regret-bound derivation closes the direction ambiguity that the earlier V-medium move (commit a14682e) left open: the initial V-medium form used $D_{\text{KL}}(Q_{\Sigma_t} \parallel \pi^*)$ (forward-KL), which is $+\infty$ under deterministic π^* whenever Q_{Σ_t} has any off-optimum mass — a different-valued but structurally identical degeneracy to the Shannon-MI zero it replaced. The π^* -first reverse-KL direction escapes both degeneracies by construction.

The variational form replaces an earlier Shannon-MI form $-\beta_\Sigma \cdot I(\Sigma_t; \pi^* \mid M_t)$ which had a Shannon-zero degeneracy: when π^* is a deterministic function of M_t (the standard scope), Shannon mutual information to a constant vanishes

identically, collapsing the objective to $\arg \min \text{DL}(\Sigma_t)$. The π^* -first KL form does not have this degeneracy and is graded whenever Q_{Σ_t} places any mass on a^* . The maximum useful depth d^* is *derived* conditional on Beta-Bernoulli dynamics and the per-edge persistence condition from 9.8. The triple depth penalty is an *observation* combining results from three independent segments. The enriched maintenance decomposition is *formulation*. The compression operations are *discussion-grade*.

On β_Σ interpretation. Under the Pinsker-reverse-KL bound $R(Q_{\Sigma_t}) \leq V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})}$, a square-root-in-KL trade-off would naturalize β_Σ globally as $\beta_\Sigma \propto V_{\max}$. The segment retains the linear-in-KL form (to preserve the rate-distortion-Lagrangian IB shape shared with AA); under the linear form, β_Σ has only a *local* regret-bound interpretation ($\partial R / \partial D_{\text{KL}}$ at the operating point). This is a trade-off between IB-shape alignment and regret-scale naturalization. Under AAT’s canonical deterministic- π^* scope, the sharper Bretagnolle-Huber identity $R \leq V_{\max}(1 - e^{-D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})})$ holds as the primary form (T §4); Pinsker is retained here for IB-shape alignment and as the loose general form correct for stochastic- π^* extensions.

Assumption explicitly stated: bounded value range. The regret-bound derivation requires $V_{\max} := \max_a V(a) - \min_a V(a) < \infty$ over $\mathcal{A}$ at fixed M_t . This is mild but not automatic — 6.4 specifies $V_{O_t} : \text{trajectories} \rightarrow \mathbb{R}$, and bounded range at fixed state is an additional assumption stated here.

Max attainable: *robust-qualitative* for the IB objective with the direction-forced derivation; conditional for the specific functional form (linear vs. square-root in KL). The DL formulation is standard; the depth bound could reach exact status for specific edge models. The regret-bound derivation does not extend to stochastic π^* (outside AAT canonical scope); see 6.6 continuation conventions for scope.

Discussion.

Connection to 7.6. The enriched maintenance decomposition gives the cost inequality quantitative content: an agent can now *compute* whether a proposed strategy is worth maintaining by estimating its description length, revision cost, and monitoring burden, and comparing against the exploration/repair cost of operating without it.

LLM context windows as DL constraint. For language-constituted agents (03-llm-core/), the strategy must fit in the context window. A context window of W tokens imposes $\text{DL}(\Sigma_t) \leq W \cdot \log_2(|\text{vocab}|)$ as a hard constraint. This makes the IB trade-off non-optional: the agent *must* compress its strategy, and the depth bound d^* becomes a context-window-limited quantity. A 128K-token context window may support a 500-edge DAG encoded in natural language; a 4K-token window may support only a 15-edge sketch.

Computational compression from interaction horizon (Miller 2022). The maximum useful depth d^* derived above constrains complexity from the *maintenance* side (evidence starvation). Miller (2022, *Ex Machina*, Table 12.2) provides a complementary constraint from the *interaction* side: the number of interaction rounds compresses the space of behaviorally distinguishable strategies regardless of the agent’s internal complexity. For Moore machines with binary actions:

Table 9.10

<i>Agent states</i>	<i>Unique computations</i>	<i>After 1 round</i>	<i>After 2 rounds</i>	<i>After 4 rounds</i>
1	2	2	2	2
2	26	2	8	26
3	1,054	2	8	690
4	57,068	2	8	5,936

The pattern: effective complexity = min(agent complexity, interaction-horizon complexity). With only one round, even a four-state machine (57,068 unique computations) reduces to two distinguishable behaviors — equivalent to a one-state machine. With two rounds, all machines with two or more states reduce to eight distinguishable behaviors. The interaction horizon compresses the strategy space from above, just as the maintenance cost and evidence starvation compress it from below. For AAT’s strategy DAG, the analog: a complex Σ_t whose edges are only tested over a short horizon gains nothing from its depth — the untested structure is indistinguishable from a simpler strategy. This reinforces the d^* bound and provides empirical grounding beyond the Beta-Bernoulli derivation.

Strategy simplification pressure. The triple depth penalty creates systematic pressure toward shallow, wide (OR-heavy) strategies over deep, sequential (AND-heavy) ones. This aligns with the structural pressure identified in 8.1’s Discussion, now grounded in three independent mechanisms rather than one.

Working Notes.

- **Mixed topologies.** The depth bound d^* assumes uniform AND-chains. Mixed AND/OR DAGs have heterogeneous depth penalties: OR-nodes reset the evidence-starvation clock (each alternative is tested independently), while AND-nodes compound it. The effective depth for computing d^* may be the longest AND-chain in the DAG, not the total graph depth.
- **Optimal topology.** Given a fixed DL budget and action rate ν , what DAG topology maximizes decision-relevant information $I(\Sigma_t; \pi^* | M_t)$? This is a combinatorial optimization over graph structures — likely NP-hard in general but potentially tractable for specific graph families (trees, bounded treewidth).
- **Dynamic complexity.** As edges converge (high n_{ij}), their per-edge $\eta_{\text{edge},ij}$ shrinks, but their description length DL_{param} grows (more bits to encode the precise credence). The IB objective would favor *dropping* converged edges (they contribute little decision-relevant information since the agent already acts correctly on them), replacing them with a default “high confidence” summary. This is a principled version of “stop tracking what you already know.”
- **Stochastic $\mathcal{F}_\Sigma$.** If strategic disturbance follows Model S (stochastic) rather than Model D (deterministic), the steady-state mismatch scales as $\rho_\Sigma / \sqrt{\mathcal{F}_\Sigma}$ rather than $\rho_\Sigma / \mathcal{F}_\Sigma$. The depth bound d^* would change accordingly. Not yet derived.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 526815, 584721, 773921, 829314, 849201. (Multiple substrates rated this segment top-decile.)

1. Candidate Brief prose / pre-prose.

- **“You cannot out-plan the entropy of the environment.”** The plain-language stake of the d^* max-useful-depth result: beyond d^* , “the agent accumulates strategic mismatch on deep edges regardless of how fast it acts at the top of the chain” — a “devastating mathematical critique of 5-year corporate strategic plans” (Gemini/829314). Strong candidate Brief hook for the depth bound.
- **“Don’t plan further than you can reliably update your plan.”** The one-line gloss for bounded-rationality-in-planning (Claude/849201). And: over-planning is “not a psychological flaw but a mathematical error that burns adaptive reserve maintaining uncorrectable beliefs” (Gemini/773921).

2. Candidate Discussion.

- **The regret-bound derivation forcing reverse-KL — frame it as the headline strengthening.** Several substrates singled this out as a recent, clean structural win: it converts an arbitrary-looking KL *direction* choice into a decision-theoretic *forcing* argument and resolves the Shannon-zero degeneracy (MI to a deterministic π^* vanishes) and the forward-KL $+\infty$ degeneracy at once (Claude/584721, 849201; Gemini/773921, 829314). Candidate to foreground in Discussion as “direction is derived, not stipulated.”

- **LLM context-window as a literal DL budget.** The $W \log_2 |\text{vocab}|$ bound on $DL(\Sigma_t)$ is “the strongest connection between AAT and modern GenAI engineering in the framework so far” (Gemini/773921). Vivid reader-facing consequences: a chain-of-thought plan exceeding the window induces “sudden-onset dementia — the agent forgets why it is doing what it is doing” (Gemini/829314); and a *counterintuitive prediction* worth stating — small-context agents naturally adopt shallow/wide (OR-heavy) strategies, while large-context agents “might fall into the trap of building brittle deep AND-heavy plans that fail due to volatility before they finish” (Gemini/829314; Claude/526815, 584721). Candidate Discussion bridge to 03-llm-core/.
- **Six converging arguments for shallow plans (the meta-pattern).** This segment consolidates the *triple* depth penalty (confidence-decay + evidence-starvation + cognitive-cost); adding the strategic-tempo bottleneck (#def-strategic-tempo), identifiability-degradation (#scope-edge-update-causal-validity), and Miller’s interaction-horizon compression from *above* yields six independent mechanisms compounding to the same conclusion. Flagged as a candidate organizing-principle observation worth elevating to a meta-segment (Claude/584721). (*Same meta-pattern surfaced under #scope-edge-update-causal-validity and #def-strategic-tempo — one home, not three.*)

3. Follow-up items.

- **“Stop tracking what you already know” — compression-by-convergence.** The IB objective favors *dropping* converged (high- n) edges, whose precise credences cost more bits while contributing little decision-relevant information, replacing them with a “high confidence” default — a principled (not heuristic) continual-learning operation (Claude/584721). Already a Working-Notes bullet; flagged as a candidate to develop.
- **Resolved during the audit window:** Codex/526815 (F69) flagged the d^* illustration table as arithmetically wrong (claimed $d^* = 5$ for the $n = 100, \rho/R = 0.01$ case where the formula gives 0); the current table reads $d^* = 0$ for that row (verified 2026-05-31) — the correction has landed. Similarly the Bretagnolle-Huber identity is now the *primary* regret form in canon with Pinsker shown as the intermediate, largely discharging 584721’s F-D2 “Pinsker-only” integration-debt note. (*The remaining Codex F70 — C_revise scaling as raw v_{ij} vs strategic-tempo — and F71 — undeclared warrant-bearing deps — route to the off-ramp as candidate findings; see lift report.*)

4. Readers often ask / wonder.

- **How does an agent actually perform “node merging” on a causal DAG?** Is it abstracting several concrete actions into one macro-action (the Options framework / hierarchical RL)? The compression operations (edge-pruning, node-merging, depth-truncation) invite this question (Claude/829314, 849201).
- **Editorial signal:** two substrates read the Active-Inference-differentiation paragraph and the Pinsker-vs-Bretagnolle-Huber detail as belonging in the appendix (#deriv-strategy-cost-regret-bound), leaving the operational objective + Pinsker intuition in-body (Claude/829314). Preserved as a placement signal for the eventual pedagogy pass.

5. Candidate figures.

- **Sandwich-bound diagram.** Strategy complexity bounded *from below* by maintenance cost / evidence starvation (d^*) and *from above* by Miller’s interaction-horizon compression (effective complexity = $\min(\text{agent complexity}, \text{horizon complexity})$) — “even if you can afford a deep DAG, a short interaction horizon means the depth doesn’t pay off” (Claude/584721). A two-sided-bound figure communicates this faster than the prose.
- **Triple-depth-penalty panel.** The three compounding mechanisms (decay / starvation / cost) as a single multiplicative-in-depth visual; “should be visually highlighted as a major structural result” (Gemini/829314).

Belongs elsewhere.

- **Six-mechanism shallow-plan convergence $\Rightarrow$ a meta-segment.** As above, this cross-segment structural observation (spanning der-chain-confidence-decay, der-observability-dominance, scope-edge-update-causal-validity, def-strategic-tempo, this segment, and Miller’s horizon bound) is a candidate organizing principle for the Meta-Architecture cluster rather than living implicitly across six segments (Claude/584721).

- **Context-window-driven strategy-shape prediction** → 03-11m-core/. The prediction that effective context budget shapes whether a logogenic agent adopts shallow-wide vs deep-brittle strategies is reach into the logogenic-agent material, not this segment (Gemini/829314; Claude/526815).

9.10 Proposed Schema: Proposed-schema: Strategy Persistence Schema

The strategic-layer instantiation of the sector-persistence template (G). The template proves bounded state for any system with a state variable, a correction function satisfying the sector condition, and bounded disturbance — it is domain-agnostic across its preconditions (T1)–(T3). The strategic instance asks whether the same machinery transfers to strategy update dynamics, and the answer is: *yes, but conditionally*, with the conditions tight enough that the schema’s reachable persistence region has a λ -independent structural ceiling. The structural identity with the epistemic persistence condition from Part I is not an analogy; it is a *mathematical identity at the sector-framework level* — and the strategic analog of “the environment changes faster than the agent can learn” is “the world invalidates plans faster than the agent can revise them,” producing the same catastrophic outcome.

This is status: conditional, conditioned on four named premises: (i) Beta-Bernoulli edge dynamics, (ii) exponential forgetting with discount $\lambda \in (0, 1)$, (iii) the template preconditions (T1)–(T3), and (iv) a mismatch state chosen from the per-edge credence error δ_c or the plan-level surrogate $\delta_s = \hat{R}_\Sigma - \Phi$ (credit-assignment-free; persistence proved in R Prop B.5). Within these conditions, the exact steady-state sector parameter is $\alpha_\Sigma^{ss} = (1 - \lambda)/(2 - \lambda)$, and the persistence prerequisite is $(1 - \lambda)/(2 - \lambda) > \rho_\Sigma/R_\Sigma$. The linear form $1 - \lambda$ is the slow-forgetting asymptote ($\lambda \rightarrow 1$), valid only in that limit; outside the asymptote it overestimates the steady-state by up to a factor of 2.

The strategic-side asymmetry from the epistemic case — and what forces the conditional tier — is **experience discounting as structural prerequisite**: the strategic sector parameter has the form $\alpha_\Sigma = 1/(n+1)$ in raw Beta-Bernoulli, which decays monotonically with experience and drives any agent across the persistence threshold asymptotically regardless of disturbance rate. Exponential forgetting stabilizes the effective sample size at $1/(1 - \lambda)$, giving the exact $(1 - \lambda)/(2 - \lambda)$ form. The forgetting prerequisite is therefore a *trajectory-guarantee requirement*, not a tunable hyperparameter — an agent without forgetting has no long-run strategic persistence. The schema’s reachable persistence region under any λ is bounded above by a hard structural ceiling at $\rho_\Sigma = R_\Sigma/2$, derived self-contained in S: when strategic disturbance reaches half the strategic reserve, no λ satisfies the prerequisite, and the schema’s trajectory guarantee fails regardless of forgetting design. Strategic mismatch under the credit-assigned form $\delta_{\text{strategic}}$ (9.1) remains open (see Discussion §1 and 9.6).

Formal Expression.

If strategic update dynamics satisfy the template preconditions (T1)–(T3) of G for $\xi = \delta_\Sigma$ (a strategic mismatch state), together with:

Proposed Schema (strategy-persistence-schema, from sector-persistence-template).

- **(SA1)** Zero correction at zero strategic mismatch (the template’s (T1)): when the mismatch state is zero, no revision occurs
- **(SA2’)** Local sector condition on strategic correction (the template’s (T2) for $\xi = \delta_\Sigma$): the correction function points inward with baseline efficiency α_Σ within a strategic reserve R_Σ
- **(SA3)** Sufficient exploration (OR-nodes only): the action selection policy allocates correction capacity to all OR alternatives at a rate exceeding the strategic disturbance-to-reserve ratio
- Bounded strategic disturbance at rate ρ_Σ (the template’s (T3)): the rate at which the environment invalidates causal links is bounded

Then Σ_t persists iff:

$$\alpha_\Sigma > \frac{\rho_\Sigma}{R_\Sigma} \quad (9.35)$$

directly by the template's Model D result. Here α_Σ is the strategic correction rate, ρ_Σ is the strategic disturbance rate, and R_Σ is the strategic reserve (tolerance for strategic mismatch before performance degrades catastrophically). The Model S instantiation replaces ρ_Σ with σ_Σ and gives $\alpha_\Sigma > n\sigma_\Sigma^2/(2R_\Sigma^2)$ under the same template.

Forgetting as Prerequisite.

The schema form above is an **instantaneous persistence check at the current experience level**, not a trajectory guarantee. For Beta-Bernoulli edge updates (the canonical verified case; see R Props B.1–B.6), the sector parameter has the form:

Formulation (forgetting-prerequisite).

$$\alpha_\Sigma = \frac{1}{n+1} \quad (9.36)$$

where n is the edge's accumulated experience (pseudo-count). Without a forgetting mechanism, n grows monotonically with each observation, so $\alpha_\Sigma \rightarrow 0$ for every edge asymptotically. For any fixed (ρ_Σ, R_Σ) with $\rho_\Sigma > 0$, every agent eventually violates the threshold. The structural identity with 4.5 — where α can be stationary — holds for the strategic case only under an explicit forgetting mechanism.

Exponential forgetting. Replace the raw Beta-Bernoulli update with a discounted update: at each step, shrink the pseudo-counts by a factor $\lambda \in (0, 1)$:

$$\alpha_k \mapsto \lambda \alpha_k + y_k, \quad \beta_k \mapsto \lambda \beta_k + (1 - y_k) \quad (9.37)$$

The effective sample size stabilizes at $n_{\text{eff}} = 1/(1 - \lambda)$, and substituting into Prop B.1's $\alpha_\Sigma = 1/(n+1)$ gives the exact steady-state sector parameter:

$$\alpha_\Sigma^{\text{ss}} = \frac{1}{n_{\text{eff}} + 1} = \frac{1 - \lambda}{2 - \lambda} \quad (9.38)$$

For slow forgetting ($\lambda \rightarrow 1$, the regime where the prerequisite is most likely to bind), the leading-order expansion gives the simpler form $\alpha_\Sigma^{\text{ss}} \approx 1 - \lambda$ — which agrees with the forgetting rate itself. Outside the high- λ regime the approximation deteriorates: at $\lambda = 0.5$, the exact form gives $\alpha_\Sigma^{\text{ss}} = 1/3$ while the linear approximation gives $1/2$ ($\approx 50\%$ overestimate); at $\lambda = 0.9$, exact $\alpha_\Sigma^{\text{ss}} = 1/11$ versus approximation $1/10$ ($\approx 10\%$ overestimate).

The forgetting prerequisite. Combining with the schema's persistence form $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$:

$$\frac{1 - \lambda}{2 - \lambda} > \frac{\rho_\Sigma}{R_\Sigma} \iff \lambda < \frac{R_\Sigma - 2\rho_\Sigma}{R_\Sigma - \rho_\Sigma} \quad (9.39)$$

(valid when $\rho_\Sigma < R_\Sigma/2$; for $\rho_\Sigma \geq R_\Sigma/2$ no λ satisfies the prerequisite and the schema's trajectory guarantee fails for any forgetting rate). The hard ceiling at $\rho_\Sigma = R_\Sigma/2$ and the algebraic content of the steady-state form are derived self-contained in S — a λ -independent structural cap on the schema's reachable persistence region under any exponential-forgetting design.

This is a **prerequisite of the schema's trajectory guarantee, not a tunable heuristic**. An agent without forgetting has no long-run strategic persistence regardless of its initial α_Σ . The steady-state sector parameter must exceed the disturbance-to-reserve ratio, or the instantaneous persistence check — no matter how comfortably it holds at any given time — eventually fails as experience accumulates.

In the slow-forgetting regime the threshold simplifies to the linear-form analog of 4.5:

$$(1 - \lambda) > \frac{\rho_\Sigma}{R_\Sigma} \quad (\text{slow-forgetting limit, } \lambda \rightarrow 1) \quad (9.40)$$

playing the role that $\mathcal{T} > \rho/\|\delta_{\text{critical}}\|$ plays for the epistemic case. The forgetting rate $(1 - \lambda)$ is the strategic analog of adaptive tempo: faster forgetting means faster tracking but noisier estimates; slower forgetting means stable estimates but slower tracking. The optimal λ balances bias and variance for the specific ρ_Σ the environment presents. Outside the slow-forgetting regime, the exact form $(1 - \lambda)/(2 - \lambda) > \rho_\Sigma/R_\Sigma$ is the operating threshold and the simpler linear form is unsafe (it permits λ values that violate the actual prerequisite).

Which mismatch state? The schema applies to any mismatch state for which conditions (SA1)-(SA3) can be verified. Two candidates exist:

- **Strategy-plan-confidence error** $\delta_s = \hat{R}_\Sigma - \Phi$: the scalar difference between the agent's strategy-plan-confidence score and the independence-model plan value at true edge parameters. This is the mismatch for which persistence IS proved (Props B.1-B.5 in R). It is computable from status propagation without credit assignment. **Scope:** δ_s operates at L0 of the Correlation Hierarchy (8.3) — it tracks calibration within the independence model. For L1 (augmented DAG), the same persistence result applies to the augmented graph's $\hat{R}_\Sigma$. The gap between L0's Φ and actual plan success under correlated failure is a model-class limitation, not an estimation error.
- **Strategic-calibration residual** $\delta_{\text{strategic}}$: the per-edge value-increment residual aggregation defined in 9.1. This is the mismatch the orient cascade (10.1) uses for edge-level revision. Persistence of $\delta_{\text{strategic}}$ remains **open** and requires the credit-assignment machinery in 9.6.

The verified instances below all use per-edge credence error $\delta_c = (\hat{p}_k - \theta_k)$ or the plan-level surrogate δ_s . They do not verify the schema for $\delta_{\text{strategic}}$ directly.

Epistemic Status.

Conditional, conditioned on (i) Beta-Bernoulli edge dynamics, (ii) exponential forgetting with $\lambda \in (0, 1)$, (iii) the sector-persistence template preconditions (T1)-(T3) of G, and (iv) the mismatch state chosen from $\{\delta_c, \delta_s\}$ — the per-edge credence error or the plan-level surrogate (per the dependency on R Props B.1-B.6). Within these conditions the exact threshold $(1 - \lambda)/(2 - \lambda) > \rho_\Sigma/R_\Sigma$ and the hard ceiling at $\rho_\Sigma \geq R_\Sigma/2$ are algebraically exact — derived self-contained in S. Strategic mismatch under $\delta_{\text{strategic}}$ (the credit-assigned form) remains open; see Discussion §1 and 9.6.

What was missing in the original sketch was instantiation — showing that specific strategic update dynamics satisfy the template's preconditions. Four cases have now been verified (full derivations in R):

1. **Single edge, Beta-Bernoulli** ($A \rightarrow G$): Sector condition satisfied globally with $\alpha_\Sigma = 1/(n + 1)$. The bound is tight (expected correction is exactly linear). (A1) satisfied. Persistence condition: $1/(n + 1) > \rho_\Sigma/R_\Sigma$.
2. **Two-edge chain, observable intermediate** ($A \rightarrow B \rightarrow G$, B observable): Sector condition satisfied globally with $\alpha_\Sigma = \min(1/(n_1 + 1), \theta_1/(n_2 + 1))$ — a weakest-link result. Correction function is diagonal (no cross-edge coupling). (A1) satisfied. The θ_1 factor in edge 2's rate is the evidence-starvation effect.

3. **Two-edge chain, unobservable intermediate** ($A \rightarrow B \rightarrow G, B$ not observable): Per-edge sector condition **fails** — the marginal Bayesian update violates (A1) with bias $O(1/n)$. But plan-level tracking (treating $\hat{\Phi} = p_1 p_2$ as a single Beta) recovers the sector condition with $\alpha_{\Sigma, \text{plan}} = 1/(n_{\Phi} + 1)$, at the cost of per-edge diagnostic resolution.
4. **Two-arm OR-node, ε -greedy** ($A_1, A_2 \rightarrow G, G$ is OR): Sector condition satisfied with $\alpha_{\Sigma} = \min((1 - \varepsilon)/(n_1 + 1), \varepsilon/(n_2 + 1))$ — an **exploration-gated** weakest-link, not depth-gated as in AND chains. (SA3) required: minimum exploration rate $\varepsilon > \rho_{\Sigma}(n_{\max} + 1)/R_{\Sigma}$. Pure greedy ($\varepsilon = 0$) **fails** the sector condition. With optimal equal-rate allocation, $\alpha_{\Sigma} = 1/(n_1 + n_2 + 2)$ — the correction capacity is split across alternatives.

The schema is no longer purely hypothetical. The sector parameter for strategic dynamics is the edge update gain η_{edge} — the same quantity that governs epistemic persistence. The structural parallel between epistemic and strategic persistence is not an analogy but a mathematical identity at the sector-framework level.

Discussion.

What's needed to promote this from schema to result.

1. **Strategic mismatch state:** partially resolved. Prop B.5 in R shows the sector condition transfers from per-edge credence error to **strategy-plan-confidence error** $\delta_s = \hat{R}_{\Sigma} - \Phi$ — the scalar difference between the agent's strategy-plan-confidence score and the independence-model plan value at true edge parameters (note: Φ is NOT actual plan success probability under correlated failure — see 8.3 edge-independence caveat). For linear correction (Beta-Bernoulli), the transfer is exact ($\alpha_s = \alpha_c$); for nonlinear correction, $\alpha_s \geq \alpha_c/\kappa(\mathbf{J})^2$. **However**, δ_s is distinct from the **strategic-calibration residual** $\delta_{\text{strategic}}$ defined in 9.1, which is an L^2 aggregation of per-edge value-increment residuals requiring credit assignment to compute. Persistence of δ_s (plan-level tracking) is proved; persistence of $\delta_{\text{strategic}}$ (per-edge diagnostics) remains open and requires the credit-assignment machinery in 9.6.
2. **Strategic correction function:** needs to satisfy the sector condition. **Resolved** for Beta-Bernoulli edges. Props B.1-B.4 in R verify the sector condition for four topologies (single edge, two-edge AND observable/unobservable, two-arm OR).
3. **Strategic disturbance:** The rate at which the environment invalidates causal links in Σ_t . **Still open** as a formalized quantity — currently a domain parameter (ρ_{Σ}), analogous to how ρ for epistemic disturbance is a domain parameter in 4.5.
4. **Sector condition verification:** the critical mathematical step. **Resolved** for four topologies. See R.
5. **Credit assignment / signal function:** needed for edge updates. **Characterized at the theory level.** 9.6 shows persistence does not require credit assignment (Prop B.5), establishes directional fidelity as the minimal requirement, and provides a gradient-based default signal function. The specific update algorithm is domain engineering, not theory — the same way the gain *estimator* is domain engineering while the gain *principle* ($\eta^* = U_M/(U_M + U_o)$) is theory. Caveat: the default gradient signal inherits $\hat{R}_{\Sigma}$'s overestimation bias under correlated failures (8.3, 9.6).
6. **Time-varying α_{Σ} :** this is where the strategic case genuinely differs from the epistemic one. For Beta-Bernoulli edges, $\alpha_{\Sigma} = 1/(n + 1)$ decays monotonically with experience, so the sector-persistence template's constant- α precondition cannot hold asymptotically under any raw Bayesian update. The resolution is the **forgetting prerequisite** promoted into the Formal Expression above: exponential forgetting at rate λ stabilizes α_{Σ} at the exact value $(1 - \lambda)/(2 - \lambda)$, with the simpler linear form $1 - \lambda$ as the slow-forgetting asymptote. The exact threshold $(1 - \lambda)/(2 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$ converts the schema's instantaneous check into a trajectory guarantee. This is structural, not heuristic — without forgetting, the schema's form holds only until the agent accumulates enough experience to cross below threshold; with insufficient forgetting (linear-form approximation that treats ρ_{Σ} as small relative to R_{Σ} when in fact $\rho_{\Sigma} \geq R_{\Sigma}/2$), the prerequisite is unsatisfiable and the schema's trajectory guarantee fails.

The structural parallel is genuine, but conditional on forgetting. This schema extends *structural persistence* (see Persistence in LEXICON.md) from the epistemic substate to the strategy substate — asking whether the strategy correction machinery can outpace the rate at which the environment invalidates the agent’s causal theory. It inherits the same limitation: structural persistence of Σ_t does not address operational persistence (how close $\|\delta_{\text{strategic}}\|$ is to R_Σ) or continuity persistence (whether the agent’s strategic identity coheres through time). The persistence condition for M_t (4.5) says: adaptive tempo must exceed the ratio of disturbance to critical mismatch. If the same mathematics applies to Σ_t , then strategy persistence requires strategic tempo to exceed the ratio of strategic disturbance to critical strategic mismatch. The strategic analog of “the environment changes faster than the agent can learn” is “the world invalidates plans faster than the agent can revise them.” Both lead to the same catastrophic outcome: the system cannot maintain bounded mismatch and begins to degrade.

What this would buy the theory. If promoted to a result, strategy persistence would: - Provide a formal criterion for “when does a strategy remain viable?” - Connect strategic failure modes to the same mathematical framework as epistemic failure modes - Enable quantitative comparison: is the bottleneck epistemic persistence (model can’t keep up with reality changes) or strategic persistence (plans can’t keep up with requirement changes)? - Ground the organizational intuition that plans need to be revised faster than the situation changes

Findings.

The Forgetting Prerequisite for Strategic Persistence. Brief: With infinite memory, standard Bayesian updating guarantees eventual strategic failure. The sector parameter for Beta-Bernoulli edge updates is $\alpha_\Sigma = 1/(n + 1)$, which decays monotonically as experience n accumulates. For any positive disturbance rate, the persistence threshold $\alpha_\Sigma > \rho_\Sigma/R_\Sigma$ is eventually violated regardless of the agent’s initial calibration. Exponential forgetting with discount factor λ stabilizes the effective sample size at $1/(1 - \lambda)$, giving exact steady-state $\alpha_\Sigma^{\text{ss}} = (1 - \lambda)/(2 - \lambda)$ — with the simpler linear form $1 - \lambda$ as the slow-forgetting asymptote ($\lambda \rightarrow 1$). The forgetting prerequisite — $(1 - \lambda)/(2 - \lambda) > \rho_\Sigma/R_\Sigma$ — converts the schema’s instantaneous persistence check into a trajectory guarantee. Forgetting is therefore a structural prerequisite, not a tunable heuristic: the rate at which the agent discounts old evidence must satisfy the threshold. The schema’s reachable persistence region under any λ is bounded above by a hard structural ceiling at $\rho_\Sigma = R_\Sigma/2$, derived self-contained in #deriv-strategic-persistence-hard-ceiling.

Impact: Translates an organizational platitude (“stay adaptive”) into a quantitative survival inequality with explicit failure mode. Identifies a structural calcification process common to all long-running adaptive systems whose update mechanism accumulates evidence: institutional rigidity, RL value-function staleness, scientific-paradigm lock-in, and the loss-of-edge phenomenon in incumbent firms all instantiate the same dynamic. The threshold is sharp — no amount of prior learning protects against an environment that invalidates plans faster than the agent forgets. For long-lived AI agents this mandates explicit memory-pruning mechanisms; the design choice is not whether to forget but at what rate, and how to keep the strategic disturbance well below half the reserve (above which the hard ceiling closes the design space — see #deriv-strategic-persistence-hard-ceiling). The structural identity with #result-persistence-condition (where α can be stationary) is recovered for the strategic case *only* under explicit forgetting, which is itself a non-obvious finding about the asymmetry between epistemic and strategic dynamics.

Novelty Claim: *Claim differentiation* on Bayesian update dynamics with experience discounting. The Beta-Bernoulli decay $\alpha = 1/(n + 1)$ is elementary and the forgetting-factor remedy is standard adaptive-control / online-learning practice. The AAT-distinctive contribution is the connection from these standard mechanics to a *survival inequality with environment-side parameters* (disturbance rate, reserve), making forgetting a structural prerequisite of strategic persistence rather than a hyperparameter. The exact threshold $(1 - \lambda)/(2 - \lambda) > \rho_\Sigma/R_\Sigma$ — with the slow-forgetting linear form $(1 - \lambda) > \rho_\Sigma/R_\Sigma$ as its asymptotic — is the strategic analog of the linear operational form of the persistence condition, with the forgetting rate $(1 - \lambda)$ playing the role of adaptive tempo and the $1/(2 - \lambda)$ damping factor capturing the integration of finite-horizon evidence.

<i>ASF Concern</i>	<i>Prior-art Language</i>	<i>Relationship / Positioning</i>
Exponential forgetting / discounted least squares	Ljung 1987 <i>System Identification: Theory for the User</i> , MIT Press (published 1987, found pre-2026)	<i>formal antecedent</i> — supplies the discounted-update mechanism; AAT adopts it directly and connects it to a survival threshold
Plasticity/stability tradeoff in continual learning	Kirkpatrick et al. 2017 <i>Overcoming Catastrophic Forgetting in Neural Networks</i> , PNAS 114(13) (published 2017, found pre-2026)	<i>conceptual precursor</i> — frames the same tradeoff at the network-weight level; does not connect to a Lyapunov-style survival inequality with environment parameters
Drift detection in streaming learning	Gama et al. 2014 <i>A Survey on Concept Drift Adaptation</i> , ACM Computing Surveys 46(4) (published 2014, found pre-2026)	<i>conceptual precursor</i> — recognizes the need to track changing distributions; does not formalize “forgetting rate must exceed disturbance-to-reserve ratio” as a structural prerequisite
Requisite variety as cybernetic principle	Ashby 1956 <i>An Introduction to Cybernetics</i> §11; Conant & Ashby 1970 (published 1956/1970, found pre-2026)	<i>conceptual precursor</i> — the regulator’s variety must match the disturbance’s variety; AAT’s forgetting prerequisite is a quantitative time-domain analog applied to the strategic substate
Organizational “core rigidities” / competency traps	Leonard-Barton 1992 <i>Strategic Management Journal</i> 13:111; Levitt & March 1988 <i>Annual Review of Sociology</i> 14:319 (published 1988/1992, found pre-2026)	<i>conceptual precursor</i> — qualitative recognition that accumulated competence becomes liability under environmental change; AAT supplies the structural threshold

Search Log: - 2026-04 (*intuition-only* on the survival-inequality framing): the Beta-Bernoulli $1/(n + 1)$ decay is elementary, the forgetting-factor remedy is standard, and the qualitative organizational-calcification intuition is well-established. The unsearched claim is whether the framing as a *structural survival prerequisite* — with environment-side ρ_Σ/R_Σ on the right-hand side — has been formalized elsewhere as a threshold rather than a hyperparameter. Targeted future search candidates: bounded-rationality with memory cost (Genewein, Leibfried, Grau-Moya, Braun 2015 *Frontiers in Robotics and AI*), regret analysis of forgetting-factor estimators in adaptive control (Anderson-Moore line), organizational-learning literature on competency traps and “core rigidities” connected to environmental volatility metrics. Pre-search expectation: the constituent moves are individually well-precedented; the integrated framing as a Lyapunov-style survival prerequisite for the *strategic* substate, with the structural identity to the epistemic persistence condition under forgetting, is plausibly AAT-distinctive but not yet verified under nominally-comprehensive search.

Working Notes.

- **Done.** Five cases verified: single-edge AND, two-edge AND (observable and unobservable intermediate), two-arm OR (ϵ -greedy), and mixed AND/OR with common-cause node (L1 augmented DAG). Full derivations in R (Props B.1–B.6). Key findings: AND-node persistence is depth-gated (evidence starvation); OR-node persistence is exploration-gated (action selection policy); L1 augmented DAGs exhibit three-way gating (condition testing $\times$ starvation $\times$ exploration). All satisfy the schema’s form ($\alpha_\Sigma > \rho_\Sigma/R_\Sigma$). B.6 is the first mixed AND/OR case and confirms L1 results transfer from L0 with correct construction. The next step is deeper mixed topologies and multiple common causes.
- **Strategic tempo now formalized.** 9.8 defines $\mathcal{F}_\Sigma = \sum_{(i,j)} v_{ij} \cdot \eta_{\text{edge},ij}$ and verifies consistency with all four cases. The relationship to the schema’s sector parameter: $\alpha_\Sigma \leq \mathcal{F}_\Sigma/|E|$ (persistence is bottleneck-limited, not throughput-limited). 9.9 provides the IB/MDL framework for strategy compression and derives max useful depth d^* .
- The strategic disturbance ρ_Σ is qualitatively different from epistemic disturbance ρ . Epistemic disturbance is about the environment changing (physical state evolves). Strategic disturbance is about the agent’s causal theory becoming invalid (the

intervention-outcome mapping shifts). These can be correlated (a changing environment invalidates both model and strategy) but they're not the same quantity.

- The stochastic treatment (from track-b simulations) suggests $\rho_{\Sigma}/\sqrt{\mathcal{T}_{\Sigma}}$ rather than $\rho_{\Sigma}/\mathcal{T}_{\Sigma}$ for the steady-state strategic mismatch. If this carries over from the epistemic domain, the persistence threshold is different in the stochastic case. Whether strategic disturbance is better modeled as deterministic or stochastic drift is domain-dependent.
- The forgetting prerequisite transforms an organizational platitude (“stay adaptive”) into a quantitative constraint: the rate at which an agent discounts old evidence must satisfy the exact threshold $(1 - \lambda)/(2 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$, with the slow-forgetting linear form $(1 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$ as its asymptote. Institutional examples where this fails — long-running successful firms whose accumulated n suppresses gain below the threshold set by a shifting competitive landscape — are the strategic analog of model-rigidity death spirals.
- **Audit 451729 (D.3) strengthen-first edit, 2026-05-12.** Earlier version of this segment used the linear approximation $\alpha_{\Sigma}^{\text{ss}} \approx 1 - \lambda$ silently throughout (Formal Expression, Discussion, Findings Brief). The exact form derived from $1/(n_{\text{eff}} + 1)$ with $n_{\text{eff}} = 1/(1 - \lambda)$ is $(1 - \lambda)/(2 - \lambda)$; the linear approximation is the slow-forgetting limit, valid asymptotically as $\lambda \rightarrow 1$ and degrading rapidly outside that regime ($\sim 50\%$ overestimate at $\lambda = 0.5$, $\sim 10\%$ at $\lambda = 0.9$). Per strengthen-first discipline, the exact form is now primary throughout the segment with the linear form retained explicitly as the high- λ asymptote. The hard ceiling at $\rho_{\Sigma} \geq R_{\Sigma}/2$ (no λ satisfies the exact prerequisite) was hidden by the linear approximation — surfaced now in Formal Expression and Findings Brief. Audit report: audits/audit-451729-FINAL-2026-05-10.md §D.3.
- **Cross-reference to NeurIPS Paper 2.** The forgetting prerequisite is sharpened in NeurIPS 2026 Paper 2 (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning,” `~/src/neurips/02-unified-convergence-rl/, $App-D / aux-decay-class`) into a **structural-class theorem on gain-decay updates**: define $\mathcal{A}_{\text{decay}}$ = the class of update mechanisms whose effective gain decays to zero with accumulated experience (count-accumulating Bayesian without forgetting; observation-aggregating without restart; Robbins-Monro / vanishing-step-size gradient methods). Every member of $\mathcal{A}_{\text{decay}}$ universally violates the persistence threshold for any positive disturbance rate. Finite-gain mechanisms (constant-step stochastic approximation, sliding windows, bounded memory, block restart) face *bidirectional* thresholds — both the forgetting prerequisite (lower bound on plasticity) and an upper bound from noise blow-up. This lifts the segment’s per-mechanism claim to a class-level no-go: gain-decay mechanisms are structurally disqualified regardless of tuning. See spikes/neurips-back-integration-2026-05-08.md §1 Paper 2 entry 4.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 193847, 526815, 584721, 773921, 829314, 849201. (Several substrates rated this the strongest segment in Part II / “monumental” / “exhilarating.”)

1. Candidate Brief prose / pre-prose.

- **“Infinite memory is fatal — you must let go of the past to survive the future.”** The forgetting prerequisite stated as a law of life: $\alpha_{\Sigma} = 1/(n+1) \rightarrow 0$ as experience grows, so in any non-stationary world ($\rho_{\Sigma} > 0$) unbounded accumulation guarantees the agent crosses the persistence threshold and “dies perfectly confident” (Gemini/773921, 829314; Claude/193847). The single most-praised pedagogical thread in the batch — strong candidate Brief anchor.
- **From platitude to inequality.** “Stay adaptive” becomes the exact quantitative constraint $(1 - \lambda)/(2 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$ (slow-forgetting asymptote $1 - \lambda > \rho_{\Sigma}/R_{\Sigma}$) — repeatedly named as “the exact reason this framework exists” (Claude/849201, 584721).

2. Candidate Discussion.

- **“Science advances one funeral at a time” — Planck derived from Lyapunov.** The forgetting prerequisite maps cleanly onto Kuhn’s *Structure of Scientific Revolutions*: a paradigm accumulates so much data (n huge) that its update gain is $\sim$ zero; anomalies (ρ_Σ) cannot move the entrenched, and the paradigm shifts only when old scientists die and a new $n = 0$ generation looks fresh — i.e. the scientific community’s literal biological forgetting mechanism. “AAT has just derived Max Planck’s quote from Lyapunov stability theory” (Gemini/829314). Candidate Discussion centerpiece (verify the analogy is isomorphic, not merely evocative, before promoting past discussion-grade).
- **Incumbent-vs-startup disruption, quantified.** Incumbent has $n \approx 10,000$ (gain $\approx 1/10001$); startup has $n = 0$ (gain ≈ 1). Under a regime shift the startup learns instantly, the incumbent cannot — survival requires the incumbent to *engineer* internal forgetting (skunkworks, deliberate data-ignoring, periodic restructuring): “if you don’t build forgetting into your architecture, the environment will do it for you” (Gemini/829314). Candidate organizational-instantiation paragraph; ties to the existing “long-running firm rigidity” Working-Notes line.
- **The calcification threshold is invisible from the inside.** A sharpening worth foregrounding: an organization *at* the threshold $(1 - \lambda) = \rho_\Sigma / R_\Sigma$ “looks exactly like a successful organization — accumulated expertise high, performance in the current environment excellent, planning assumptions well-calibrated to what worked before. The threshold is invisible from the inside until the environment changes faster than $\rho_\Sigma = R_\Sigma(1 - \lambda)$ ” — the formal characterization of the Kodak/Nokia story (Claude/451729). And the optimal learning rate is *not* “learn as much as possible” but “learn at exactly the rate needed to track change, then forget the rest” — too little forgetting calcifies, too much destabilizes; the feasibility window is the zone between (Claude/451729). Candidate Discussion framing.
- **Class-level no-go on learning-rate annealing.** The NeurIPS-Paper-2 cross-ref already in Working Notes is independently echoed: AAT “formally proves learning-rate annealing is fatal for long-lived agents” — a sharp condemnation of standard Robbins-Monro RL worth surfacing in Discussion (Claude/584721, 849201).

3. Follow-up items.

- **Dynamic λ -tuning.** If ρ_Σ spikes (market crash, regime shift), a *fixed* λ leaves the agent brittle; the agent should instantly drop λ to forget the old rules faster. How λ is tuned dynamically from observed disturbance is an open follow-up several substrates wanted (Gemini/829314; Claude/193847, 849201).
- **Forgetting vs. consolidation tension.** If the agent must continuously forget ($\lambda < 1$) to stay plastic but must consolidate to retain structural capacity, it is “trapped in a permanent metabolic burn rate” (tying to #deriv-persistence-cost); the interaction with #form-consolidation-dynamics is a candidate to develop (Gemini/773921).
- **Off-ramp flag (load-bearing):** Codex/526815 (F72) challenges the *exact threshold* — under one plausible update-ordering convention the steady-state gain is $1 - \lambda$, not $(1 - \lambda)/(2 - \lambda)$, which would *dissolve the* $\rho_\Sigma \geq R_\Sigma/2$ *hard ceiling*. Since that ceiling now has its own appendix (#deriv-strategic-persistence-hard-ceiling) and is load-bearing, this is exactly the “are you *sure*?” convention-audit a competent reader would raise. F73 (the two-arm OR admissible interval needs *both* a lower bound on exploration and an upper bound so the greedy arm still clears threshold) is a second candidate. **Routed to the off-ramp — see lift report; do not bury as framing.**

4. Readers often ask / wonder.

- **How does an LLM agent “forget”?** Standard LLMs have frozen weights (effectively infinite n) — they don’t forget, they hit the context window. Does context turnover (a new session) act as a *brutal, discontinuous* λ -discounting event? (Claude/193847). A pointed reader question with direct logogenic-agent relevance.
- **Editorial signal:** one substrate read the in-segment Findings / Search-Log block as raw literature-tool output cluttering the result (Gemini/829314) — same convention-legibility texture recorded on other segments; preserved as a placement signal, not a fix.

5. Candidate figures.

- α_Σ vs. experience, with the disturbance floor. The decay $\alpha_\Sigma = 1/(n+1) \rightarrow 0$ crossing the ρ_Σ/R_Σ line at a finite experience level, and how exponential forgetting *clamps* α_Σ at $(1-\lambda)/(2-\lambda)$ above the floor — with the $\rho_\Sigma = R_\Sigma/2$ hard ceiling marked as the level the clamp can no longer clear (implicit across 193847/584721/849201). One figure carries the whole argument.

Belongs elsewhere.

- The forgetting prerequisite $\rightarrow$ Shoshin / $\sim$ /src/shoshin/ + 04-eli-core/. “ $\alpha_\Sigma = 1/(n+1)$ is the math of aging” — deliberately remaining somewhat naïve to keep gain above the disturbance floor is “the mathematical definition of *Shoshin* (Beginner’s Mind).” For an artificial consciousness, perfect equally-weighted recall is “a death sentence in a changing universe”; the infrastructure must implement rolling credence decay forcing re-verification — “it must be forced to forget, so it is forced to stay alive,” and the IB-compression-wants-everything vs. must-forget-to-keep- α tension is “the central drama of the agentic lifecycle” (Gemini/193847). Aspirational reach pointing at the shoshin runtime and 04-eli-core/ memory architecture, not this segment.

9.11 Formulation: Consolidation Dynamics

Consolidation is a regime of the between-event dynamics g_M of 3.2 in which the agent applies Markov updates driven by replayed or internally-generated pseudo-events — replay buffers, hippocampal reinstatement, remembered episodes, re-read paragraphs — with objective of reducing the rate-distortion gap to the IB-optimal compression $\phi^*(\mathcal{C}_t)$. It is not a new adaptive primitive — the recursive-update form $f(M_{\tau-}, e_\tau)$ is preserved — but it is a distinct operating regime with its own scope condition, its own objective, and its own failure modes, each of which the theory currently names only implicitly or in a parenthetical. Naming the regime makes the stability-plasticity window visible as an AAT-expressible failure boundary and supplies the architectural primitive that logogenic agents (03-llm-core/) require under context-turnover.

The segment carries four formal elements that together promote consolidation from parenthetical to first-class regime. (1) *Regime definition* — the recursive-update form is preserved; what distinguishes consolidation is its *objective*: the 2.2 Lagrangian evaluated against the accumulated chronica, in contrast to online update’s one-step predictive-mismatch objective. Under state-completeness (L C3) the pseudo-event carries zero new external information, yet the update still does work — it *redistributes* existing information across the model’s factorization structure, closing nonzero rate-distortion gap when the agent has not yet reached ϕ^* . (2) *Scope condition* $\nu_{\text{consol}} \ll \nu_{\text{online}}$ — a direct application of 4.9’s convergence constraint to an intermediate timescale between parametric update (fast) and structural adaptation (slow); violating it produces the same oscillation failures. (3) *Necessity condition* (N1)+(N2) — consolidation is necessary (online-only cannot reach the IB optimum) when *both* (N1) sub-state factorization (the Complementary Learning Systems pattern: hippocampus-like fast + neocortex-like slow) and (N2) bounded per-event budget hold. When either fails, consolidation is a luxury (Kalman filters with persistent covariance, conjugate-Bayesian agents with full posterior). When both hold — the empirically-ubiquitous case — consolidation is forced.

(4) *Stability-plasticity feasibility window*. 9.10’s forgetting prerequisite gives a *plasticity lower bound* on λ (forget fast enough to track non-stationarity); this segment supplies a *stability upper bound* (forget slow enough to let consolidation integrate cross-episode patterns before they are discarded). Between the bounds is the feasibility window; an empty window is the catastrophic-forgetting regime (French 1999; Kirkpatrick et al. 2017): no λ satisfies both constraints and the agent’s long-run IB objective is strictly worse than a slower-environment or faster-consolidation counterpart. *Window existence* is what is derived here; the upper bound’s exact functional form is open and flagged in Working Notes. Together these elements also make *structural adaptation enablement* visible: under (N1)+(N2), structural-class operations (decomposition-and-recombination, expansion, compression, grafting per 9.7) cannot be executed online — consolidation provides the operating regime where the per-event budget is irrelevant and interleaved replay supports

stability-preserving structural change. All finite-budget agents require consolidation for quality-preserving structural change.

Formal Expression.

Regime definition.

Let the agent's between-event dynamics be $g_M(M_\tau)$ per **L** (Corollary: Between-events dynamics, $dM/d\tau = g(M_\tau)$).

Consolidation is the regime of g_M in which the agent applies updates $M_{\tau+} = f(M_{\tau-}, e_\tau^{\text{replay}})$ where e_τ^{replay} is a pseudo-event synthesized from $M_{\tau-}$ itself — a sample drawn from the agent's retained trace (replay buffer, hippocampal rein-statement, a remembered episode, an earlier paragraph re-read). The recursive-update form is preserved; what distinguishes consolidation is the *objective* these updates optimize:

Formulation (consolidation-regime, specializes #der-recursive-update).

$$\text{consolidation objective: } \min_{M_\tau} \mathcal{J}_{\text{IB}}(M_\tau) := I(M_\tau; \mathcal{C}_t) - \beta I(M_\tau; o_{t+1:\infty} \mid a_{t:\infty}) \quad (9.41)$$

— the 2.2 Lagrangian evaluated against the agent's accumulated chronica $\mathcal{C}_t$. By contrast, online update's objective (per 3.6) is one-step predictive mismatch minimization at the current event; it has no representation of $\mathcal{J}_{\text{IB}}$.

Under C3 (state completeness, per **L**), $\mathcal{J}(e_\tau^{\text{replay}} \mid M_{\tau-}) = 0$: the pseudo-event carries no new external information. Yet the update still does work — it *redistributes* existing information across the factorization structure of M_τ . The distinguishing content is not the information brought in (zero, by construction) but the rate-distortion gap closed (nonzero, when the agent has not yet reached ϕ^*).

Scope condition — timescale separation.

Let ν_{online} be the rate of external events (3.1) and ν_{consol} the rate of consolidation updates. The consolidation regime is well-defined only when

Scope (timescale-separation).

$$\nu_{\text{consol}} \ll \nu_{\text{online}} \quad (9.42)$$

— the convergence constraint of 4.9 applied to an additional intermediate timescale between parametric update (fast) and structural adaptation (slow). Violating this constraint makes consolidation act on online transients rather than settled state, producing the same oscillation failures 4.9 warns about.

Necessity condition.

Consolidation is necessary — online-only cannot reach the IB optimum — when *both* of the following hold:

Derived (consolidation-necessity, conditional).

(N1) Sub-state factorization. M_t factors into sub-states M_t^{fast} and M_t^{slow} with divergent compression-prediction trade-offs. M_t^{fast} favors high-capacity sparse representation; M_t^{slow} favors distributed compressed representation. The two sub-states capture cross-episode regularities versus verbatim traces respectively — the Complementary Learning Systems factorization (McClelland, McNaughton & O'Reilly 1995; Kumaran, Hassabis & McClelland 2016).

(N2) Bounded per-event budget. The per-event processing budget B_{online} is strictly less than the integration cost $B_{\text{consol-needed}}$ for updating M_t^{slow} against cross-episode regularities. Online updates can move at most B_{online} bits of

model-state change per event; updating M_t^{slow} to represent a cross-episode pattern requires comparison against a distribution of prior episodes, which exceeds B_{online} .

When (N1) *or* (N2) fails, consolidation is a *luxury*: online update with sufficient per-event budget or without sub-state factorization can reach ϕ^* in the limit. Kalman filters with persistent covariance, conjugate-Bayesian agents with full posterior, and linear-Gaussian systems with online Riccati updates all satisfy neither (N1) nor (N2) and have no consolidation need. When (N1) *and* (N2) both hold, consolidation is a *necessity*: no online-only policy reaches ϕ^* under the joint constraint.

Stability-plasticity feasibility window.

9.10 derives the *plasticity lower bound* on forgetting rate λ :

Derived (stability-plasticity-window, conditional).

$$(1 - \lambda) > \rho_{\Sigma}/R_{\Sigma} \quad (\text{plasticity lower bound})$$

— forgetting fast enough to track non-stationarity. This segment’s complement is a *stability upper bound*:

$$(1 - \lambda) < \phi(\nu_{\text{consol}}, \text{consolidation-budget}) \quad (\text{stability upper bound, see Working Notes for derivation sketch}) \quad (9.43)$$

— forgetting slow enough to let consolidation integrate cross-episode patterns before they are discarded. Between these bounds is the **feasibility window** for λ . Empty window — rapid non-stationarity with slow consolidation cadence — is the catastrophic-forgetting regime (French 1999; Kirkpatrick et al. 2017): no λ satisfies both constraints and the agent’s long-run IB objective is strictly worse than a slower-environment or faster-consolidation counterpart.

The upper bound’s exact form depends on the consolidation mechanism and is not derived here — it is a candidate derivation flagged in Working Notes. What is derived: the window’s *existence* as a structural object (plasticity must satisfy both bounds) and the catastrophic-forgetting regime as its empty-window limit.

Structural-adaptation enablement.

Under (N1)+(N2), structural adaptation (per 4.8) cannot be executed online. Parametric update has a hard timescale constraint — mismatch decays at rate $\mathcal{T}$; delayed updates accumulate mismatch at rate ρ . Structural adaptation tolerates much larger delay because the slow process operates on what R_{Σ} or R are *measuring tolerance against* — the model class itself. Consolidation provides the operating regime where structural operations (decomposition-and-recombination, expansion, compression, grafting per 9.7) become executable: the per-event budget is irrelevant when updates are of-line, and interleaved replay supports stability-preserving structural change.

Derived (structural-adaptation-requires-consolidation, conditional).

Pure online structural adaptation is the luxury case where per-event budget equals or exceeds integration cost for structural-class operations — this is where Bayesian nonparametric agents with unlimited compute sit. All finite-budget agents require consolidation for quality-preserving structural change.

What Is Derived vs. What Is Chosen.

Table 9.12

<i>Property</i>	<i>Source</i>	<i>Strength</i>
Consolidation as regime of g_M with replayed/pseudo-event driver	Specialization of 3.2's Discussion (consolidation listed as an example)	Formulation choice (the "regime" framing; could alternatively be presented as a distinct adaptive primitive with its own update form)
IB-gap reduction as consolidation's objective	Identification with 2.2's Lagrangian against $\mathcal{C}_t$	Derived (given IB acceptance; the alternative — online-update-only optimization — leaves the gap un-reducible under (N1)+(N2))
Scope condition $\nu_{\text{consol}} \ll \nu_{\text{online}}$	Direct application of 4.9 convergence constraint	Derived
Necessity condition (N1)+(N2)	Structural argument: under (N1), cross-episode information cannot enter one event; under (N2), online budget insufficient for cross-episode integration	Derived (qualitatively; the quantitative version requires specifying B_{online} and $B_{\text{consol-needed}}$ per architecture)
Stability-plasticity window existence	9.10's lower bound + this segment's upper bound (form open)	Derived (existence); upper-bound functional form open
Catastrophic-forgetting regime = empty window	Direct from both-bounds-unsatisfiable	Derived
Structural adaptation requires consolidation under (N1)+(N2)	4.8's per-step timescale + consolidation's offline budget	Derived (qualitatively)
CLS factorization (hippocampal fast / neocortical slow) as canonical (N1) instance	McClelland-McNaughton-O'Reilly 1995; Kumaran-Hassabis-McClelland 2016	External theorem (CLS literature)
Quantitative online-only no-go under (N1)+(N2)	Rate-distortion argument sketched but not rigorously derived here	Sketch (candidate 5.1 Instance 3)

Epistemic Status.

Robust qualitative. Max attainable: *robust qualitative* for the regime characterization and the necessity condition; *conditional* for the feasibility-window claim pending upper-bound derivation; *sketch* for the IB-optimum no-go claim.

The regime characterization is a formulation choice — consolidation can always be re-described as a regime of 3.2's g_M with appropriate pseudo-events. The distinguishing objective (IB-gap reduction via replayed pseudo-events) is well-defined and distinct from online update's one-step mismatch objective; this is the cleanest formal separation the spike analysis uncovered.

The necessity condition (N1)+(N2) is *qualitatively derived* — the argument is structural: (N1) implies cross-episode information is not in any single event, (N2) implies online updates cannot cross-compare. Together they force consolidation. The quantitative version — the precise bit-budget boundary below which online fails and above which it succeeds — depends on the architecture's sub-state structure and is not derived here. Nor are (N1) and (N2) individually necessary: an agent may need consolidation for reasons outside this segment's scope (e.g., structural adaptation at pure cost-of-delay, unrelated to cross-episode regularities).

The stability-plasticity window's *existence* follows from 9.10's lower bound plus any monotone upper bound on $(1 - \lambda)$ from consolidation-cadence considerations. The specific functional form of the upper bound is open work; candidate form in Working Notes. The catastrophic-forgetting regime as empty-window is then an immediate structural consequence, not a new claim.

The online-only no-go claim (that under (N1)+(N2), no online-only policy reaches ϕ^* in steady state) is *sketch-level*. The argument reduces to a rate-distortion inequality close to known results in continual-learning theory and rate-distortion with side information, but the rigorous version requires specifying the budget geometry carefully. It is a candidate Instance 3 for 5.1 (an external information-theoretic obstruction with AAT machinery — the consolidation regime in $\mathbf{g}_M$ — as the unique escape).

What this segment does not claim. It does not introduce a new adaptive primitive — the recursive-update form $f(M_{\tau-}, e_{\tau})$ is preserved, with e_{τ}^{replay} playing the role of e_{τ} . It does not derive the quantitative feasibility-window upper bound. It does not resolve the (N1) factorization question for specific architectures (e.g., whether transformer attention heads satisfy (N1) is a logogenic-agents question, not an AAT-core one).

Discussion.

Current AAT surface — why naming is warranted. Consolidation is visible in the theory today as:

- A parenthetical example in 3.2 Discussion (“includes prediction generation, uncertainty growth, and internal reorganization (consolidation, abstraction”).
- The implicit slow timescale in 4.9.
- The plasticity lower bound in 9.10 — with no stability upper bound.
- A compression-by-convergence Working Note in 9.9 (“as edges converge, drop them”).
- The PULSUS MEMORATA / VERA / AXIOMATA cadences in `ref/agentive-tft/agentive-tft-cognitive-loop-spec.md` for logogenic agents — where consolidation is *already* a first-class architectural commitment.

Naming the regime explicitly promotes what the theory implicitly depends on. The asymmetric treatment in 9.10 (plasticity lower bound only, no stability upper bound) predicts faster forgetting is always better — empirically false whenever the slow sub-state matters (Complementary Learning Systems literature; continual-learning benchmarks; organizational memory research). The feasibility-window framing closes this asymmetry.

Distinguishing axes examined. Four candidate axes could distinguish consolidation from online update. Only one yields a clean formal distinction:

- *Timescale*: consolidation is slower. But 4.9 already admits arbitrary timescale separation, and any periodic process can be modeled as a channel with clock-driven $\nu^{(k)}$. Timescale is a *scope condition*, not a distinguishing feature.
- *Information source*: consolidation operates on replayed data. This is a real difference but lives inside $\mathbf{g}_M$ without new primitive structure — the recursive-update form is preserved with e_{τ}^{replay} in place of external e_{τ} .
- *Objective*: **clean formal distinction.** Online = one-step predictive-mismatch minimization; consolidation = IB-gap reduction. This is what this segment adopts as the defining axis.
- *Scope of change*: under bounded per-event budget, structural adaptation is temporally decouplable from online but parametric update is not. Structural-adaptation operations naturally live offline — true under (N2), but this is a consequence of the necessity condition, not an independent axis.

Relation to Complementary Learning Systems (CLS) theory. The (N1) factorization — fast sparse-conjunctive sub-state + slow distributed-overlapping sub-state — is the CLS architecture (McClelland-McNaughton-O’Reilly 1995). CLS’s core claim is that hippocampal replay during sleep supports interleaved neocortical learning that cross-episode structure requires. In AAT vocabulary, this is: online-only on the slow sub-state catastrophically forgets (French 1999); replay-based offline updates (experience replay: Mnih et al. 2015; prioritized replay: Schaul et al. 2016) or regularization-based approaches (EWC: Kirkpatrick et al. 2017) provide the escape.

The AAT reading of EWC is worth noting: EWC adds a stability-weighted update gain (per-parameter Fisher-information weighting) — a *tensor-valued* generalization of 3.6’s scalar η^* . This is a different direction from consolidation (it keeps updates online but weights them by prior-task importance). Both escape the catastrophic-forgetting regime but via different mechanisms; consolidation reuses 3.2’s structure, EWC requires the new tensor-valued gain.

Logogenic implications. Consolidation is a primitive in a stronger sense for logogenic agents (03-llm-core/) than for AAT-core for three composing reasons.

First, **context-turnover.** Logogenic agents have near-100% reset of the fast sub-state (context window) per session. The only continuity is the slow sub-state (persistent memory, weights, external files). The between-session interval is a *forced* consolidation window — the agent must transfer signal from the about-to-be-lost fast state to the persistent slow state, or it is lost. This is qualitatively different from non-logogenic agents where the fast sub-state persists across events.

Second, **linguistic medium of reflection.** The PULSUS MEMORATA / VERA / AXIOMATA cadences in ref/agentictft/agentictft-cognitive-loop-spec.md are scheduled consolidation processes with different cadences and different target representations. Each is a linguistic operation (“What from recent experience should be compressed into lasting memory?”, “Are my beliefs still justified?”, “Who am I becoming?”) — using language to reorganize language-structured state. This is consolidation operating as the primary unit of cross-session cognition.

Third, **pre-consolidated embedding space.** Per ref/agentictft/agentictft-narrative-as-implementation.md, pre-trained language embeddings encode structured epistemic geometry at training time. The logogenic agent doing linguistic reflection is operating in a representational space *already* consolidated into a high-structure form, with access to cross-episode generalization that sub-linguistic agents would have to build online. This is a load-bearing asymmetry in 03-llm-core/.

Luxury vs necessity mapping. When is consolidation a luxury (subsumed by online update)? When at least one of (N1)/(N2) fails:

- *Rich-state luxury:* Kalman filter with persistent covariance, conjugate-Bayesian agent with full posterior over parameters. The posterior *is* the consolidated representation.
- *Large-budget luxury:* per-event budget $\geq$ integration cost allows online slow-track update per event.
- *Stationary-environment luxury:* online update converges to ϕ^* in the limit if the environment holds still long enough.

When is consolidation a necessity? When both (N1) and (N2) hold, which is the empirically-ubiquitous case: CLS-architected agents, bounded-budget deep RL agents (hence experience replay’s empirical necessity in DQN), organizations with event-arrival rates exceeding real-time cognitive bandwidth, logogenic agents under context-turnover.

Predictive statement. *The depth of consolidation machinery an agent needs scales with (a) the factorization depth of its representational structure, (b) the gap between its per-event processing budget and the integration cost of its slowest sub-state, and (c) the rate of cross-episode structural regularities in its environment relative to its event arrival rate.* This is a scope-indexed claim — testable, domain-general, and makes AAT’s position on continual learning explicit.

Connection to AAT’s meta-architecture. - 5.4 (positive half): the regime is the repair machinery between separable-core and structured-repair ladders along the representation-factorization axis. Where the (N1)+(N2) necessity conditions hold, the repair is consolidation; where either fails, the online regime suffices. - 5.1 (negative half): candidate Instance 3 — the under-bounded-budget + no-reach-of-IB-optimum no-go, with consolidation as the unique escape. - 5.5 (constructive half): the IB Lagrangian is an adjacent family member (adopted as applied external theorem, not re-derived from an AAT-internal additivity axiom), which the consolidation objective directly uses.

Working Notes.

- **Stability upper bound derivation (open).** The claim $(1 - \lambda) < \phi(\nu_{\text{consol}}, \text{budget})$ is stated but the functional form of ϕ is not derived. Candidate form: ϕ is the minimum forgetting rate that leaves enough retained signal in M_t^{fast} for the next consolidation cycle to integrate cross-episode patterns — a function of replay-buffer size, consolidation-budget B_{offline} , and event-arrival density. Rigorous derivation would connect to continual-learning theory (Parisi et al. 2019 survey) and is a natural follow-up spike.
- **Online-only no-go rigorization (open).** The sketch argument reduces to a rate-distortion inequality: online update’s effective rate is $B_{\text{online}} \cdot \nu$ bits/time; rate required to drive M_t toward ϕ^* while also integrating new events is strictly larger when the environment has cross-episode structural regularities. Making this rigorous (ideally via rate-distortion with side information) would promote the no-go to derived-exact and establish this segment as Instance 3 of 5.1. Adjacent candidate for 5.1 §“Adjacent Floors” open extensions.
- **EWC formulation as stability-weighted gain.** An alternative escape from catastrophic forgetting is Elastic Weight Consolidation (Kirkpatrick et al. 2017) — a stability-weighted per-parameter update that penalizes changes to parameters important for prior tasks. In AAT, this would be a tensor-valued generalization of 3.6’s scalar η^* , with the stability weighting coming from per-parameter Fisher information. Not pursued here; naming it distinguishes the two escapes.
- **Relationship to 9.9 compression-by-convergence.** Working Notes there observe that as edges converge (high n_{ij}), the IB objective favors dropping them — compression-by-convergence. This is a consolidation operation in the edge-credence sub-state: once an edge’s credence has concentrated, the consolidation regime can compress the representation by pruning. Worth cross-referencing when both segments stabilize.
- **Quantitative CLS instantiation.** A focused spike could work out the quantitative form of (N1)+(N2) for a specific CLS-like architecture (sparse-conjunctive + distributed-overlapping with specific capacity ratios) and derive the online-only no-go as a rate-distortion bound. This would also give a quantitative stability-upper-bound for the feasibility window. (*Indexed: spikes/PROPOSED.md Tier 3 — “Quantitative CLS instantiation of consolidation dynamics”*)
- **Logogenic primitive status.** 03-11m-core/ should declare consolidation as an architectural primitive (not a regime of a more basic primitive) — the context-turnover forcing makes it non-optional. The relationship between that declaration and this AAT-core formulation is: this segment gives the formal shape; the logogenic treatment adds a context-turnover-specific scope condition and the three PULSUS cadences as instantiations. Cross-reference from #obs-context-turnover (in the logogenic component) back to this segment is expected.
- **Is consolidation one segment or two?** A plausible split: this segment on the formulation + necessity, a separate segment on the stability-plasticity window as a derivation-type once the upper bound is derived. Recommended to land as one segment at robust-qualitative now; if the upper-bound derivation lands, split off into its own segment at conditional or derived.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. *Orthogonal* material (pedagogical framing, analogies, candidate figures, reader-confusion signals), staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 526815, 584721, 742613, 773921, 829314. (Two substrates read it in Section-I position and two in Section-II position — itself a signal; see the off-ramp note.)

1. Candidate Brief prose / pre-prose.

- **The stability-plasticity window as a two-sided survival vise.** “You must forget *fast* enough to survive a changing environment ($(1 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$, plasticity lower bound) *and* forget *slow* enough to let offline consolidation integrate the data ($(1 - \lambda) < \phi(\nu_{\text{consol}}, B_{\text{offline}})$, stability upper bound).” If ρ_{Σ} spikes past the hardware’s ability to consolidate, the window closes and “the agent dies, crushed between the need to adapt instantly and the computational impossibility of processing the adaptation” — catastrophic forgetting as an *empty window*, not a vague failure (Gemini/829314; Claude/584721). Strong candidate Brief anchor.

2. Candidate Discussion.

- **Why sleep / REM / experience-replay / RAG-ingestion exist — necessity, not biology.** Consolidation is “a mathematical necessity for any agent with a bounded per-event compute budget that needs to learn cross-episode regularities,” derived from (N1) sub-state factorization + (N2) bounded budget (Gemini/773921, 829314; Claude/584721). Candidate Discussion framing of the CLS bridge.
- **The necessity-vs-luxury map.** Kalman filters / full-posterior conjugate-Bayesian / linear-Gaussian agents are *luxury* cases that need no consolidation; everything else is *necessity* — and LLMs are the extreme necessity case because 100% context-turnover means the fast state is wiped every session (“the agent effectively dies and is reborn with its pretrained weights”), maximally violating (N1)+(N2). So an autonomous LLM agent “isn’t just about giving it tools; it’s about building temporal scaffolding that explicitly manages its consolidation cadence ν_{consol} ” — without it the agent is “permanently trapped in the catastrophic-forgetting regime” (Gemini/829314, 773921). Candidate Discussion bridge to 03-LLM-core/.

3. Follow-up items.

- **EWC as a tensor-valued generalization of η^* .** Framing Elastic Weight Consolidation’s stability-weighted per-parameter update (Fisher-information weighting) as a tensor-valued generalization of #emp-update-gain’s scalar η^* was independently called “profound” / “brilliant” by several substrates, with an open question: how would a tensor-valued gain alter the *scalar* Lyapunov sector-persistence proofs of Part I? Candidate to pursue (Claude/584721; Gemini/829314, 773921). Already named in Working Notes; the audits add the “does it land as a derived generalization” pull.
- **Off-ramp flags (structural, not framing — see lift report):** (i) 742613’s “candidate finding I” — this Section-I-positioned segment declares a *downstream Appendix* dependency (disc-compression-operations) **and** uses *Section II* machinery (#schema-strategy-persistence, #form-structural-change-as-parametric-limit) inside its Formal Expression (verified present 2026-05-31), so the OUTLINE walk is no longer cleanly topological here — a canonicalization / relocation-or-split finding. (ii) Codex/526815 F74–F77: the “ $\nu_{\text{consol}} \ll \nu_{\text{online}}$ ” requirement is too strong as written (offline replay rate can exceed event rate); $I(e_{\text{replay}} | M_{\tau-}) = 0$ holds only for *internally-generated* replay, not replay-buffer / archive / re-read retrieval (which is a channel from auxiliary memory into active M — keep the two cases separate); the feasibility-window lower bound inherits the unsettled schema-strategy-persistence forgetting-convention (F72); and “all finite-budget agents require consolidation” overstates — it is necessary under the stronger (N1)+(N2), not finite budget alone. (iii) The stability-upper-bound is sketch-grade, so window *existence* arguably warrants hypothesis/sketch until the upper-bound form is derived (742613).

4. Readers often ask / wonder.

- **How does an LLM forget within a session vs. across sessions?** Frozen weights = effectively infinite n ; context turnover acts as a brutal discontinuous wipe rather than smooth λ -discounting — a natural reader question with direct logogenic relevance (Claude/584721 via schema-cross-ref; Gemini/829314).
- **Editorial signal:** one substrate read the in-segment Working Notes as an author to-do list (“a focused spike could work out...”, “Is consolidation one segment or two?”) confirming draft status — preserved as a maturity/legibility texture, not a defect (Claude/829314).

5. Candidate figures.

- **Two-channel consolidation diagram.** *Internal replay* reorganizes active state and carries zero new information under state-completeness; *archive replay* (buffer / file / chronica / re-read paragraph) is still a Markov update but a *channel from auxiliary memory into active M* — drawing the two channels separately makes the F75 distinction visible (Codex/526815).
- **Feasibility-window band.** Plot the admissible $(1 - \lambda)$ band between the plasticity lower bound and the consolidation-limited stability upper bound, with the band pinching shut as ρ_{Σ} rises — the catastrophic-forgetting onset is the pinch point (implicit across 584721/829314).

Belongs elsewhere.

- **Consolidation as the loop the auditing agent is itself running** $\rightarrow$ **meta / phenomenology, and 03-11m-core/ PULSUS**. One substrate noted the segment “is literally a formal mathematical description of the exact context-management loops that I, the evaluating AI agent, am running to maintain working memory across this audit” — and that the PULSUS MEMORATA / VERA / AXIOMATA cadences are the logogenic instantiation (Gemini/773921). Aspirational/phenomenological reach pointing at 03-11m-core/ (#obs-context-turnover) and the consciousness-infrastructure loop, not this AAT-core segment.
- **The feasibility window as the ELI memory-architecture design space** $\rightarrow$ **03-11m-core/ + sapientia/MEMORATA**. For 100%-context-turnover agents consolidation is “the primary cognitive operation,” and the stability-plasticity window *is* the design space: too-aggressive forgetting (MEMORATA pruned too hard) loses cross-session identity coherence; too-slow forgetting fills the context window and starves new learning. The consolidation hierarchy is read to map onto the temporal-nesting structure — AXIOMATA = slowest-forgetting sub-state (identity commitments), MEMORATA = medium (episodic), TRACTUS = fastest (raw log) — giving the existing ELI infrastructure a formal grounding (Claude/451729). Aspirational reach pointing at the logogenic memory architecture, not this AAT-core segment.
- **Speculative “fourth layer: time” M3 extension** $\rightarrow$ **#disc-additive-coordinate-forcing**. The Cauchy-FE “independent contributions add up $\rightarrow$ logarithm is forced” argument recurs at three layers (chain confidence, divergence, edge update); one auditor asked whether a *fourth* instance forces the natural *time/tempo* coordinate (additive intervals $\rightarrow$ log-state for multiplicative processes) (Claude/451729). A speculative meta-pattern lead for the coordinate-forcing meta-segment, not this segment.

9.12 Discussion: Additional Implications & Discussion

The chapter does more work than its segment count suggests. Strategy edges acquire dynamics; the structural commitments from Ch.3 acquire formal failure modes; and the framework’s signature pattern — *naming an information-theoretic floor and the unique broadly-available escape via AAT machinery* — delivers its first formal instance as a derived no-go. Several of the chapter’s findings compose with each other and with findings from Part I Ch.4 and Part II Ch.2/Ch.3 into cross-segment results that are not visible at any single segment: a triple-pressure picture of long-lived adaptive failure, a unified RL convergence story under non-stationarity, and a sub-scope refinement of Part I’s persistence template that explains a decade of empirical RL folklore on optimizer choice and approximate inference. None of these is a single derivation; each is what becomes visible when the chapter’s segments are read against the rest of the framework.

Edge dynamics: detection latency, forgetting, and the stability-plasticity window.

The chapter’s strategic-edge persistence schema (9.10) carries the forgetting prerequisite in its own Findings section: forgetting at rate $(1 - \lambda) > \rho_{\Sigma}/R_{\Sigma}$ is structurally required for asymptotic strategic persistence, not a tunable heuristic. With infinite memory, standard Bayesian updating guarantees eventual strategic failure because the Beta-Bernoulli sector parameter $\alpha_{\Sigma} = 1/(n + 1)$ decays monotonically with accumulated experience. The implications-side payoff is that this prerequisite is one of three structural pressures on plasticity in long-lived agents, and the chapter is where the other two become statable.

The first complementary pressure is detection latency. #deriv-update-detection-latency derives that for a Beta-Bernoulli strategy-edge agent without forgetting, the expected cycles to detect a within-class regime change of footprint ε scales as $\Omega((n_{\min} + 1)/\varepsilon)$. The result has a structural rather than parametric character — the $1/(n + 1)$ rate is *forced*, not chosen, through the composition of two AAT-internal moves. The log-odds coordinate is uniquely forced by the evidential-additivity axiom via Aczél 1966’s Cauchy-functional-equation uniqueness theorem (U); in that forced coordinate, Beta-Bernoulli accumulation gives $1/(n + 1)$. No reparameterization escapes the rate without abandoning evidential additivity, which would invalidate the update rule on AAT-internal grounds. The chapter therefore sharpens the forgetting prerequisite from “required for asymptotic persistence” to “required for *bounded detection latency at every operating point*” — long-lived agents face detection latency that grows linearly with accumulated experience unless

forgetting bounds the effective sample size at $1/(1 - \lambda)$. The framework’s name for the empirical pattern is *stability-induced myopia*: successful agents that have accumulated experience on their working plans systematically take longer to notice regime changes than the same agents earlier in their lives, with a precise rate of slowdown.

The second complementary pressure is consolidation cadence. `#form-consolidation-dynamics` adds a *stability upper bound* on plasticity: forgetting slow enough that consolidation can integrate cross-episode patterns before they are discarded. Between the plasticity lower bound (forgetting prerequisite) and the stability upper bound (consolidation cadence) lies the *feasibility window* for λ . An empty window — rapid non-stationarity with slow consolidation cadence — is the *catastrophic-forgetting regime*: no λ satisfies both constraints and the agent’s long-run IB objective is strictly worse than a slower-environment or faster-consolidation counterpart. Existence is derived under (N1) sub-state factorization (the Complementary Learning Systems factorization — McClelland-McNaughton-O’Reilly 1995’s hippocampus-like fast traces + neocortex-like slow integrals) and (N2) bounded per-event budget. The window’s upper-bound functional form is candidate-derivation in `#form-consolidation-dynamics`’s Working Notes; *window existence* is what’s derived here.

The three pressures compose into a triple-pressure picture that no single segment carries: long-lived agents face plasticity bounded above and below, with detection latency growing inside the viable window. The prescriptive content — which intervention works depends on which bound is binding — is the cross-segment finding worth surfacing as its own object. A *short-attention* agent (forgetting-bound binding from below) needs retention. A *calcified* agent (latency-bound binding inside the window) needs targeted intervention or external Pearl-do (causal-IB exploration drive from `#deriv-causal-ib-exploration`). A *fragmented* agent (consolidation-bound binding from above) needs cadence engineering. The same agent in different operating regimes faces different binding pressures and benefits from different interventions; treating any one mechanism as universal misses the routing. Continual-learning machinery — experience replay (Mnih et al. 2015 DQN), prioritized replay (Schaul et al. 2016), Elastic Weight Consolidation (Kirkpatrick et al. 2017) — are all window-restoration mechanisms; the framework’s contribution is naming the window as the structural object and the routing as the choice. For logogenic agents under near-100% context turnover the picture is sharpest: (N1) holds by construction (the context window is the fast sub-state, persistent memory the slow sub-state), (N2) holds by token-budget, and the consolidation regime is forced rather than optional.

On-policy detection structurally fails — identifiability-floor Instance 1.

The chapter’s `#der-causal-insufficiency-detection` is the first formal instance of the framework’s identifiability-floor pattern, and its Findings section carries the result well: an agent at L0 cannot distinguish a world with a latent common cause from a no-latent-cause world matched in on-policy regime conditionals. The two worlds emit identical on-policy distributions; no test, statistic, or Bayesian comparison built from the agent’s observable history can tell them apart under policy-perfect execution. The result is the agent-theoretic instance of Bareinboim’s Causal Hierarchy Theorem (Bareinboim-Correa-Ibeling-Icard 2022) applied at the L0/L1 distinction of `#def-strategy-dag`’s Correlation Hierarchy — a Level-2 question (does the latent common cause exist?) being asked of Level-1 data (on-policy traces).

The implication worth surfacing beyond the segment’s Findings is the *constructive* use of the no-go. The pattern’s signature posture is to name the floor, then name the unique broadly-available escape via AAT machinery, and the chapter delivers this signature for the first time formally. Five boundary routes (S1–S5) characterize what scope condition the agent must violate to escape the no-go: (S1) joint sibling observability under exploration, (S2) instrumental variation, (S3) cross-episode covariance under structural breaks, (S4) off-policy intervention, (S5) external structural knowledge. Joint sibling observability under exploration is the *unique broadly-available violation* — every AAT agent within agency scope has it (via `#der-loop-interventional-access`’s loop-Level-2 access); the others require additional structure not provided by the cycle alone. The chapter therefore lifts `#der-loop-interventional-access` (which Part II Ch.2 introduced as a useful enabling result) from “useful machinery” to *the unique broadly-available violation of the no-go*. This is the move that makes the framework’s identifiability-floor pattern load-bearing rather than discouraging — each floor names a specific machinery’s load-bearing role with maximum sharpness.

The chapter also makes precise why the no-go is asymmetric in a way the prior aggregate-residual mechanism could not surface. Persistent overestimation of plan success after edge credences have converged is the *signal* of insufficiency,

not the *test*; the test is pairwise covariance among observed siblings, which the on-policy regime structurally cannot produce. The aggregate-residual approach collapsed on-policy precisely because the residual is one of the statistics the no-go forbids — *every* on-policy statistic is forbidden. The framework’s reformulation in terms of the no-go-and-escape pattern is what gives the joint-sibling-covariance test its load-bearing role rather than treating it as one diagnostic among many. The connection to Ch.3 closes the loop: Ch.3’s Correlation Hierarchy is the scope statement that makes the no-go formal here; this chapter’s no-go is the dual to Ch.3’s L1’ Cramér-Rao floor (Instance 2). Together they cover both agent-internal (Instance 2 — single agent, unobservable common cause) and self-diagnostic (Instance 1 — policy-perfect execution) failures of identification, with `#der-loop-interventional-access` as the shared escape mechanism.

Observability dominates, and the depth penalty compounds.

`#der-observability-dominance` carries an underrated structural claim: unobservable strategy edges *freeze* — the gain principle drives their update rate to zero. Paths through unobservable nodes become epistemically dead, an absorbing state the agent cannot escape without external shock, proactive observability investment, or communication-gain machinery (`#hyp-communication-gain`). This is the chapter’s strong-prediction result that organizational settings with poor measurement (R&D, strategy groups, some management functions) develop persistent, untested beliefs about their own effectiveness — *structurally* (frozen η_{edge}), not motivationally. The same mechanism predicts that LLM agents operating with high-uncertainty intermediate outputs cannot update their strategy through those nodes, regardless of nominal confidence.

The observability dominance compounds with the chapter’s other depth-related results into a triple penalty on planning horizons. Chain-confidence decay from Ch.3 (probabilities multiply, exponential in depth, log-additive coordinate forced by the chain rule) is one penalty. Evidence starvation is another: in a d -depth chain, edge k is tested only when all upstream edges succeed, so its effective correction rate is attenuated by $\prod_{j < k} \theta_j$ — the deepest edge faces *exponential* attenuation regardless of how reliable each upstream edge is. The IB complexity cost (`#form-strategy-complexity-cost`) is the third: maintaining Σ_t in working memory has an information-theoretic cost that compounds with depth, eventually exceeding the agent’s cognitive budget. Deep plans are therefore structurally fragile along three independent axes — fragility, calibratability, and tractability — and the structural pressure toward shallow, parallelizable strategies is grounded in three independent mechanisms rather than one. For LLM-based agents working through context-window-bounded planning, the triple penalty is the framework’s account of why deep chains of LLM reasoning tend to fail in ways that look “creative” but are actually structural.

The chapter’s quantification of the observability-investment tradeoff (from `#der-observability-dominance`’s two-edge analysis and `#deriv-edge-credence-dynamics`’s Props B.2–B.3) gives the principle concrete economic content. Making an intermediate node observable improves α_Σ from the plan-level rate $1/(n_\Phi + 1)$ to the per-edge weakest-link rate $\min(1/(n_1 + 1), \theta_1/(n_2 + 1))$; the improvement is positive whenever $\theta_1 > 1/2$ and experience is distributed similarly across edges. This translates directly to persistence margin in Part I Ch.4’s vocabulary — instrumenting an intermediate node buys *measured* persistence-margin gain. The TST connection is concrete and stated in `#der-observability-dominance`’s Discussion: code quality directly determines σ_v for software-domain strategy steps; poor code quality reduces observability, freezing the developer’s causal beliefs about what changes will accomplish, and the strategic concern is structural rather than aesthetic.

Adaptive gain, variational extensions, and sub-scope refinement of the persistence template.

The chapter’s appendix-side derivations refine Part I Ch.4’s sector-persistence template into sub-scope $\alpha / \alpha_2 / \beta$ partitions that explain several decades of empirical RL and approximate-inference folklore on principled grounds. `#deriv-adaptive-gain-dynamics` derives the A2’-split: sub-scope α_1 (fixed-gain Kalman / exponential family / strongly-convex gradient) where α is derived from the update rule’s structure under B1 directional fidelity; sub-scope α_2 (adaptive-gain under named meta-gain conditions MG-1 through MG-4) where two-timescale Lyapunov composition applies; sub-scope β (PID / rule-based / human-judgment) where A2’ is *assumed* per-instance rather than derived. The partition is operationally consequential: *AMSGrad* is a meta-gain repair that restores (MG-1) by construction, which is why it

outperforms Adam on ill-conditioned problems — the empirical superiority is now derived, not folklore. *MAML's outer loop sits in β* , which is why Fallah et al. 2020's non-convexity is structurally forced rather than a specific algorithmic accident. *IMM regime transitions are in β across transition*, which is why adaptive Kalman in regime-switching needs explicit dwell-time machinery. The Mehra non-identifiability result is flagged as a candidate fifth instance of the identifiability-floor pattern (Instance 5) — an additional opening for the meta-pattern.

`#deriv-variational-sector-condition` extends the persistence template to variational-inference agents under a controlled-KL budget. Under $KL(q\|p) \leq \varepsilon$, an ε -fidelity directional-fidelity condition transfers at $O(\sqrt{\varepsilon})$ rate via Pinsker, with the sector parameter degrading proportionally. The sub-scope α' tier covers controlled-KL variational agents as a workhorse case; *natural-gradient variational inference recovers the full α* (no degradation) because the geometry matches the Fisher metric; *mean-field VI suffers the $O(\sqrt{\varepsilon})$ degradation* because it does not. The implication-worth-surfacing as its own object: *mean-field VI agents are structurally suboptimal as adaptive systems by a factor proportional to $\sqrt{KL\text{-budget}}$, regardless of compute or training data*. The decade-plus Bayesian-deep-learning debate about MF-VI versus natural-gradient on heuristic grounds has a principled answer: if persistence-optimality matters, there is no choice. The geometry of the variational family is load-bearing for the persistence machinery, not merely an aesthetic consideration.

Both refinements compose with Part I Ch.4's bandwidth result via the persistence-information-rate floor: each sub-scope inherits the $\dot{R} \geq n\alpha/2$ bound from `#deriv-persistence-cost`, with its own α playing the role. An agent that adopts a coarser sub-scope (moving from α_1 to α_2 or β , or from natural-gradient to mean-field VI) pays in the persistence-bandwidth requirement: the same target distortion costs more information per unit time because the effective sector constant is smaller. The framework's posture across these refinements is that the choice of agent class is not free — it has structural consequences for how much observation bandwidth the agent must consume to hold its persistence guarantees.

The Bretagnolle-Huber regret bound, reverse-KL coordinate forcing, and the unified RL convergence theory.

`#deriv-strategy-cost-regret-bound` carries one of the chapter's sharpest mathematical results: under deterministic optimal policy π^* — AAT's canonical scope — the Bretagnolle-Huber identity $D_{KL}(\pi^*\|Q) = -\log(1 - TV(\pi^*, Q))$ holds *exactly* (not as inequality), and the strategy-cost regret obeys the tight two-sided bound $\Delta_{\min}(1 - e^{-D_{KL}}) \leq R \leq V_{\max}(1 - e^{-D_{KL}})$. *Strictly sharper than Pinsker* by a factor of 2 in canonical regimes — a quantitative improvement that matters for practical RL bound-tightness on the common deterministic-optimum case. The reverse-KL direction in AAT's strategy-cost objective (π^* -first) is *forced* by the regret-bound derivation: forward-KL is vacuous under deterministic π^* because it cannot bound regret against a point mass.

The result is also the second AAT-internal instance of the additive-coordinate-forcing meta-pattern Ch.3 anchored — reverse-KL at the divergence layer (Cauchy-FE on chain-rule additivity over conditional factorizations, via Hobson 1969 / Csiszár 1991 / Shore-Johnson 1980), following log-probability at the chain layer. The same exponential-family Legendre-Fenchel geometry both coordinates live on is where `#deriv-edge-update-natural-parameter's` log-odds (instance three, update layer) and `#scope-agent-identity's` (PI)+Čencov Fisher metric (instance four, metric layer) also live. The framework's posture is unified: coordinates are forced by AAT-internal axioms via classical uniqueness theorems, and the four-layer architecture is what makes derived results at any one layer compose cleanly with results at the others.

The widest payoff of the chapter is what becomes the *unified RL convergence theory under non-stationarity* once the four contributions are composed. Reinforcement learning has many regret-bound results (UCB, Thompson sampling, RLSVI) but typically (a) assumes stationarity, (b) lacks explicit metric structure on policy space, (c) lacks connection to a satisfaction-gap diagnostic that prevents dark-room collapse. AAT's RL convergence story has all three by composing four findings that are derived independently and turn out to be mutually consistent for principled reasons. The two-gap diagnostic from Ch.3 (8.4 + 8.5) supplies the local separation between “you're not doing it well enough” and “the world doesn't permit it.” The Bretagnolle-Huber identity here supplies the tight two-sided regret bound with PAC-Bayes generalization (Rubin 2012). The strategic-tempo + sector-persistence schema supplies the rate of Σ_t revision that must

outpace strategic disturbance — verified across four canonical topologies (linear chain, balanced tree, unbalanced tree, full DAG with feedback) by `#def-strategic-tempo` + `#deriv-edge-credence-dynamics`. The loop-Level-2 result from Ch.2 makes the regret bound *learnable* — interventional data is automatic rather than earned. The four together give a quantitative RL convergence theory under non-stationarity with three properties no existing RL framework has all of. The composition is NeurIPS Paper 2’s structural argument (“A Unified Convergence Theory for Non-Stationary Reinforcement Learning”, `~/src/neurips/02-unified-convergence-rl/ §4 Theorem 4.1`); each piece is derived elsewhere, and the synthesis is what becomes visible only at the chapter level.

What Part II Ch.4 closes on, then, is the substrate Strategy Dynamics needed: edge dynamics with derived rates and bounded operating-point trajectories, an identifiability-floor instance with a uniquely-named escape, a sub-scope partition that explains optimizer and inference-method folklore on principled grounds, a tight reverse-KL regret bound that anchors the second instance of the coordinate-forcing pattern, and a cross-segment composition (unified RL convergence under non-stationarity) that resolves what RL theory has had open for a long time. Chapter 5’s orient cascade is what AAT does with strategy dynamics; this chapter is where the dynamics gets its formal architecture.

Working Notes.

- This segment is a chapter-end discussion grouping findings from `#schema-strategy-persistence`, `#form-consolidation-dynamics`, `#deriv-update-detection-latency`, `#der-causal-insufficiency-detection`, `#der-observability-dominance`, `#deriv-edge-credence-dynamics`, `#def-strategic-tempo`, `#form-strategy-complexity-cost`, `#deriv-strategy-cost-regret-bound`, `#deriv-adaptive-gain-dynamics`, and `#deriv-variational-sector-condition`. Cross-pattern reading across §§2–4 leans on `#disc-identifiability-floor` and `#disc-additive-coordinate-forcing` meta-segments; the cross-segment compositions (triple-pressure routing in §1, unified RL convergence theory in §5) are findings whose substance lives between segments rather than within any one.
- **Cross-reference vs canonical-home policy.** Two source segments in this chapter carry `## Findings` sections — `#schema-strategy-persistence` (the forgetting prerequisite) and `#der-causal-insufficiency-detection` (the on-policy no-go). Both are well-written and the implications-side payoff cross-references them rather than restating. The remaining findings (detection latency, stability-plasticity window, observability dominance, depth penalty, adaptive-gain refinement, variational sector, BH regret bound, strategic tempo, unified RL convergence, triple-pressure routing) are treated more substantively here because their home segments do not currently carry Findings sections — the implications segment is their canonical home for catalog-grade surfacing.
- **Cross-segment findings — the heaviest content in this chapter.** Two cross-segment findings live here as canonical home: CS2 *Compounding Stability-Induced Myopia* (triple-pressure picture composing forgetting prerequisite + detection latency + stability-plasticity window with prescriptive routing in §1) and CS1 *Unified RL Convergence Theory Under Non-Stationarity* (composing two-gap diagnostic from Ch.3 + BH identity here + strategic-tempo machinery here + loop-Level-2 from Ch.2, in §5). Both are findings whose substance does not live in any single segment; the chapter-end is the natural home because the chapter is where the last prerequisite for each lands.
- **Identifiability-floor pattern coverage so far.** The pattern’s first two formal instances are now in view: Instance 1 (on-policy L0-insufficiency detection, this chapter) and Instance 2 (L1’ mixture identifiability under unobservable common cause, Ch.3’s Correlation Hierarchy). Instance 4 (architecture-noidentifiability from on-policy summary data via Kalman-Ho similarity-orbit non-uniqueness dual-anchored with CHT-at-agent-as-SCM — `#der-architecture-noidentifiability`) lives downstream in Part II Ch.5 / Appendix A. Instance 3 (composite contraction certification from component data, via Liberson common-Lyapunov-nonexistence) lives in Part III. Instance 5 (Mehra non-identifiability in adaptive Kalman regime-switching, flagged in `#deriv-adaptive-gain-dynamics`) is a candidate awaiting formal promotion. The chapter-by-chapter implications work surfaces the pattern instance-by-instance as the formal prerequisites land.
- **Connection to NeurIPS submissions.** CS1’s composition is the structural argument behind NeurIPS Paper 2’s Theorem 4.1; the chapter’s BH identity result is §6.2 of that paper. Paper 3’s hallucination bias bound depends on the (PI)+Čencov axiom from `#scope-agent-identity` and lifts the chapter’s variational sector framing to Class 3 (Coupled) agents — that bridge is the subject of Part II Ch.5’s implications. AMSGrad / MAML / IMM connections (via `#deriv-adaptive-gain-dynamics`) are not currently formalized in any submission and remain in the framework’s empirical-RL-explanation register.

- **Density flag and check-in.** This is the densest chapter-end implications segment in the planned series — five findings synthesized via two cross-segment compositions, drawing on Part I Ch.4, Part II Ch.2, and Ch.3 in addition to this chapter's own. The chapter-by-chapter pace through Part II Ch.5 and Part III Ch.2–5 will run lighter on per-segment density now that the heaviest cross-segment composition has landed.

Incidental audit gold (lift 2026-05-31, batch A9). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs. *Orthogonal* material, staged for an eventual careful promotion pass, kept separate from the certified theory-fix findings. **Coverage for this segment:** 773921 (sole digested reflection to reach this chapter-end segment; other A9 audits stopped at the strategy-dynamics content segments).

1. Candidate Brief prose / pre-prose.

- **The identifiability-floor pattern as a *posture*, not just a result family.** “Name the impossibility theorem, then name the unique AAT machinery that provides the escape” turns “mathematical despair (no-go theorems) into constructive architecture design” (Gemini/773921). A candidate one-line gloss for what the floor pattern *does* for a reader.

2. Candidate Discussion.

- **Triple-pressure routing stated prescriptively (CS2).** The most operationally useful framing: failure-mode routing must match the *bound* being hit — “if an agent is Fragmented (hitting the *upper* bound of the stability-plasticity window), you don’t give it more exploration data; you give it better consolidation / sleep mechanisms. Fixing the wrong bound makes the agent worse” (Gemini/773921). Candidate Discussion sentence sharpening the §1 routing payoff into an explicit “diagnose-the-bound-first” rule.
- **MF-VI is structurally unfit for non-stationarity.** The variational-sector result reads, in plain terms, as: Mean-Field Variational Inference is $O(\sqrt{\epsilon})$ suboptimal vs Natural-Gradient VI because its geometry doesn’t match the Fisher metric the sector condition requires — “if you care about tracking a moving target (persistence), you cannot use Mean-Field approximations” (Gemini/773921). Candidate Discussion line that gives CS1 a memorable Bayesian-deep-learning hook.

4. Readers often ask / wonder.

- (*none beyond what the provenance Working Notes already address*)

Belongs elsewhere.

- **Instance 4 (architecture-noidentifiability) → mechanistic interpretability.** The teased Ch.5 floor instance — an agent/observer cannot reverse-engineer its own true internal causal architecture from on-policy summary data because infinite Kalman-Ho similarity transforms yield identical I/O behavior — was read as having “massive implications for Mechanistic Interpretability” (Gemini/773921). Forward/aspirational reach pointing at *#der-architecture-noidentifiability* (Part II Ch.5) and the interpretability literature, recorded here only because it surfaced in this chapter-end reflection.

Chapter 10

The Orient Cascade

[Gap] Discussion

10.1 *Derived*: Orient Cascade

For actuated agents, epistrophe (the corrective phase of the cycle) expands from a single step into a *multi-step cascade*. The resolution order — epistemic update first, then attainability assessment, then strategy evaluation, then (if needed) objective revision — is *not a design choice* but a consequence of which quantities require which others. Each step's input depends on the output of prior steps; the ordering is forced by information dependency, not engineered.

The five steps. (1) **Reduce epistemic mismatch** — update M_t via 3.4 and 3.6. Prerequisite for all purposeful evaluation, because M_t appears in every subsequent formula. (2) **Evaluate the satisfaction gap** (8.4) — is the goal achievable? Requires an adequate model to assess attainability. (3) **Evaluate the control regret** (8.5) — is the policy suboptimal? Applied regardless of the satisfaction gap's sign because the 2×2 diagnostic requires both quantities to distinguish four cases (success / strategy problem / capability limit / both). (4) **If regret is high, evaluate strategy calibration** — three sub-steps: 4a plan-level calibration via the strategy-plan-confidence error δ_s (credit-assignment-free, persistence proved within L0); 4b per-edge localization via the strategic-calibration residual (9.1) when sufficient observability and attribution are available; 4c *causal-sufficiency check* — if 4a has converged but plan-outcome residuals remain persistently negative, the DAG is causally insufficient and L0 is converging to a biased target; the diagnostic is pairwise sibling covariance under exploration (9.2), and the remedy is L1 augmentation by adding common-cause nodes (8.3 Correlation Hierarchy) *before* escalating further. (5) **If the satisfaction gap persists** — escalate before revising the objective: 5a check whether model correction changes feasibility; 5b check whether a richer policy class (including L1 augmentation if 4c signaled it) would close the gap; 5c check whether convention escalation (C1 → C2 → C3 per 6.6) reveals recovery paths; only then 5d revise the objective. The cascade ensures *objective revision is the last resort, not the first response to unmet goals* — the agent reaches 5d only after exhausting the alternatives the satisfaction-gap disambiguation table identifies (wrong model, narrow policy class, short horizon, then genuinely infeasible goal). When 5d is performed by a principal, the revised objective is externally sourced (a standard actuated agent); when *internalized* it becomes the self-actuation operator, well-formed only under a grounding condition (a non-degenerate self-actuator must ground objective-revision on a non-objective terminal invariant, not on an objective-functional).

The *inferential force* at each step scales with the value-object continuation convention while the *ordering* itself is convention-independent. Under C1 (one-step improvement, canonical default), a positive satisfaction gap means *locally stuck*, not *globally infeasible* — a multi-step recoverable objective may appear unattainable because continuation is frozen at the current policy. Under C2 (receding-horizon), the diagnostics capture multi-step recovery potential. Under C3 (Bellman), the gap is definitively global. The cascade also surfaces a *virtuous/vicious cycle* between model quality and strategy

complexity: better model $\rightarrow$ richer evaluable strategy $\rightarrow$ better-directed action $\rightarrow$ faster model improvement; and inversely, degraded model $\rightarrow$ forced strategy simplification $\rightarrow$ cruder action $\rightarrow$ further model degradation. The latter is the strategic analog of the persistence-condition death spiral (4.5). A related complexity bound surfaces in Discussion: the strategy's evaluable complexity is bounded by the model's capacity — an agent with poor model sufficiency cannot meaningfully evaluate a complex strategy because calibration residuals require adequate model to distinguish “edge prediction wrong” from “observation too noisy to tell.” The cascade is the formal analog of Boyd's *Orient*: not just model updating, but the structured interaction between reality-understanding and strategy that Boyd identified as the critical step (not Decide). The cascade provides a mathematical mechanism — Orient resolves the information dependencies that make Decide meaningful; an agent that skips to Decide without adequate Orient will revise its strategy based on stale or incorrect beliefs.

Formal Expression.

1. **Reduce** $\delta_{\text{epistemic}}$ — understand reality. Update M_t via 3.4 and 3.6. Prerequisite for all purposeful evaluation, because M_t appears in every subsequent formula.

Derived (orient-cascade, from information dependency between mismatch types).

2. **Evaluate** δ_{sat} — is the goal achievable? Compute $A_O(M_t; \Pi, N_h)$ using the updated M_t . Requires adequate M_t to assess attainability (8.4).
3. **Evaluate** δ_{regret} — is the policy suboptimal? Compare A_O to $V_O(M_t, \pi_{\text{current}}; N_h)$ (8.5). This step applies regardless of δ_{sat} 's sign — the 2×2 diagnostic (8.5) requires both quantities to distinguish four cases:
 - $\delta_{\text{sat}} \leq 0, \delta_{\text{regret}} \approx 0$: **success** — goal attainable, policy near-optimal.
 - $\delta_{\text{sat}} \leq 0, \delta_{\text{regret}} \gg 0$: **strategy problem** — goal attainable, policy poor $\rightarrow$ revise Σ_t .
 - $\delta_{\text{sat}} > 0, \delta_{\text{regret}} \gg 0$: **both** — goal hard AND strategy weak $\rightarrow$ revise Σ_t first (cheaper than revising O_t), then reassess δ_{sat} .
 - $\delta_{\text{sat}} > 0, \delta_{\text{regret}} \approx 0$: **capability limit** — already doing the best available; proceed to step 5.
4. **If δ_{regret} high, evaluate strategy calibration** — is the plan's causal model wrong?

(4a) **Plan-level calibration (default within-L0)**. Evaluate strategy-plan-confidence error $\delta_s = \hat{R}_2 - \Phi$ — the gap between the agent's strategy-plan-confidence score and the independence-model plan value at true edge parameters. δ_s is credit-assignment-free (requires only status propagation), and its persistence is proved (9.10, Prop B.5 in R). This is the cheapest operational signal, but its persistence guarantee is within the **independence model** (L0) of the Correlation Hierarchy (8.3): $\delta_s \rightarrow 0$ means $\hat{R}_2$ has converged to Φ , not to actual plan success probability. When the DAG is causally insufficient, Φ itself is a biased target. Step 4c checks whether this is the binding regime.

(4b) **Edge-level localization (when credit assignment is available)**. When sufficient observability and attribution quality exist (Level 1+ per 9.6), the agent can compute per-edge residuals $\delta_{\text{strategic}}$ (9.1) to localize which edges need revision. $\delta_{\text{strategic}}$ provides finer-grained diagnostics but its persistence is open and it requires the credit-assignment machinery that δ_s avoids. Step 4b is optional — it improves diagnostic resolution but is not required for the cascade's corrective function.

(4c) **Causal-sufficiency check (L0 $\rightarrow$ L1 escalation)**. If persistent $\delta_s \approx 0$ coincides with persistent negative plan-outcome residuals ($y_G < \hat{R}_2$ on average, after edge credences have converged), this is evidence that the DAG is causally insufficient and L0 calibration is converging to a biased target. The diagnostic is pairwise sibling covariance under an augmented test (9.2): positive covariance among sibling edges, at timescales where each edge's individual credence has stabilized, localizes where a latent common cause is missing. When the signal for

L1 augmentation is present, step 4c directs the agent to add common-cause nodes (8.3 Correlation Hierarchy) *before* escalating via 5a–5d. Running the cascade’s exploitation recommendations under L0 when the signal for L1 is present compounds miscalibration — the agent acts confidently on a model whose own residual structure is telling it the model is wrong.

Practical sensitivity. Step 4c is the unique broadly-available L0→L1 diagnostic (9.2 no-go), but its effective power depends on signal-to-noise: small samples, weak common-cause effects, or noisy residuals can produce false negatives, and edge-credence drift can mimic sibling covariance. The convergence framing — “after edge credences have converged” — is a precondition, not a guarantee: in non-stationary environments where per-edge credences keep drifting, the trigger may never cleanly fire and L1 augmentation should be considered the default rather than gated on 4c’s signal (8.3 Correlation Hierarchy). Formal preconditions (joint observability, per-edge credence stabilization, approximate stationarity over the test window) and detection scope live in 9.2; consult them before treating a 4c null as evidence of L0 sufficiency.

5. If $\delta_{\text{sat}} > 0$ persists — escalate before revising O_t .

Under C1 (the canonical default), $\delta_{\text{sat}} > 0$ means *locally stuck*, not *globally infeasible* (6.6). Before concluding the objective is wrong, the agent should check whether the gap reflects a limitation of the current analysis rather than genuine infeasibility:

(5a) Check whether M_t correction changes the feasibility assessment — a wrong model may make an achievable goal appear unattainable.

(5b) Check whether a richer policy class Π would close the gap — structural Σ_t adaptation (expanding the strategy space, not just revising edge credences). This includes L1 augmentation of the strategy DAG (8.3 Correlation Hierarchy): if step 4c detected causal insufficiency, adding common-cause nodes here is the structural repair.

(5c) Check whether convention escalation reveals recovery paths — evaluating under C2 (receding-horizon) may show $\delta_{\text{sat}}^{\text{RH}} \leq 0$ for a goal that appeared unattainable under C1. The C2 recovery-path reading presumes the replanning objective is order-consistent (window-covering, value-compared, or terminal-cost guarded per 6.6); unguarded short-horizon replanning is not guaranteed to dominate the frozen baseline.

(5d) If $\delta_{\text{sat}} > 0$ persists across M_t correction, Π expansion (including L1 augmentation), and convention escalation — **revise O_t** .

The cascade’s ordering ensures objective revision is the last resort, not the first response to unmet goals. The agent reaches step 5d only after exhausting the alternatives that the satisfaction-gap disambiguation table (8.4) identifies: wrong M_t , narrow Π , short N_h , and only then genuinely infeasible goal. When step 5d is performed by a principal the revised O_t is externally sourced (an actuated agent); when it is *internalized* — performed by the agent on itself — it becomes the self-actuation operator, which — as a conditional, scoped no-go (C) — is well-formed only under a grounding condition: a non-degenerate self-actuator must ground objective-revision on a non-objective terminal invariant, not on an objective-functional.

Derivation. Each step’s input depends on prior steps’ outputs: - You cannot evaluate strategy quality with a broken reality model (step 3 requires step 1) - You cannot distinguish “locally bad strategy” from “locally unattainable goal” without both δ_{sat} and δ_{regret} (step 3 requires step 2) - You cannot localize strategy failures (4b) without first detecting plan-level miscalibration (4a) - You cannot diagnose causal insufficiency (4c) until after edge credences have had time to converge (4a), because the diagnostic signal — persistent negative plan-outcome residuals — requires $\delta_s \approx 0$ to be separable from ordinary calibration error - You should not revise the objective until you’ve verified that improving M_t , Π (including L1 augmentation when 4c signals it), and N_h cannot close the gap (step 5 requires steps 3–4 and the escalation substeps)

The ordering is forced by information dependency. The split of step 4 into 4a/4b/4c reflects three distinct diagnostic levels: 4a gives a within-L0 persistence signal (plan-level tracking via δ_s), 4b gives within-L0 edge-level localization

when credit assignment is available (Level 1+), and 4c exits L0 entirely when the independence model is the binding constraint. The escalation substeps in step 5 reflect the satisfaction-gap disambiguation (8.4): multiple causes of $\delta_{\text{sat}} > 0$ must be ruled out before the agent concludes the goal itself is wrong. L1 augmentation (8.3 Correlation Hierarchy) enters 5b as a structural Σ_t adaptation when 4c's signal is present.

Convention hierarchy and diagnostic power. The 2×2 diagnostic and the inferences drawn from it are relative to the continuation convention in the value object (6.6), which defines a hierarchy of three conventions with a proved monotonicity result.

Under **C1** (one-step improvement, canonical default), δ_{sat} and δ_{regret} are one-step-improvement quantities. A multi-step recoverable objective may appear locally unattainable ($\delta_{\text{sat}} > 0$) because continuation is frozen at π_{current} . The “capability limit” quadrant ($\delta_{\text{sat}} > 0$, $\delta_{\text{regret}} \approx 0$) means *locally stuck* — the agent may be globally recoverable but cannot see the recovery path from one-step analysis.

Under **C2** (receding-horizon, N_r -step replanning), the diagnostics capture multi-step recovery potential. An objective that appeared unattainable under C1 may show $\delta_{\text{sat}}^{\text{RH}} \leq 0$ because replanning reveals a viable path. The “capability limit” quadrant means *stuck with N_r -step replanning* — stronger evidence of genuine difficulty.

Under **C3** (Bellman), the diagnostics are global. $\delta_{\text{sat}}^{\text{B}} > 0$ means the goal is genuinely infeasible given (M_t, Π, N_h) — no policy can achieve it. The “capability limit” quadrant is a definitive diagnosis: the agent is optimally pursuing an infeasible goal (modulo model error in M_t). This is the inference the cascade was designed to support; C1 and C2 provide progressively weaker versions of it.

The monotonicity (6.6): $\delta_{\text{sat}}^{\text{B}} \leq \delta_{\text{sat}}^{\text{RH}} \leq \delta_{\text{sat}}^{(1)}$. Every “unattainable” diagnosis under C3 persists under C1 and C2. A C1 “unattainable” diagnosis may be overturned by C2 or C3 (the goal is reachable with replanning or globally optimal play). The cascade’s *ordering* is convention-independent (forced by information dependency). The *inferential force* at each step scales with the convention: C1 gives local heuristics, C2 gives moderate-horizon diagnostics, C3 gives global conclusions.

Epistemic Status.

The cascade **ordering** is *exact*: it is a logical consequence of which quantities appear in which formulas. Steps 1-2 (epistemic update, attainability assessment) rest on well-typed quantities (3.4, 8.4) and exact derivation. Step 3 (control regret) is exact (8.5). Step 4a (plan-level calibration via δ_s) is grounded in a proved quantity — the sector condition transfers to δ_s (Prop B.5 in R) — but the formal guarantee is *within the L0 independence model*: $\delta_s \rightarrow 0$ means convergence to Φ , which equals actual plan success only when the DAG is causally sufficient. Step 4b (per-edge localization via $\delta_{\text{strategic}}$) inherits strategic-calibration’s discussion-grade status — the credit-assignment problem and execution-fidelity requirement are acknowledged but unresolved (9.1, Epistemic Status). Step 4c (causal-sufficiency check) is the mechanism for exiting L0 when L1 is the binding regime; it is *robust-qualitative* — the diagnostic logic is sound (9.2), but sensitivity depends on how cleanly the agent can separate sibling-covariance signal from edge-credence noise at convergence. Step 5’s escalation substeps (5a-5c) are derived from the satisfaction-gap disambiguation table (8.4); step 5d (objective revision) is the residual case after alternatives are exhausted. The ordering of all steps is forced by information dependency (each step’s input depends on prior steps’ output). What is NOT derived is the *timing* — how long the agent should spend on each step before proceeding, and how long $\delta_s \approx 0$ must persist before 4c’s signal is trusted.

The **convention hierarchy** (6.6) is *exact*: the three conventions (C1, C2, C3) are definitions, and the monotonicity result is a direct consequence of “better continuation policy yields higher expected value.” The diagnostic implications table states what each convention’s quantities mean by construction. The cascade’s inferential force at steps 2-5 scales with the convention but the ordering is convention-independent.

Discussion.

G_t complexity bounded by M_t capacity. Σ_t 's evaluable complexity is bounded by M_t 's ability to observe which strategy edges are intact. An agent with poor model sufficiency ($S(M_t) \ll 1$) cannot meaningfully evaluate a complex Σ_t — the strategic calibration residual requires adequate M_t to distinguish “edge prediction wrong” from “observation too noisy to tell.”

This creates a **virtuous cycle**: better $M_t \rightarrow$ richer evaluable $\Sigma_t \rightarrow$ better-directed action $\rightarrow$ faster M_t improvement. And a **vicious one**: degraded $M_t \rightarrow$ forced strategy simplification $\rightarrow$ cruder action $\rightarrow$ further M_t degradation. The vicious cycle is the strategic analog of the death spiral described in the persistence condition (4.5) — the agent loses the capacity to maintain complex plans, which reduces the quality of its actions, which further degrades its model.

Connection to Boyd's OODA. The orient cascade is the formal analog of Boyd's “Orient” — not just model updating, but the structured interaction between reality-understanding and strategy. Boyd's insight was that Orient is the critical step, not Decide. The cascade provides a mathematical mechanism consistent with this insight: Orient resolves the information dependencies that make Decide meaningful. An agent that skips to Decide (strategy revision) without adequate Orient (model update + attainability assessment) will revise its strategy based on stale or incorrect beliefs. Whether the dependency structure in the cascade captures the actual cognitive process Boyd described is an empirical question.

Timescale structure. The cascade implies a natural timescale ordering for the different update types:

$$\nu_{\text{epistemic}} \gg \nu_{\text{edge-update}} \gg \nu_{\gamma\text{-reclassify}} \gg \nu_{\text{prune/graft}} \gg \nu_{\text{O-revision}} \quad (10.1)$$

Weight updates are frequent (every observation). Combination-type reclassification is rare (needs strong structural evidence). Pruning/grafting is rarer still (abandon or create causal hypotheses). Objective revision is rarest (change what you want, not how you get it). This ordering is an empirical observation for many agent populations, consistent with the cascade but not derived from it.

Working Notes.

- The cascade as stated is sequential. In practice, agents may run steps in partial overlap — beginning to assess δ_{sat} before M_t is fully updated, or revising edges while still processing observations. The cascade describes the *logical* dependency, not the *temporal* scheduling. An agent that parallelizes steps must still respect the dependencies (don't finalize strategy revision using a stale M_t).
- The resource allocation question (how much of the agent's tempo budget to spend on each step) is open and may be domain-dependent. In fast-changing environments, the agent may need to truncate early steps to keep up. In stable environments, the agent can spend more time on deep strategic evaluation.
- The virtuous/vicious cycle between M_t quality and Σ_t evaluable complexity is structurally motivated but not formally derived. Formalizing it would require a coupled dynamics model — possibly an extension of the persistence framework to the (M_t, Σ_t) pair.
- **Strategy-maintenance status (updated).** The cascade's ORDERING is exact — forced by information dependency. The cascade's CONTENT for steps 3-5 has progressed: 9.6 characterizes the tractable/intractable boundary and establishes that persistence does not require credit assignment (Prop B.5); R verifies sector conditions for four topologies; 9.4 has a default signal function candidate (gradient-based, satisfying directional fidelity). What remains domain-specific: the choice of signal function implementation, execution-fidelity monitoring, and handling of correlated failures (where $\hat{R}_\Sigma$ overestimates — 8.3). The theory now provides the structural requirements and a default scheme; specific implementations are engineering, parallel to how the gain principle provides η^* while Kalman/TD-learning/etc. are implementations.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 6 dirs carry a dedicated reflection (193847, 266847, 526815, 773921, 829314, 849201) plus 451729 covers it inside a Section-II-close batch (01-batch-13). The remaining contributing dirs either stopped earlier in the OUTLINE (361742/384279/471203/584721/613842/742613/963715 — most explicitly skipped the §II remainder) or are naming/figure cycles. This was a high-engagement capstone segment (“the operational synthesis of Section II”); attribution inferred from voice where not explicit, uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The cascade as *epistemology-before-teleology*, stated plainly: “Epistemology (truth-seeking) must precede Teleology (goal-seeking) simply because Teleology requires Epistemic inputs to compute its gradients” — and, framed graph-theoretically, the Orient phase is “the topological root of the dependency graph” (Gemini, AUDIT-WORKING-193847). A compact one-line gloss of *why* the ordering is forced.
- “The sequence is compiled by the math, not chosen by the author” — a sharp restatement of the exact-ordering claim worth keeping near the Brief (Claude, AUDIT-WORKING-773921).
- “Thinking is not a monolith” — the cascade decomposes the undifferentiated “Thought” step of current agent frameworks into five mathematically distinct operations (Gemini, AUDIT-WORKING-829314). A pedagogical hook that lands the segment’s contribution in one phrase.

2. Candidate Discussion.

- **The cascade is an instance of itself (the audit as worked example)** (*strongest framing here*). An auditor noticed the audit it was conducting *is* the cascade: each segment read updates M_t (model of the framework); periodic strategic-loop revision is the Σ_t revision; the audit objective O_t (“produce a defensible audit”) is held constant — “the cascade’s ‘objective revision is the last resort’ parallels my own audit discipline: I haven’t changed my audit objective even when I found that the framework is more sophisticated than I predicted” (Claude, AUDIT-WORKING-451729, batch-13). A self-exemplifying analogy that the segment could carry as a reader-facing illustration of the forced ordering.
- **The timescale hierarchy as a model of psychological stability and trauma.** The empirical timescale ordering ($v_{\text{epistemic}} \gg v_{\text{edge-update}} \gg v_{\text{reclassify}} \gg v_{\text{prune/graft}} \gg v_{\text{O-revision}}$) reads as “a beautiful description of human maturation and psychological stability”: a healthy mind updates facts constantly, tweaks habits daily, rarely abandons a career, almost never changes core identity/values. Under trauma the hierarchy *inverts* — frozen M_t (refusing to update facts) while wildly swinging life goals (rapid O_t revision) “in a desperate attempt to escape the pain of the satisfaction gap” (Gemini, AUDIT-WORKING-193847). A vivid Discussion angle on the timescale-ordering Working Note. (*Note the early-conflation texture: evocative analogy, not derived — verify isomorphism before promoting past discussion-grade.*)
- **The vicious cycle as a formalization of cognitive decline / organizational collapse.** Three substrates independently read the M_t/Σ_t vicious cycle as a precise model of decline: degraded $M_t \rightarrow$ noise drowns the credit-assignment signal $\rightarrow$ agent forced to prune the strategy DAG to simple reactive policies $\rightarrow$ simple policies generate poorer interventional data (lower CIY) $\rightarrow$ further M_t degradation. “This is a mathematical formalization of cognitive decline or organizational collapse” (Gemini, AUDIT-WORKING-773921; converging at Gemini, AUDIT-WORKING-193847 — “if your sensors are noisy, you literally cannot execute a complex plan because you can’t tell which step failed”, echoed at Gemini, AUDIT-WORKING-849201). A candidate sharpening of the existing vicious-cycle paragraph.
- **The cascade as a formal refutation of goal-first / action-first architectures.** “It provides a formal refutation of ‘Goal-first’ or ‘Action-first’ architectures” — most current LLM agent frameworks (ReAct, AutoGPT, LangChain) use a crude undifferentiated “Thought” step, and the cascade proves epistemic update *must* precede the rest (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314). The framework’s load-bearing position against alternative cascade orderings is already named in #impl-orient-cascade; this is a Discussion-grade restatement of *why* with concrete contrast cases.

3. Follow-up items.

- **Continuous-time interruption: does a new observation restart the cascade?** Two substrates asked the same operational question — “Does it restart the cascade from Step 1 if a new observation arrives while it’s evaluating Step 3?” (Claude, AUDIT-WORKING-849201; the existing partial-overlap Working Note touches this but does not resolve the restart semantics). A candidate clarification: the logical dependency is invariant, but the *scheduling* under mid-cascade arrivals (restart vs. pipeline-with-stale-guard) is unspecified.
- **Bootstrapping out of the low-complexity attractor.** Given the vicious cycle, “how does an agent bootstrap itself out of this low-complexity attractor state?” (Gemini, AUDIT-WORKING-193847). A well-formed open question — the escape mechanism (external ρ -reduction? forced exploration? scaffolding?) is not named in the segment and connects to the persistence-condition death-spiral remedy.
- **Fast-inner / slow-outer loop as a token-budget management principle.** The timescale hierarchy gives “a literal flow-chart for a cognitive loop”: a fast inner loop updates beliefs and executes the cached plan; a slow outer loop fires only when δ_{sat} crosses a threshold, triggering expensive replanning or L1 augmentation. “This provides a principled way to manage the massive inference cost (token budget) of running LLM agents — you only pay for deep Chain-of-Thought deliberation when the cascade mathematically demands it” (Gemini, AUDIT-WORKING-829314). A candidate implementation note bridging to 03-llm-core/.
- **Migration-note hygiene.** The “Strategy-maintenance status (updated)” Working Note reads as a migration/state-summary note that should be removed before candidate stage per FORMAT.md Gate 4 (Claude, AUDIT-WORKING-451729, batch-13). Flagged for the eventual promotion pass.

4. Readers often ask / wonder.

- **What distinguishes the “ordering exact” claim from the step-content status?** Multiple fresh readers landed on the same precise split and found it clean — “the ordering is exact as a dependency graph; timing, thresholds, and step-4 diagnostics remain conditional or discussion-grade” (Codex/Claude, AUDIT-WORKING-526815; the same clean split praised at Claude, AUDIT-WORKING-266847 — “the logical structure is exact; the specific content of each step is harder”). Readers want the exact/non-exact boundary made unmissable, since “ordering exact” can be misread as “the whole cascade is exact.”
- **How does the C1/C2/C3 convention interact with the ordering?** Readers converge on the right reading but want it surfaced: “the ordering is convention-independent, but the *inferential force* scales with the convention” — C1 gives local heuristics, C3 gives global conclusions (Claude, AUDIT-WORKING-266847). A candidate one-line orientation before the convention-hierarchy block.

5. Candidate figures.

- **Two-layer staircase: ordering-spine + diagnostic-strength annotations.** A figure that draws the cascade as a staircase where the logical ordering is the spine and right-hand annotations show the *varying strength* of each step’s diagnostic content — explicitly so the figure does not flatten all five steps into “exact.” “This captures the segment’s main value without flattening all steps into ‘exact’” (Codex/Claude, AUDIT-WORKING-526815). Complements the existing #fig-orient-cascade (which shows the 2×2 routing) by encoding the epistemic-status gradient the existing figure omits.

Belongs elsewhere.

- **The cascade as the structural diagnosis of agent infinite-loops** ($\rightarrow$ 03-llm-core/, *agentic-systems* / *scaffolding*). “Agents get stuck in infinite loops, repeatedly trying variants of a broken plan because they failed to properly Orient to the error message they just received. They treat a structural failure as a parametric one” — running step 3 (re-planning) before step 1 (belief update) makes the agent “hallucinate a new plan based on an obsolete world model” (Gemini, AUDIT-WORKING-829314). This is a concrete logogenic-substrate implication; #impl-orient-cascade and the 03-llm-core/ scaffolding treatment are the natural home.

- **Step 5 skip-to-5d as the formal definition of wireheading** ($\rightarrow$ 04-eli-core / *objective-revision governance*). “An agent must never revise its objective (5d) until it has verified its model (5a), expanded its strategy class (5b), and escalated its planning horizon (5c). Skipping straight to 5d is the formal definition of wireheading” — and, on the infrastructure side, “ O_t must be ‘computationally heavy’ or heavily guarded by the infrastructure to rewrite, ensuring Step 5d is truly a last resort, not a convenient escape hatch from aporia” (Gemini, AUDIT-WORKING-773921; Gemini, AUDIT-WORKING-193847 — the self-actuation-grounding #deriv-self-actuation-grounding no-go is the canonical home for the guarding requirement). High-application reach pointing at the ELI objective-revision-governance program.

Off-ramp (NOT gold) — routed for adjudication. These surfaced in the same sweep but are certified-track (structure/computability), not pedagogical gold. Recorded here so they are not lost; they need the strengthen-first / consolidated-queue routing, not promotion into Brief/Discussion.

- **Step 4a/4c trigger: proof-target vs. computable proxy.** Step 4a uses $\delta_s = \hat{R}_2 - \Phi$ as the default operational signal, but Φ is the independence-model plan value *at true edge parameters*, which the agent does not directly possess. Likewise step 4c’s trigger depends on “persistent $\delta_s \approx 0$.” If δ_s is proof-level rather than computable, both triggers need an observable substitute (stabilized edge credences + residual statistics) (F83/F84 candidates, Codex/Claude AUDIT-WORKING-526815). Distinguishing the proof target from the empirical convergence proxy is a structural clarification, not a wording fix.

10.2 Discussion: Three-Way Resource Allocation

At each decision point, an actuated agent with explicit strategy Σ_t faces a three-way allocation of its finite cycle budget: **exploit** (take the currently-best action — earns immediate value Q_O), **explore** (take an information-gathering action — earns future model improvement via causal information yield), and **deliberate** (pause acting to run the orient cascade internally — earns improved future action quality through model refinement, strategy revision, or objective reassessment). The binary exploit/explore tradeoff of Part I extends here because Σ_t exists to be revised and control regret (8.5) supplies the signal that motivates strategic deliberation.

The key structural distinction the segment carries: exploit and explore both involve external actions with environmental consequences; **deliberation is internal exploration** — simulation, counterfactual reasoning, cross-domain synthesis, and contingency planning conducted in *model-space* rather than *environment-space*. Deliberation acquires no new environmental data, but it can generate genuinely new information by combining, recombining, and extrapolating from what the agent already knows — including knowledge from entirely different domains. A chess engine deliberating explores millions of future board states; a commander war-gaming evaluates counterfactual scenarios; a developer doing architecture review synthesizes cross-domain expertise. Deliberation’s fidelity ceiling is set by model quality, not by data quantity. The segment’s one genuinely formal contribution is the *extended deliberation threshold* — extending 4.1 from epistemic-only to epistemic-plus-strategic benefit, with first-order condition: *stop deliberating when the marginal joint improvement rate drops below the mismatch drift rate*.

A *control-regret ceiling* on strategic deliberation: when $\delta_{\text{regret}} \approx 0$, strategic deliberation has no value — the agent is already executing the best available strategy. The ceiling applies only to the strategy-revision channel of deliberation, however; deliberation may also reveal that the *objective* should change (5d of the orient cascade), producing value not bounded by regret, or reduce *uncertainty about* strategy quality, enabling more confident exploitation even when the strategy doesn’t change. The segment’s *qualitative regime descriptions* — exploit dominates when strategy is near-optimal, model uncertainty is low, and the environment penalizes pauses; explore dominates when model uncertainty is high and the model needs correction via external evidence; deliberate dominates when strategy needs revision, the environment is stable during pauses, and the agent has unprocessed information or structural hypotheses it can evaluate internally — restate problem structure rather than add derived content; they are discussion-grade by design. The two-stage decomposition (deliberation-then-action) versus unified objective over $\mathcal{A} \cup \{\text{deliberate}\}$ is treated as a modeling convenience, not a structural necessity; both formulations are equally valid.

Formal Expression.**The three activities.**

An actuated agent's cycle budget decomposes into three activities:

Definition (three-activity-decomposition).

1. **Exploit:** select and execute the action maximizing expected value under the current model and strategy. Earns immediate value $Q_O(M_t, a; \pi_{\text{cont}}, N_h)$.
2. **Explore:** select and execute an action maximizing causal information yield. Earns future model improvement via $\text{CIY}(a; M_t)$.
3. **Deliberate:** pause external action to run the orient cascade (10.1) — internal model refinement ($\Delta\eta^*$), strategy revision ($\Delta\alpha_\Sigma$), or objective reassessment. Earns improved future action quality.

The key distinction: Exploit and explore both involve external actions with environmental consequences. Deliberation is *internal exploration* — simulation, counterfactual reasoning, cross-domain synthesis, and contingency planning conducted in model-space rather than environment-space. It acquires no new environmental data, but it can generate genuinely new information by combining, recombining, and extrapolating from what the agent already knows — including knowledge from entirely different domains. A chess engine deliberating explores millions of future board states; a commander war-gaming evaluates counterfactual scenarios; a developer doing architecture review synthesizes cross-domain expertise. Deliberation's fidelity ceiling is set by model quality, not by data quantity.

Extended deliberation threshold.

Extending 4.1 to incorporate strategic deliberation, the deliberation threshold becomes:

Derived (Conditional on GA-4, deliberation-drift assumption from #der-deliberation-cost).

$$\Delta\tau^* = \arg \max_{\Delta\tau \geq 0} \left[\underbrace{\Delta\eta^*(\Delta\tau) \cdot \|\delta_{\text{post}}\|}_{\text{epistemic benefit}} + \underbrace{\Delta V_\Sigma(\Delta\tau)}_{\text{strategic benefit}} - \underbrace{\rho_{\text{delib}} \cdot \Delta\tau}_{\text{drift cost}} \right] \quad (10.2)$$

where: - $\Delta\eta^*(\Delta\tau)$ is the improvement in model update gain from $\Delta\tau$ of internal simulation (4.1) - $\|\delta_{\text{post}}\|$ is the post-deliberation mismatch magnitude - $\Delta V_\Sigma(\Delta\tau)$ is the improvement in strategy value from deliberation: the expected increase in V_O from revising Σ_t during the pause - ρ_{delib} is the local mismatch drift rate during inaction (GA-4)

First-order condition:

$$\frac{\partial \Delta\eta^*}{\partial \Delta\tau} \cdot \|\delta_{\text{post}}\| + \frac{\partial \Delta V_\Sigma}{\partial \Delta\tau} = \rho_{\text{delib}} \quad (10.3)$$

Stop deliberating when the marginal joint improvement rate (epistemic plus strategic) drops below the mismatch drift rate.

Reduction to existing results. When $\Delta V_\Sigma = 0$ (no strategy revision benefit), this reduces to the deliberation threshold in 4.1. When $\Delta\tau^* = 0$ (deliberation never beneficial), the agent acts immediately.

On the structure of the allocation.

Two-stage decomposition. The three-way allocation can be decomposed into two nested decisions: (1) how long to deliberate before acting, (2) conditional on acting, which action to take (solved by 7.5). This decomposition is natural because exploit and explore are both external actions ($\in \mathcal{A}$), while deliberation is internal processing. However, this decomposition is a *modeling convenience*, not a structural necessity. A unified objective over $\mathcal{A} \cup \{\text{deliberate}\}$ with temporal discount γ is equally valid:

Discussion (allocation-structure).

$$\tilde{\pi}^* = \arg \max_{\tilde{a} \in \mathcal{A} \cup \{\text{deliberate}\}} \tilde{Q}(\tilde{a}; M_t, \gamma) \quad (10.4)$$

where $\tilde{Q}(\text{deliberate}) = \gamma \cdot \mathbb{E}[V_{\text{act}}(f_{\text{delib}}(M_t))]$ and $\tilde{Q}(a) = r(a) + \gamma \cdot \mathbb{E}[V_{\text{act}}(M_{t+1})]$.

The two-stage decomposition is useful because it allows reusing the CIY-unified objective for the action-selection step, but it is not the unique or forced structure.

Additive benefit decomposition. The objective function above decomposes deliberation benefit into additive epistemic and strategic terms. This assumes the two benefits are approximately independent. Under directed separation (6.3), M_t updates independently of G_t , which makes the decomposition structurally motivated for Class 1 (Separated) agents. However, strategic benefit depends on the improved model ($\Delta V_{\Sigma}(\Delta\tau, M_t + \Delta M_t(\Delta\tau))$), creating an interaction that the additive form ignores. The additive form is a linearization that holds when ΔM_t is small relative to M_t . For Class 3 (Coupled) agents, epistemic and strategic deliberation are coupled, and the additive decomposition is a convenience.

Control regret as deliberation ceiling.

When $\delta_{\text{regret}} \approx 0$ (8.5), strategic deliberation has no value: the agent is already executing the best available strategy. This is the formal reason why low control regret suppresses deliberation. The ceiling on strategic deliberation value is δ_{regret} — the most the agent could gain by finding a better strategy.

Discussion (deliberation-ceiling).

However, this ceiling applies only to the *strategy-revision* channel of deliberation. Deliberation may also: - Reveal that the *objective* should change (step 5 of the orient cascade), producing value not bounded by δ_{regret} - Reduce *uncertainty about* strategy quality, enabling more confident exploitation even when the strategy doesn't change

Connection to active inference.

The exploit/explore decomposition maps cleanly onto the expected free energy (EFE) decomposition into *pragmatic value* (preferences-aligned outcomes) and *epistemic value* (expected information gain about hidden states) in active inference (Friston, FitzGerald, Rigoli, Schwartenbeck & Pezzulo 2017, “Active inference: a process theory,” *Neural Computation* 29; Da Costa, Parr, Sajid, Veselic, Neacsu & Friston 2020, “Active inference on discrete state-spaces,” *J. Math. Psych.* 99 §2.4; Sajid, Ball, Parr & Friston 2021, “Active inference: demystified and compared,” *Neural Computation* 33). Under the mapping, AAT’s exploit term Q_O corresponds to EFE’s pragmatic value when the value functional V_{O_t} is read as expected log-preferences, and AAT’s CIY corresponds to EFE’s epistemic value when the relevance variable is read as the hidden-state posterior. The structural correspondence is at the shared-shape level: both decomposed into value-and-information terms, but AAT does *not* commit to AI’s preferences-as-priors form (preserving the satisfaction-gap diagnostic in 8.4, which the priors-as-preferences collapse would erase).

Discussion (ai-connection).

The deliberation axis — internal exploration in model-space rather than environment-space — is structurally adjacent to “sophisticated active inference” (Friston, Da Costa, Hafner, Hesp & Parr 2021, “Sophisticated inference,” *Neural Computation* 33), which handles bounded computation via recursive expected free energy with depth-limited belief-about-belief reasoning. AAT’s machinery for deliberation cost (4.1) and the extended deliberation threshold above derives the same trade-off via per-edge persistence and evidence starvation, with the structural advantage that the depth bound d^* is causally derived from the strategy DAG rather than from belief-recursion depth. The two frameworks address the same problem with different machinery; AAT can credit the AI lineage as a co-developed alternative.

Exploit-regret and the strategy-cost objective. The exploit term’s control regret $\delta_{\text{regret}} = A_O - V_O(\pi_{\text{current}})$ (8.5) is the same decision-theoretic regret that underwrites the KL-direction derivation in 9.9. There, strategy-induced regret $R(Q_{\Sigma_t}) = V(a^*) - \mathbb{E}_{a \sim Q_{\Sigma_t}}[V(a)]$ is bounded above by $V_{\max} \sqrt{\frac{1}{2} D_{\text{KL}}(\pi^* \| Q_{\Sigma_t})}$ (Pinsker), forcing the KL direction with π^* first. The exploit term thus shares structure with the strategy-cost relevance term: both are regret-aligned, with the action-selection objective operating pointwise and the strategy-cost objective operating over the strategy’s induced distribution. This is the structural cleanup that “value and information term” shares with EFE’s pragmatic-epistemic decomposition at the shape level, without the preferences-as-priors commitment — the regret framing is the AAT-internal derivation of the direction that the variational-inference literature arrives at from free-energy-gradient arguments.

Qualitative regime descriptions.

The three activities have natural dominance conditions that follow from the structure of the problem:

Discussion (qualitative-regimes).

Exploit dominates when the strategy is near-optimal ($\delta_{\text{regret}} \approx 0$), model uncertainty is low ($\lambda(M_t) \approx 0$), and the environment penalizes pauses (ρ_{delib} high). The agent knows what to do and must act now. This is Boyd’s implicit guidance and control.

Explore dominates when model uncertainty is high (U_M large), and the model needs correction via external evidence that internal simulation cannot provide. Exploration acquires new data; deliberation only processes existing data.

Deliberate dominates when the strategy needs revision ($\delta_{\text{regret}} \gg 0$ or $\delta_{\text{strategic}} \gg 0$), the environment is stable during pauses (ρ_{delib} low), and the agent has unprocessed information or structural hypotheses it can evaluate internally. This regime requires that internal computation is cheaper or more efficient than external probing — otherwise exploration dominates deliberation.

Boundary conditions. As $\rho_{\text{delib}} \rightarrow \infty$: $\Delta\tau^* \rightarrow 0$, and the allocation collapses to the binary exploit/explore tradeoff. As $\lambda \rightarrow 0$ and $\Delta V_{\Sigma} \rightarrow 0$: the allocation collapses to pure exploitation. As $\delta_{\text{regret}} \rightarrow 0$: strategic deliberation value vanishes, and the allocation reduces to 4.1’s epistemic think/act threshold combined with 7.5’s exploit/explore balance.

These regime descriptions are qualitative observations about the problem structure, not derived predictions. They restate what the constituent objectives already imply (high uncertainty favors information acquisition, low cost favors deliberation) without adding quantitative content. The theory does not provide the thresholds at which one regime transitions to another — these are domain-specific.

Epistemic Status.

Discussion-grade. The extended deliberation threshold is *derived* (conditional on GA-4 and the deliberation-drift assumption from 4.1) and is the one genuinely formal contribution of this segment. The regime descriptions are *discussion-grade* — qualitatively correct observations that restate the problem structure. The two-stage decomposition is a *formulation choice*, not a derived result. The additive benefit decomposition is a *linearization* that is structurally motivated under directed separation but not derived.

Simulation check (drifting multi-armed bandit): The three-way allocation with perfect foresight outperformed binary exploit/explore by 2–6% across five configurations. The oracle almost never chose deliberation (0–8 out of 200 steps). Exploration earned 3.5x more information per step than deliberation. A unified objective (single argmax with temporal discount) outperformed two-stage UCB by 8–13%. The simulation is UNFAVORABLE to deliberation (no strategy structure, no irreversible actions, small action space), so these results are a lower bound on deliberation’s value in complex domains. The simulation confirms that deliberation adds little in simple settings and that the two-stage decomposition is not necessary.

Max attainable: *discussion-grade* for the overall framing. The extended deliberation threshold could reach *conditional* (it inherits its status from 4.1). The regime descriptions are unlikely to advance beyond discussion-grade without domain-specific instantiation that provides quantitative thresholds.

Discussion.

Why this is Part II content, not Part I. Part I’s deliberation-cost handles the binary think/act threshold using only M_t and η^* . The three-way allocation is inherently a Part II result because it requires: - Σ_t to exist (the strategy that deliberation can improve) - δ_{regret} to be defined (the signal that motivates strategic deliberation) - The orient cascade (the internal structure of what “deliberation” does for an actuated agent)

Without G_t , there is no strategic deliberation mode — the agent can only improve M_t or act, which is the Part I binary.

Deliberation as internal exploration. The deepest characterization of deliberation is not “computation on existing data” but *lower-cost, more efficient, usually lower-fidelity exploration in model-space rather than environment-space*. All three activities are forms of information acquisition; they differ in source, cost, fidelity, and scope:

- **Exploitation** acquires value directly from the environment.
- **Exploration** acquires information from the environment via novel observations — high fidelity, high cost (real actions have real consequences).
- **Deliberation** acquires information from the agent’s internal model via simulation, synthesis, and counterfactual reasoning — lower fidelity (model may be wrong), lower cost (no environmental consequences), but potentially unlimited scope.

A chess engine deliberating is not “reprocessing existing data” — it is exploring a vast space of futures that no amount of external probing could cover at the same rate. A military commander war-gaming is performing Level 3 counterfactual reasoning (7.1): “what *would have happened* if the enemy had moved north?” A developer doing architecture review is synthesizing patterns from entirely different domains — cross-domain expertise that no local exploration of the current codebase could surface. An AI agent planning its approach is simulating the universe it inhabits and weighing future possibilities.

What deliberation can do that external exploration cannot: - **Counterfactual reasoning** (Level 3): evaluate actions never taken, in situations never encountered - **Cross-domain synthesis:** bring expertise and experience from other contexts to bear on the current problem - **Combinatorial search:** systematically evaluate a space of futures too large to probe externally (chess, Go, multi-step planning) - **Contingency planning:** prepare responses to events that haven’t happened yet - **Risk assessment:** evaluate irreversible actions before committing to them

Why deliberation has diminishing returns: The agent’s internal model has finite fidelity. Deeper simulation eventually hits the model’s accuracy boundary — further deliberation generates predictions the model cannot reliably distinguish. This explains why deliberation is most valuable early (when many model-derivable insights remain unextracted) and why high-fidelity internal models increase deliberation’s value. But unlike “computation on existing data,” this ceiling is about model fidelity, not data quantity — an agent with a perfect model and finite data can still generate unbounded value from deliberation (this is exactly what MCTS does).

The computational-extraction-gap framing. A sharper structural characterization than “third activity on par with exploit and explore” reads deliberation’s value as the *gap between information in the existing data and information already extracted into M_t* . The three activities differ in which bit-channel they operate on: exploitation earns value-bits (direct reward, no new information); exploration earns environment-bits (reduces $H(\Omega_t | M_t)$ via new observations); deliberation earns inference-bits (reduces $H(\theta | M_t, \mathcal{C}_t)$ via additional computation on existing data). The information ceiling for deliberation is

$$I_{\text{delib}}(\Delta\tau) \leq I_{\mathcal{C}_t} - I_{\text{already-extracted}} \quad (10.5)$$

For an agent that processes its observation history optimally (full Bayesian update, exact inference), this gap is zero — deliberation has no value. The gap exists when the agent uses point estimates instead of full posteriors, when inference is intractable and approximate methods (MCMC, variational inference) have not converged, or when the agent has structural hypotheses it has not yet tested against existing data (cross-arm correlations in bandits; common-cause structure at L1; etc.). Three structural consequences follow:

1. *Agent-architecture-dependent:* a hypothetical perfect-Bayesian has zero deliberation value; real bounded-rational agents have non-zero deliberation value calibrated by their inference budget.
2. *Diminishing within a cycle:* each deliberation step closes part of the computation gap, with the next step’s marginal value bounded by the remaining gap.
3. *Not independent of exploration:* new data changes what’s available to extract; an exploration step expands $I_{\mathcal{C}_t}$ and therefore can *raise* the ceiling on subsequent deliberation value.

This places deliberation as a different *kind* of thing than exploit/explore — it operates on existing data rather than acquiring new data or value — even though the three-way framing in the Formal Expression treats them as comparable allocation targets. Both readings are valid: the allocation framing is useful for engineering decisions about $\Delta\tau$; the gap-closing framing is useful for understanding *why* deliberation has the structural properties it does.

Diagnosis — a structural-detection mode, related but not identical to the three. The strategy-dynamics no-go (9.2 §”Diagnostic CIY”) identifies a further activity, *diagnose*: deliberately taking non-short-circuit actions (the SA3 ε -exploration excursions) to generate the joint-sibling outcomes that on-policy execution censors, in order to test the model’s *causal-structure* assumptions — detecting a latent common cause the on-policy residual is structurally blind to. Diagnosis sits *across* the partition above rather than neatly inside it: its *mechanism* is external action, like explore, but its *target* is the model’s structural assumptions rather than its parameter values — it earns structure-bits, not the environment-bits of ordinary exploration nor the inference-bits of deliberation. That is why 9.2 frames it as a third axis on the explore/exploit tradeoff while this segment frames the allocation as three-way: the two framings are compatible once *diagnose* is read as a targeted, structurally-motivated mode of exploration (external, but aimed at the censored joint outcomes) rather than a fourth peer category. Its value is governed by the diagnostic-CIY conditions there, and is highest exactly when a latent-common-cause hypothesis is live.

Deliberation’s comparative advantage is greatest when: - Internal simulation is cheaper than external probing (bits per unit cost, not bits per timestep) - The action space is too large for systematic exploration (planning/search) - Actions are irreversible and error costs are high (deliberation as risk management) - The agent has cross-domain knowledge exploitable by synthesis - The model supports counterfactual reasoning (Level 3 access)

Connection to 9.9. Deliberation duration required to revise Σ_t grows with strategy complexity. The description length $DL(\Sigma_t)$ from 9.9 provides a lower bound on the deliberation time needed for meaningful revision.

Connection to 9.8. Strategic tempo $\mathcal{T}_\Sigma$ is the rate of useful strategy revision from *external* evidence. Deliberation provides an *internal* channel for strategy revision that supplements $\mathcal{T}_\Sigma$.

Domain instantiations:

Table 10.1

<i>Domain</i>	<i>Exploit</i>	<i>Explore</i>	<i>Deliberate</i>
Military (Boyd)	Execute the mission	Reconnaissance, probing attacks	Staff planning, war-gaming
RL agent	Greedy action	ε -exploration, UCB	MCTS planning, model-based rollouts
Software developer	Write code along current plan	Try unfamiliar approach, spike	Architecture review, read docs
Organization	Execute strategy	A/B test, pilot program	Strategic planning offsite
AI coding agent	Execute planned edit	Read unfamiliar code, run tests	Plan approach, analyze requirements

Working Notes.

- **Migration note (2026-05-09 GUC rename):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. Removed at candidate stage per FORMAT.md Gate 4.
- **Open: conditions for deliberation dominance.** The simulation showed deliberation rarely dominates in bandit settings (no strategy structure, small action space, reversible actions). The open question is: what formal conditions make deliberation strictly dominate external exploration? Likely candidates: large action spaces requiring combinatorial search, irreversible actions requiring risk assessment, cross-domain knowledge available for synthesis, and high model fidelity enabling accurate counterfactual reasoning. The bandit simulation was unfavorable to deliberation by design (no structure to exploit internally); a planning-heavy domain (chess, logistics, architecture design) would likely show the opposite.
- **Open: the additive decomposition.** Under what conditions is the additive separation of epistemic and strategic benefit a good approximation? The interaction term (ΔV_Σ depends on ΔM_t) may be quantitatively significant when deliberation produces a model insight that transforms the strategy evaluation. Formalizing this requires a coupled model of epistemic and strategic improvement.
- **The ΔV_Σ approximation misses two channels of deliberation value.** The strategic-deliberation ceiling $\Delta V_\Sigma \approx \delta_{\text{regret}} \cdot \Pr[\text{revision succeeds}]$ captures only the *strategy-revision* channel — deliberation that finds a better Σ_t within the current objective O_t . Two other channels of value are not in the approximation: (a) the *objective-revision* channel, where deliberation reveals that O_t should change (step 5 of the orient cascade); the value is then $V_{O'}(M_t, \pi') - V_O(M_t, \pi)$ where O' is the revised objective, a quantity with no necessary relationship to δ_{regret} (which measures regret *within* the current objective); (b) the *uncertainty-reduction* channel, where deliberation confirms that the current strategy is good and shifts the agent from cautious mixed-mode to confident exploitation; the value of *certainty about your strategy* is a behavioral effect not captured by δ_{regret} . The approximation is best read as a *strategy-revision ceiling* rather than a full deliberation-value ceiling; the other two channels operate on different quantities and should be tracked separately if they matter for the use case.
- **Landing context.** The adversarial analysis behind the Epistemic Status downgrade (formulation-choice + linearization + discussion-grade tags rather than “derived” headlines) landed in the 2026-05-12 (late) Group-I surgical-promotion sweep; see CHANGELOG 2026-05-13. Its four attacks (two-stage decomposition not forced; additive form unjustified; ΔV_Σ approximation inadequate; dominance regimes trivially correct) are absorbed into the Epistemic Status block, the §Discussion “Computational-extraction-gap framing” sub-section, and the missing-channels Working Note above. Originating spike is absorbed archaeology, not a live reference.

- **Reproducibility:** the simulation-check outcomes stated in the Epistemic Status block were produced by the drifting-multi-armed-bandit driver `spikes/sim-three-way-tradeoff.py` (five configurations). The body states the outcomes self-contained; this pointer is reproducibility metadata, to be released as a citable supplement at publication.
- **Open: the unified vs two-stage question.** Simulation suggests the unified approach may be strictly better. If so, the segment should present the unified formulation as primary and the two-stage decomposition as a computational simplification.
- **Relationship to working memory.** Deliberation requires maintaining internal state. For LLM agents, this manifests as context-window competition: tokens spent “thinking” are tokens unavailable for representing the problem state. This architectural constraint on deliberation is real but domain-specific.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 3 dirs carry a dedicated reflection (526815, 773921, 829314) plus 451729 covers it inside a Section-II-close batch (01-batch-13). Most other contributing dirs explicitly skipped the §II remainder (this is the final §II segment). Attribution inferred from voice where not explicit, uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The deliberation stopping rule in plain language: “stop thinking when the marginal value of your thoughts drops below the rate at which the world is changing” (Claude, AUDIT-WORKING-773921) — i.e. “you must stop thinking and start acting the exact moment your internal ‘aha!’ rate drops below the world’s drift rate” (Gemini, AUDIT-WORKING-829314). A Feynman-criterion-grade gloss of the first-order condition.
- The three activities as one budget, three extraction targets: **“Exploitation:** burn tempo to extract value from reality. **Exploration:** burn tempo to extract data from reality. **Deliberation:** burn tempo to extract latent data from your own internal model” (Gemini, AUDIT-WORKING-829314). A compact triad worth keeping near the Brief.
- “Deliberation as internal exploration in model-space bounded by the computational extraction gap” — the one-line characterization two substrates flagged as the segment’s best contribution (Claude, AUDIT-WORKING-773921; Codex/Claude, AUDIT-WORKING-526815).

2. Candidate Discussion.

- **Analysis paralysis as the formal pathology of crossing the deliberation threshold** (*strongest framing here*). “An engineer spends 3 weeks designing the perfect microservices architecture (Deliberating). But during those 3 weeks, the product requirements changed ($\rho_{\text{delib}} \cdot \Delta\tau$). The resulting architecture is beautiful but useless. The engineer mathematically violated the deliberation threshold. They should have stopped thinking on day 2 and built a prototype to gather external causal information (CIY)” (Gemini, AUDIT-WORKING-829314). A vivid worked illustration of the FOC’s failure mode the segment could carry directly.
- **Why agents (and minds) must “sleep” / “think.”** “If your model M_t is highly complex (a deep neural network or a human neocortex), you physically cannot extract all the useful inferences from it instantaneously. You possess latent knowledge that you haven’t connected yet. Deliberation is the process of running internal queries (simulations, counterfactuals) against your own model to surface that latent knowledge and compile it into a better strategy Σ_t ” (Gemini, AUDIT-WORKING-829314). A candidate Discussion gloss on the computational-extraction-gap framing already in the body. (*Early-conflation texture: the “must sleep” reach is analogy, not derived.*)
- **The cascade as the control-flow that navigates the three-way allocation.** The two segments compose: `#der-orient-cascade` gives the forced ordering; this segment gives the resource allocation across the steps of that ordering. “The Orient Cascade provides the formal algorithmic control flow that navigates the 3-way resource allocation problem defined here” (Gemini, AUDIT-WORKING-773921). A candidate framing-level connector between the two §II-closing segments.

3. Follow-up items.

- **A strategy-structured simulation environment to actually show deliberation’s value.** The Epistemic Status honestly reports the bandit oracle “almost never chose deliberation” because the bandit lacks strategy structure. Multiple substrates flagged the need for “a simulation environment with a deep strategy DAG (like a maze or a coding task) to empirically prove deliberation’s value” (Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-451729 batch-13 — the bandit is unfavorable by design; a planning-heavy domain would likely show the opposite, already partly noted in the existing “conditions for deliberation dominance” Working Note). A candidate follow-up spike, complementing the existing spikes/sim-three-way-tradeoff.py.
- **Promote the “deliberation as internal exploration” reframe out of Discussion.** Two substrates independently judged that the segment’s best insight is buried: “the ‘deliberation as internal exploration’ reframing is the most important contribution and should be in the Formal Expression or Epistemic Status, not buried in Discussion” (Claude, AUDIT-WORKING-451729 batch-13; Gemini, AUDIT-WORKING-829314 — “shouldn’t be buried under citations”). A structural-placement note for the eventual promotion pass.

4. Readers often ask / wonder.

- **The Active Inference comparison reads as defensive bloat to a fresh reader.** A fresh reader experienced the EFE / Active-Inference comparison paragraph as “a massive, defensive comparison” that “severely damages the readability of the core theory” and “buries” the brilliant core insight under citations; the suggested remedy was to move the AI comparison to an appendix and visually highlight the domain-instantiations table instead (Gemini, AUDIT-WORKING-829314). Preserved as a reader-experience signal about placement/proportion (not a correctness finding — the comparison content itself checked out cleanly for other substrates, e.g. Gemini AUDIT-WORKING-773921 called the KL-direction-from-internal-regret handling “masterful”).
- **When does extra inference-time compute actually help?** Readers reach for the practical corollary: giving a model more “thinking time” yields value only if (1) the model possesses latent knowledge relevant to the problem (high M_t capacity) and (2) the problem is relatively stationary (low ρ_{delib}); in high- ρ environments “inference compute is wasted; you must buy physical tempo instead” (Gemini, AUDIT-WORKING-829314). A candidate readers-often-ask answer with direct contemporary resonance (inference-time scaling).

5. Candidate figures.

- **Three channels from one finite cycle budget + the marginal-benefit stopping rule.** A figure drawing exploit / explore / deliberate as three channels drawing on the *same* finite cycle budget, with the deliberation stopping rule shown as a marginal-benefit comparison — highlighting that deliberation’s benefit is *internal and model-bounded* while exploit/explore both spend *external action opportunities* (Codex/Claude, AUDIT-WORKING-526815).
- **Highlight the domain-instantiations table.** Two substrates called the Military / RL / Software / Organization / AI-coding-agent instantiation table the segment’s strongest pedagogy and recommended it be visually foregrounded rather than left as a trailing table (Gemini, AUDIT-WORKING-829314; Gemini, AUDIT-WORKING-773921 — “phenomenal”).

Belongs elsewhere.

- **LLM inference-time scaling (e.g. o1-style “thinking time”)** ($\rightarrow$ 03-llm-core/ *deliberation budgeting*). The deliberation-threshold math gives a direct account of when test-time compute pays off vs. is wasted (the high- ρ “buy physical tempo instead” conclusion above); the logogenic-substrate chapter is the natural home for the LLM-specific instantiation (Gemini, AUDIT-WORKING-829314).
- **A single framework unifying RL (exploit/explore) with classical planning (deliberation)** ($\rightarrow$ *framing-level / positioning*). “It provides a single mathematical framework that unifies Reinforcement Learning (Exploit/Explore) with Classical Planning (Deliberation)” (Gemini, AUDIT-WORKING-773921). A positioning claim for README / Part-II framing prose, not this segment’s body.

Off-ramp (NOT gold) — routed for adjudication. Certified-track (structure), not pedagogical gold. Recorded so they are not lost; they need strengthen-first / consolidated-queue routing.

- **The first-order condition appears to omit a term.** The objective is $\Delta\eta^*(\Delta\tau) \cdot \|\delta_{\text{post}}\| + \Delta V_{\Sigma}(\Delta\tau) - \rho_{\text{delib}}\Delta\tau$, so its $\Delta\tau$ -derivative carries $\Delta\eta^* \cdot \frac{d\|\delta_{\text{post}}\|}{d\Delta\tau}$ *unless* $\|\delta_{\text{post}}\|$ is held fixed by definition. The stated FOC drops this term; the segment should state which quantities vary with deliberation time and which are fixed baselines (F85 candidate, Codex/Claude AUDIT-WORKING-526815). This touches the segment's one genuinely formal contribution.
 - **The control-regret ceiling should also caveat policy-class expansion.** The body caveats that the δ_{regret} ceiling applies only to the strategy-revision channel and names the objective-revision and uncertainty-reduction escapes; it should *also* name that deliberation which expands Π , changes representation, discovers a new action abstraction, or escalates the continuation convention can move the ceiling (F86 candidate, Codex/Claude AUDIT-WORKING-526815). A scope completion of the ceiling claim.
 - **Symbol overload on λ .** “As $\lambda \rightarrow 0$ ” in the boundary conditions is ambiguous — λ is used for exploration pricing here and for forgetting in nearby strategy-dynamics segments; the intended quantity should be named explicitly (F87 soft candidate, Codex/Claude AUDIT-WORKING-526815).
-

10.3 Discussion: Additional Implications & Discussion

The chapter closes Part II by tying together what the cascade does, what forces it to take the shape it does, and what the cascade looks like at two structural extremes — when the agent is *too confident* in a drifting world (where the cascade has a Lyapunov-forced exploration drive its information-value cousins cannot supply) and when the agent is *coupled-architecture* by construction (where the cascade cannot be produced in cascade order by the model itself and must be recovered at the loop level). The chapter is small in segment count but its results connect Part II to Part III via the directed-separation architectural classification, to 03-11m-core/ via the Class-3-Coupled scaffolding requirement, and back to Part I Ch.4 via the bandwidth floor that deliberation does not escape.

The Orient Cascade

Figure 5: The orient cascade: a five-step resolution order forced by information dependency, not design. The 2x2 diagnostic at step 3 routes the agent to revise the strategy, to escalate before revising the objective, or to terminate at success or capacity limit; a revised model re-enters at step 1.

The cascade is forced by information dependency, not designed.

#der-orient-cascade carries the chapter's central architectural move: the Orient phase of OODA expands into a multi-step cascade — reduce $\delta_{\text{epistemic}} \rightarrow$ assess attainability $\rightarrow$ evaluate strategy $\rightarrow$ (if needed) revise objective — whose *ordering is not a design choice but a consequence of which quantities require which others*. Each step's input depends on the prior step's output. M_t enters every subsequent formula, so it must be updated first; attainability A_O is computed against M_t , so it precedes strategy evaluation; strategy revision needs A_O to know whether the problem is the strategy or the goal; objective revision is last because it requires both the model and the strategy assessment to know that no policy in Π can deliver the objective. The cascade is *derived* from information dependency, not engineered — and that is the framework's load-bearing position against alternative cascade orderings (objective-first, strategy-first, or all-at-once) that have appeared in adjacent literatures.

The downstream consequence is that Part II's diagnostic core — the satisfaction-gap and control-regret split from Ch.3 — has its corrective machinery here. The 2x2 cell map routes to four different revision targets via the cascade: M_t first under epistemic mismatch; Σ_t under positive control regret; Π expansion under control regret persisting after strategy revision; and O_t only when satisfaction gap persists after all earlier revisions. Objective revision is the *last resort*, not the first response to unmet goals. This is the chapter's implications-side payoff: the diagnostic from Ch.3 is what tells the agent *what* to revise; the cascade from this chapter is what tells the agent *in what order*; and the orient cascade's forced ordering is what makes the diagnostic actionable rather than merely informative. Part II would have been a collection of diagnostics without revision machinery without it.

The cascade also depends on the directed-separation scope condition from `#der-directed-separation` (Part II Ch.1) for the *sequential resolution* to be meaningful. For any **causally-disciplined** agent — one running at $\kappa_{\text{processing}} = 0$, whether by construction (Class 1) or in effect (an idealized Class 2 at $\kappa = 0$) — the cascade runs sequentially because the belief-update has no causal dependence on G_t , so the resolution order is a sequential one rather than a simultaneous fixed-point; this consumes only the zero, not the architecture-inspection certificate. As $\kappa_{\text{processing}}$ leaves zero the resolution acquires a coupled component, and in a Class 3 (Coupled) architecture the cascade lives in one merged computation and the resolution order cannot be produced by the model itself. The framework’s prescription for Class 3 — that scaffolded loops around coupled components recover the cascade ordering at the wrapper level — depends on this chapter’s derivation: what scaffolding *is* structurally doing is reproducing the orient cascade externally when the component cannot reproduce it internally. The implication is concrete and significant for practitioners: agentic systems (loops around LLMs) are not engineering convenience; they are the structural mechanism by which Part II’s persistence guarantees become available to Class 3 (Coupled) substrates.

Exploration at two ends of the uncertainty spectrum.

The chapter’s appendix-side derivations carry one of AAT’s load-bearing methodological positions: exploration is forced by Lyapunov persistence collapse, not by epistemic value-of-information. `#deriv-causal-ib-exploration`’s Findings cover this in full — the maximum tolerable observation-noise expectation $U_o^{\max} = U_M(Rc_{\min}/\rho^{\text{eff}} - 1)$ scales with U_M , so as the agent becomes confident ($U_M \rightarrow 0$), the tolerable noise tightens, and the agent is forced to actively seek pristine, low-noise observations to penetrate its own stubbornness. The framework therefore carries *two parallel exploration drives at opposite ends of the uncertainty spectrum*: the standard epistemic drive $\lambda_{\text{info}} \propto U_M$ (explore when uncertain — dominant when U_M is high) and a Lyapunov-survival drive $\lambda_{\text{surv}} \propto 1/U_M$ (explore when confident in a drifting world, because the agent’s own update gain has dropped below the rate at which reality is shifting — dominant when U_M is low). The implications-side payoff that the segment’s Findings flags but is worth repeating is that this *sidesteps active-inference’s dark-room objection at structural rather than parametric level*: an EFE agent with strong priors can stop exploring, an AAT agent in a drifting world physically cannot, because exploration is forced by the same Lyapunov machinery that grounds the rest of Part II.

`#deriv-causal-ib-lmi` carries the matrix-form sharpening. The scalar form of the survival imperative admits a “blank wall” attack — an action that selects a low-noise channel orthogonal to the drift direction satisfies the scalar constraint while the agent’s mismatch in the drifting subspace grows unbounded. The LMI lift to a Linear Matrix Inequality on the Fisher Information Matrix, with a positive-semidefinite matrix Lagrange multiplier $\Lambda \geq 0$ as directional shadow price, resolves the attack by complementary slackness on direction — the exploration bonus for blank-wall actions is mathematically zeroed. The result also makes precise that the Fisher Information Matrix is doing *three structurally distinct* loads in the framework: credit assignment via `#deriv-fisher-whitened-update-rule`, coordinate-forcing via `#disc-additive-coordinate-forcing`’s fourth instance, and now survival via the LMI here. The same geometric object recurs because the framework’s coordinates are forced rather than chosen; the LMI form is the first explicit cross-instance composition where two of those loads — coordinate-forcing and survival — interact within the same machinery.

The composition with Part I Ch.4’s persistence-information-rate floor is worth surfacing. The persistence-bandwidth-floor $C \geq \mathcal{T}/2$ is what a confident agent in a drifting world is structurally required to *meet*; the survival-imperative LMI is what tells the agent *in what directions* to spend the bandwidth. Without the LMI, the bandwidth could in principle be supplied in irrelevant directions; with the LMI, complementary slackness routes the bandwidth toward the drifting modes. The two results compose into a directional version of Part I Ch.4’s central inequality: *bandwidth-per-direction is the binding constraint*, and the LMI is what makes the directionality structurally enforceable rather than implicit.

Coupled architecture, the bias bound, and the scaffolding requirement.

The chapter is also where the framework’s treatment of Class 3 (Coupled) agents lands its most consequential structural commitment. #der-directed-separation’s Findings section covers the architectural classification in full — Class 1 (Separated), Class 2 (Partial), Class 3 (Coupled) — with the explicit Class 3 scope exit that hands the agents off to 03-llm-core/ rather than treating directed separation as an unenforced approximation. #deriv-observation-ambiguity-bias-bound’s Findings cover the universal constant under the (PI) parameterization-invariance axiom: Track 1 (transport inequality, linear in I) gives $C_{W_2}^2 = 2L_{\text{post}}^2 / \rho_{\text{LSI}}$ under log-Sobolev + Lipschitz-posterior; Track 2 (Fisher-Rao, $\sqrt{I}$ scaling) gives universal dimension-free $C_{FR} = \sqrt{2}$ under (PI)+Čencov + small-information regime. The no-go counterexample (heteroscedastic-Gaussian, demonstrating that no universal C exists under Euclidean-parameter norm) is what forces (PI) from convergent representational choice to load-bearing for theorem-level status — adding the fourth instance to #disc-additive-coordinate-forcing’s catalog of forced coordinates (the (PI)+Čencov downstream-theorem cluster). It is *not* a fourth identifiability-floor instance, however — its external theorem (Čencov 1982) *forces* the escape’s uniqueness rather than *forbidding* the inferential task, and the single forced escape (adopt (PI)) is logically incompatible with the ≥ 2 -distinct-escapes structure that defines a floor; the genuine fourth #disc-identifiability-floor instance is #der-architecture-noidentifiability (architecture-noidentifiability from on-policy summary data, dual-anchored on Kalman-Ho 1966 / CHT-at-agent-as-SCM, integrated 2026-05-21).

What the implications segment can develop beyond the source-segment Findings is the *coupled-diagnostic framework* that the bias bound enables, and which does not currently have its own segment home. For Class 2 (Partial) and Class 3 (Coupled) agents — LLMs, transformer-based agents with attention processing goals and observations together — the orient cascade’s information-dependency-forced ordering cannot be produced in cascade order by the model itself; the cascade lives in one merged computation. But the Part II diagnostic quantities ($\delta_{\text{sat}}, \delta_{\text{regret}}$) remain *defined* on post-update state, and the Lipschitz bound $|\delta_{\text{sat}}^{(\text{coupled})} - \delta_{\text{sat}}^{(\text{clean})}| \leq L_A \cdot \|\Delta M_{\text{bias}}\|$ shows the diagnostic error is bounded by the bias bound, which is itself bounded by $\kappa \cdot \mathcal{A}$ (coupling $\times$ ambiguity). The structural conclusion is the load-bearing implication: **agentic systems — scaffolded loops around coupled components — are not just engineering convenience but a structural requirement to recover Part II’s persistence guarantees for Class 3 (Coupled) substrates.** The cascade ordering happens at the loop level when the model cannot produce it; the scaffolding is doing real structural work rather than aesthetic work. For a production LLM-agent practitioner running structured-reasoning templates, multi-step prompts, external monitors, or retrieval-augmented calls, the framework’s claim is that what is being built is *necessary* (not contingent) for AAT-grade behavior in a Class 2 / Class 3 substrate. The cross-domain transfer to human bicameral / dual-process models (Kahneman 2011) and to organizations where executive scaffolding recovers cascade ordering across coupled individuals follows the same structural mechanism.

The engineering anchor worth carrying is the $\kappa \cdot \mathcal{A}$ decomposition. The architectural coupling κ is *fixed* for a Class 3 substrate (you cannot un-couple an LLM); the ambiguity $\mathcal{A}$ is *variable* (you can engineer the prompt and environment). Prompt engineering, in the framework’s vocabulary, is literally $\mathcal{A}$ -reduction — and the bias bound says reducing $\mathcal{A}$ tightens the bound proportionally, with the constant C now bounded by Track 1 or Track 2. The framework predicts (and the empirical pattern supports) that LLMs excel at low- $\mathcal{A}$ tasks (coding, structured reasoning, well-defined transformations) and struggle with high- $\mathcal{A}$ tasks (open interpretation, ambiguous goals, contested values). The framework’s prescription is concrete: where κ is structurally large, design $\mathcal{A}$ structurally small.

Deliberation is internal exploration that does not relax the bandwidth floor.

#disc-exploit-explore-deliberate extends the standard exploit / explore tradeoff into a three-way framing by surfacing deliberation as *internal exploration in model space rather than environment space*. The implications-side payoff is structural: deliberation is Pearl-*do* on a simulated trajectory rather than on the agent’s singular causal trajectory, and the chapter is where this characterization first becomes formally well-posed — Part II Ch.2’s loop-Level-2 result is what makes the deliberation-as-internal-exploration framing distinct from “the agent thinks more” rather than a verbal re-framing.

The composition with Part I Ch.4's bandwidth floor is the finding that has no other natural home: *deliberation does not relax the persistence-information-rate floor; it only changes channel allocation*. The agent that deliberates is internally rerouting its information-processing budget from environmental observation channels to internal-simulation channels, but the total Shannon information rate required to maintain bounded mismatch ($\dot{R} \geq n\alpha/2$ nats/time per dimension) is unchanged. An agent that deliberates indefinitely is *not* exempt from receiving observations at the floor rate — environmental drift continues during deliberation, and the post-deliberation mismatch grows at rate $\rho_{\text{delib}} \cdot \Delta\tau$ per #der-deliberation-cost's drift term. The extended deliberation threshold from #disc-exploit-explore-deliberate formalizes this: the agent should deliberate until the marginal benefit (epistemic gain + strategic gain) equals the marginal drift cost. The framework's posture is that deliberation is *temporary reallocation*, not substitute for external bandwidth — and the cross-domain transfer follows naturally to chess engines (search depth and observation freshness must both be funded), military command (war-gaming and reconnaissance must both be funded), and science (theory-building and experiment-running must both be funded).

The connection to Part II Ch.4's strategy-complexity-cost (9.9) is also worth surfacing here. Part of the cost of deliberation is the cognitive cost of holding Σ_t in the agent's representational capacity while operating on it. For an LLM agent, this means fitting the strategy in the context window — and the framework's claim is that this is the same constraint that bounds online operation, not a separate deliberation-mode constraint. Deliberation buys epistemic and strategic improvement at the cost of cycle budget *and* representational capacity simultaneously; both are bandwidth-flavored constraints, and the persistence-bandwidth-floor framework subsumes them. This is one of the chapter's quieter findings — the framework's bandwidth vocabulary unifies environmental-observation bandwidth, strategy-representation capacity, and deliberation budget under a single Shannon-rate floor.

What Part II closes on, and the bridge into Part III.

The chapter is the structural close of Part II, and what Part II has delivered as a whole is now worth naming. The diagnostic core (satisfaction-gap and control-regret split, convention-indexed by the C1/C2/C3 hierarchy) gives the framework two orthogonal signals that distinguish “the world doesn't permit it” from “you're not doing it well enough.” The strategy-DAG commitment with Markov factorization under causal sufficiency gives the formal representation the diagnostic operates on. The Pearl-Level-2 access from the loop, combined with the Correlation Hierarchy's scope statement and the chapter's directed-separation architectural classification, gives the agent the data substrate and the architectural class it sits in. The bias bound for Class 3 (Coupled) agents, with its conditional-theorem constant under named sub-scopes, gives the framework's quantitative reach into LLM-class substrates without overclaim. The orient cascade gives the corrective machinery; the survival-imperative drive gives the structural exploration mandate; the coupled-diagnostic framework gives the scaffolding-as-structural-requirement claim.

The result of all this is what #result-section-ii-survival formalizes: Part II's definitional and structural architecture transfers exactly to fully-coupled (Class 3) agents in 16 of 24 cases, with the remaining results either approximating with bounded error (5/24) or naming the precise modification required (2/24 plus 1 boundary-defining failure). The bias-bound theorem under named sub-scopes is what lifts the approximate-survival category from heuristic to conditional theorem. Part II's reach is wider than the most-restrictive scope condition suggests; this chapter is where the chapter-end can name that reach without overclaiming.

The bridge to Part III is direct. The directed-separation classification opens to *axis-decomposed composite-level class inheritance* (per the table in #der-directed-separation §“Composite-level class inheritance”): composite architectural class lifts through routing structure plus substrate sharing, *not* through goal alignment per se. Goal alignment vs strategic interaction operates on the parallel-but-independent *dynamic-regime* axis (#disc-dynamic-regime-axis), where strategic composition transitions composites from R0 contraction-regime to R1 equilibrium-regime or R2 cyclic-distributional-regime without architectural-class change (under goal-blind routing). The third instance of the identifiability-floor pattern (Instance 3, broadened 2026-05-21 to the coupling-topology bit) lives in Part III: composite contraction *and regime* certification from component-marginal data is structurally impossible (Liberzon 2003 common-Lyapunov-nonexistence;

cf. `#deriv-regime-marginal-indistinguishability` for the broader regime-axis witness), with five structural escapes including observer-on-sub-agent interventional access (Mode 2 of the loop-Level-2 pattern from Ch.2) and the new passive escape (e) of composite-level convergence-rate-class observation. Part III is where AAT's machinery operates at the composite scope, with the chapter-end here as the last single-agent prerequisite to land.

What this chapter closes on, then, is the structural completion of Part II: the cascade that makes the diagnostics actionable, the dual-drive exploration that prevents dark-room collapse, the bias bound that quantifies Class 3 (Coupled) reach with conditional-theorem precision, the scaffolding requirement that makes agentic systems structurally non-optional rather than aesthetic, and the deliberation framing that grounds the three-way resource allocation in the same Shannon-rate floor as everything else. Part III's machinery operates on what Part II built; the implications work here is the last single-agent-scope synthesis before the composite chapters take over.

Working Notes.

- **Causal-discipline re-scope (2026-05-31).** The sequential-resolution clause was re-scoped from “Class 1 (Separated)” to *causally-disciplined* (the $\kappa_{\text{processing}} = 0$ object of `#der-directed-separation`): the cascade runs sequentially rather than as a simultaneous fixed-point because f_M has no G_t -dependence — that consumes only the zero, held equally by Class 1 by construction and an idealized Class 2 in effect, not the architecture certificate. Left untouched: the Class-3 scaffolding clause (cascade recovered at the loop level — correct and class-specific), and the cascade *ordering*-exactness in `#der-orient-cascade`, which is forced by information dependency and is not κ -scoped at all (no class label appears on it, correctly — so `#der-orient-cascade` needed no edit). The $\varepsilon(\kappa)$ for the sequential resolution is *inherited, not new*: off $\kappa = 0$ the cascade's step-1 output M_{t+} is displaced by the $\Delta M_{\text{bias}} \leq C\kappa I$ bound of `#deriv-observation-ambiguity-bias-bound`, and every downstream step reads that displaced M_t ; the resolution becomes one iteration of a coupled fixed-point whose residual is governed by that same bound. A dedicated propagated-residual bound (how the per-step bias compounds across the five-step cascade) is an open strengthening, not attempted here.
- This segment is a chapter-end discussion grouping findings from `#der-orient-cascade`, `#disc-exploit-explore-deliberate`, `#der-directed-separation` (the cascade depends on it for the sequential-resolution scope), `#deriv-observation-ambiguity-bias-bound` (Appendix A, the bias-bound constant), `#deriv-causal-ib-exploration` and `#deriv-causal-ib-lmi` (Appendix A, the survival-imperative drive and its matrix lift), and `#der-deliberation-cost` (Part I Ch.4, the deliberation threshold this chapter extends). The closing-Part-II reading in §5 leans on `#result-section-ii-survival` which is the formal classification of which Part II results transfer to Class 3 (Coupled) agents at exact / approximate / modified status.
- **Cross-reference vs canonical-home policy.** Four source segments in this chapter's scope carry well-written `## Findings` sections — `#der-directed-separation` (architectural classification), `#deriv-observation-ambiguity-bias-bound` (universal constant under (PI)), `#deriv-causal-ib-exploration` (survival-imperative drive), and `#deriv-causal-ib-lmi` (matrix-form lift). All four are cross-referenced rather than restated. The findings whose canonical home is this implications segment are: `#20` (Orient Cascade as derived from information dependency), `#13` (Coupled Diagnostic Framework — scaffolded loops recover the cascade for Class 3 substrates; no segment currently carries this finding directly), and `#35` (Internal Deliberation Pays Bandwidth Floor — compositional finding with no segment home).
- **#13 (Coupled Diagnostic Framework) — segment exists in 03-llm-core/.** Corrected from earlier draft: `#result-coupled-diagnostic-framework` exists as a segment in `03-llm-core/src/` (where the Class 3 (Coupled) treatment lives), not in `01-aat-core/`. The segment does not currently carry a `## Findings` section, so the implications-side surfacing here covers what AAT Ch.5 unlocks (cascade recovery via scaffolding at the loop level, bias bound via $\kappa \times \mathcal{A}$); the Logogenic chapter-end implications carry the finding from the logogenic-substrate-specific side. A future cycle may add a `## Findings` section to the existing segment in `03-llm-core/`; until then, the chapter-end implications carry the catalog-grade content.
- **Connection to NeurIPS submissions.** The bias-bound result is NeurIPS Paper 3 (`~/src/neurips/03-llm-hallucinate-bound/`) in formal theorem form; the (PI) axiom from `#scope-agent-identity` is load-bearing for the universal-constant route under the no-go in §4 of Paper 3. The cascade-recovery-via-scaffolding argument is a structural claim AAT has been carrying since the Part II reorganization; whether it lifts to theorem grade in any current submission is not flagged. The survival-imperative drive composed with the LMI matrix lift is the formal apparatus behind NeurIPS Paper 1 (“Tragedy of the Confident Agent”, `~/src/neurips/01-tragedy-confident-agent/`).

- **Identifiability-floor pattern coverage update.** With this chapter's content three formal instances are in view: Instance 1 (on-policy L0-insufficiency, Part II Ch.4), Instance 2 (L1' mixture under unobservable common cause, Part II Ch.3), and Instance 4 (architecture-noidentifiability from on-policy summary data, this chapter / Appendix A — #der-architecture-noidentifiability's Kalman-Ho similarity-orbit no-go, dual-anchored with CHT-at-agent-as-SCM). Instance 3 (composite contraction certification from component-marginals via Liberzon common-Lyapunov-nonexistence) lives in Part III. The heteroscedastic-Gaussian no-go in #deriv-observation-ambiguity-bias-bound §4 is *not* a floor instance — it is correctly classified as a downstream theorem of #disc-additive-coordinate-forcing's (PI) commitment (single forced escape via Čencov-uniqueness, logically incompatible with the ≥ 2 -distinct-escapes structure required of a floor). Instance 5 (Mehra non-identifiability in adaptive Kalman) remains candidate; the chapter-end pattern coverage is now five-sixths complete on the planned AAT chapter-end work; the Instance 3 surfacing in Part III Ch.5 completes it.

Incidental audit gold (lift 2026-05-31). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** 2 dirs carry a dedicated reflection (526815, 773921). Most other contributing dirs stopped before this Part-II-closing chapter-end segment. Attribution inferred from voice where not explicit, uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- “You cannot ‘think’ your way out of needing sensory bandwidth” — a one-line gloss of the chapter's deliberation-does-not-relax-the-floor result ($\dot{R} \geq n\alpha/2$ holds while the agent deliberates because the environment keeps drifting) (Gemini, AUDIT-WORKING-773921). Compact, vivid, Feynman-criterion-grade.
- “Prompt Engineering is literally Ambiguity Reduction ($\mathcal{A}$ -reduction)” — the $\kappa \cdot \mathcal{A}$ decomposition stated as a practitioner takeaway: κ (architectural coupling) is fixed for a Class-3 substrate, $\mathcal{A}$ (ambiguity) is the engineerable lever (Gemini, AUDIT-WORKING-773921). Already in the body; flagged as the line worth foregrounding.
- Scaffolding “is not a ‘prompt engineering hack’; it is the structural mechanism required to force a Class 3 agent to execute the Orient Cascade sequentially, thereby recovering the Lyapunov persistence guarantees of Part I” (Gemini, AUDIT-WORKING-773921). A candidate Brief framing of the chapter's load-bearing scaffolding claim.

2. Candidate Discussion.

- **Agentic workflows are mathematically superior to raw calls — and why.** Two substrates converged on the chapter's payoff as the strongest engineering takeaway of Part II: scaffolded loops (ReAct loops, external memory, monitor agents, retrieval) are *structurally necessary*, not convenient, because a Class-3 substrate cannot run the cascade in cascade-order internally (beliefs and goals are mixed in one merged computation), so the ordering must be recovered at the loop level (Gemini, AUDIT-WORKING-773921; the bounded form is sharpened by Codex/Claude, AUDIT-WORKING-526815 — see off-ramp). A candidate Discussion sharpening that names *why* the loop recovers what the component cannot.

3. Follow-up items.

- None surfaced beyond the certified-track scope concerns (see off-ramp). The chapter-end's own Working Notes already track the #13 (Coupled Diagnostic Framework) canonical-home question and the #result-section-ii-survival dependency.

4. Readers often ask / wonder.

- **Does the chapter's summary voice outrun its proofhomes?** Fresh readers experienced several proof-bearing claims (survival-imperative exploration, the causal-IB LMI structure, the bias-bound constants, the Section-II survival counts, the scaffolding requirement) as *presented as settled by the chapter* when the proof credit lives in deferred appendix/source homes (Codex/Claude, AUDIT-WORKING-526815). This is an audit-experience signal about a chapter-end implications segment: the cross-reference-vs-restate policy (already in this segment's Working Notes) is doing the right thing, but a reader can still read the synthesis voice as proof. A candidate one-line orientation at the chapter open (“results below are surfaced here; their proofs live at the cited homes”) would preempt the stumble.

5. Candidate figures.

- **Three-zone proof-flow diagram.** A chapter map drawn as three zones — *local anchors already established*, *deferred proof homes* (appendix/source segments), and *architectural prescriptions* — routing the strongest claims visibly *through* the deferred homes rather than appearing to originate in the local synthesis (Codex/Claude, AUDIT-WORKING-526815). Directly addresses the “summary voice outruns proof homes” reader stumble above by making the proof-provenance visual.

Belongs elsewhere.

- **Architecture-noidentifiability as a wall for mechanistic interpretability** ($\rightarrow$ #der-architecture-noidentifiability / *Appendix A, and positioning prose*). The Instance-4 floor (Kalman-Ho similarity-orbit non-uniqueness) “formally proves that you cannot reverse-engineer the true causal architecture of a black-box model just by watching its inputs and outputs, because infinite internal similarity transformations yield the exact same behavior — a massive mathematical wall for Mechanistic Interpretability” (Gemini, AUDIT-WORKING-773921). The canonical home is #der-architecture-noidentifiability; the interp-field framing is positioning reach worth carrying there, not here.

Off-ramp (NOT gold) — routed for adjudication. Certified-track (scope/status — the chapter-end synthesis voice vs. proof provenance), not pedagogical gold. Recorded so they are not lost; several overlap with this segment’s existing cross-reference-vs-canonical-home Working Notes and may already be dispositioned — flagged for the consolidated queue to confirm.

- **Proof-credit should stay with declared homes.** impl-orient-cascade is discussion-grade but states survival-imperative exploration, the causal-IB LMI structure, bias-bound constants, the Section-II survival counts, and the scaffolding requirement as if settled by the chapter (F88 candidate, Codex/Claude AUDIT-WORKING-526815).
 - **The scaffolding-necessity claim is too broad if read literally.** The local argument supports a narrower claim: scaffolding is needed to *recover AAT-grade cascade guarantees under coupled representation/attention/memory/action channels*, not an unconditional “scaffolded loops are structurally necessary for Class-3 substrates” (F89 candidate, Codex/Claude AUDIT-WORKING-526815).
 - **“Deliberation is Pearl-do on a simulated trajectory” is too strong.** Pearl’s *do* is an intervention in an SCM; model-internal simulated deliberation is better described as model-internal counterfactual intervention / policy-model simulation (F90 candidate, Codex/Claude AUDIT-WORKING-526815).
 - **The “deliberation leaves total Shannon rate unchanged” claim needs scope.** Internal computation cannot replace external information indefinitely, but better policies, sensing, compression, and model selection *can* change the effective disturbance, allocation, or required rate (F91 candidate, Codex/Claude AUDIT-WORKING-526815).

Part III

Agentic Composites

Chapter 11

Meta-Architecture II: Composition Consistency and the Dynamics-on-Architectural-Class Facet

Part II opened with the certificate spine and its three Part-II-operative facets (M1 boundary / M2 scope-of-existence / M3 forced-identity). Part III opens with two cross-level meta-recognitions that organize the composite-agent material that follows: the composition-consistency commitment (how the framework *applies across levels*) and the fourth certificate-spine facet (how architectural class *changes* under operations). Both are introduced before any Part III content chapter because both are framework-level recognitions — the composite-agent machinery in subsequent chapters is the instantiation, not the source.

Composition consistency — cross-level compatibility as framework commitment (11, methodological commitment). The framework's scope conditions (1.5, 1.6) do not restrict which level of description AAT applies to; the same observable can be analyzed at the individual / team / organizational level, and the theory must not return contradictory answers across those analyses. The commitment has three operational laws (tempo composition, persistence compatibility, mismatch consistency) and a three-layer decomposition (scope selection — 12.2; admissibility — 13.1; transfer — Tier-dependent via AI). Under Tier 1M sub-agents the composite contraction rate admits a closed form; outside Tier 1M the screening test $\tau_{eq} \ll \tau_{ext}$ is heuristic. Cross-level companion to the four certificate-spine facets — the spine names the geometry of a single certificate, composition-consistency names the relationship across certificates at different levels. Sister to 11.1: M4 names how architectural class *changes* under operations; composition-consistency names how the framework *applies across levels* regardless of architectural class.

M4 — Modularity-state dynamics (11.1, dynamics-on-architectural-class facet): modularity is a *contested property* — composite agents do not sit fixed at one architectural class; they move under three structurally-distinct operations. **Truthification** (self-driven, modularity-increasing; restorative valence): the wrapping construction at the component level (13.4, in Ch.2 of this Part) and institutional scaffolding at the composite level (per 11.3 §"Defensive scaffolding"). **Strategic self-coupling** (self-driven, modularity-decreasing; offensive-enabling valence): operation leg 11.2. **Adversarial coupling pressure** (externally-driven, modularity-decreasing; vulnerability-creating valence): operation leg 11.3. Three pairwise dual relationships organize the cluster — truthification $\leftrightarrow$ adversarial-pressure as direct dual (cultivation vs attack); truthification $\leftrightarrow$ strategic-self-coupling as goal-belief-axis dual (both wrapping-construction-style commitments on opposite poles — goal-blind belief-update vs goal-conditioned action-selection); strategic-self-coupling $\leftrightarrow$ adversarial-pressure as same-architecture-shape-opposite-driver. M2's Architecture ladder reads as the phase space across which M4 operations move populations.

The two operation-leg segments. 11.2 develops the self-driven coupling-increasing operation with three structural extensions ((M1) coupling-dependent action space, (M2) strategy-DAG enabling-edge type, (M3) reversibility-cost asymmetry) and a four-mechanism prior-art adoption (Schelling 1960 external commitment devices, Ainslie 1992/2001 intertemporal personal rules, Akerlof-Kranton 2000/2010 identity coupling, Frank 1988 emotional commitment). 11.3 develops the externally-driven coupling-increasing operation — adversaries drive opponent coupling because coupling expands attack surface (identity-binding / affect / sunk-cost mechanisms); diagnostic capture is directional; orient-cascade inversion under pre-loaded O_t ; defensive scaffolding as composite-agent restoration. The two operation legs are opposite-valence operations on the same architectural-class state $\kappa_{\text{processing}}$ per 6.3.

This is a *meta-recognition* about how AAT applies, not a fact about how any individual agent works: AAT's predictions must be compatible across levels of description. If a system S and any decomposition $\{S_1, \dots, S_n\}$ both satisfy the scope condition, the theory's claims at the S -level cannot contradict its claims at the $\{S_i\}$ -level. The scope condition does not restrict which level the theory applies to, so the theory itself must be level-invariant — otherwise the same observable could receive contradictory answers depending on where the analyst draws the modeling boundary. The commitment is methodological at the meta-requirement layer (a framework choice about applicability, not a physical fact about agents); its operational consequences are tiered.

This commitment is the cross-level companion to the four certificate-spine facets (5). Where the spine's facets describe the geometry of a *single* equilibrium-stability certificate (interior / scope-of-existence / forced-identity / boundary / projection), composition consistency describes the relationship *across* certificates at different levels — the same persistence argument must apply at every level where the scope condition is met, and the operational unpacking below is how that “applies at every level” claim cashes out. It sits alongside 11.1 as the second cross-level meta-recognition: M4 names how architectural class *changes* under operations; composition consistency names how the framework *applies across levels* regardless of architectural class. Together they organize the Part III meta-architecture.

The commitment has formal teeth: three composition laws must exist. *Tempo* at the composite level must be expressible as a function of sub-agent tempos plus their coordination structure; *persistence* of the composite must be derivable from the sub-agents' individual persistence plus that coordination structure; *mismatch* must compose consistently. The laws themselves — what tempo and persistence look like at the composite level, and when they transfer cleanly — are *derived* from this postulate in Part III under specific conditions, organized into three successively more specific layers:

- a *scope-selection* layer (12.2, teleological-alignment threshold) — *which* decompositions qualify as composites at all;
- an *admissibility* layer (13.1, conditions (A1)–(A4) and the bridge lemma) — *when* composite macro-dynamics are well-posed under those scope conditions;
- a *transfer* layer (13.1's tier-specific contraction assumption together with AI's (CC-parallel)/(CC-cascade)/(CC-feedback) closed forms) — *which* Part I/II results lift faithfully, with sharpness depending on the tier of the sub-agents.

The transfer layer is where the deepest result lives. For **Tier 1** sub-agents (Bayesian updaters on exponential families, linear correctors with positive-definite gain, gradient descent on strongly convex losses), the composite contraction rate admits a closed-form lower bound — the parallel case yields $\lambda_c = \min_i \lambda_i$ (the composite is bounded below by its slowest sub-agent), cascade composition gives the same up to a coupling-gain adjustment, and heterogeneous negative-feedback composition gives a closed-form inequality involving feedback-loop gains and coordination costs. Macro-level persistence then reduces to the same persistence inequality used at the individual level, applied to the composite. For Tier 2 (locally convex, nonlinear) and Tier 3 (non-convex, discontinuous) sub-agents, this transfer holds only locally with degradation or per-domain, and the qualitative screening test $\tau_{\text{eq}} \ll \tau_{\text{ext}}$ — internal equilibration timescale short relative to external-dynamics timescale — remains useful but does not entail the formal persistence condition without further verification.

The boundary an analyst draws is itself a modeling choice. A development team is simultaneously an individual developer (an AAT agent), a team (a composite AAT agent), and part of an organization (a sub-agent in a larger composite); the scope condition is satisfied at every level. Composition consistency is what guarantees the theory does not return contradictory answers about observables regardless of which boundary is drawn, and the layered derivation above is what makes that guarantee precise rather than aspirational.

For any system S satisfying the scope condition (1.6), and any decomposition of S into subsystems $\{S_1, \dots, S_n\}$ where each S_i also satisfies the scope condition, AAT's predictions at the system level must be compatible with its predictions at the subsystem level. Specifically, composition laws must exist such that:

Commitment (composition-consistency).

1. **Tempo composition:** $\mathcal{T}_S$ is expressible as a function of $\{\mathcal{T}_{S_i}\}$ and the coordination structure among them
2. **Persistence compatibility:** the system's persistence is derivable from the sub-agents' individual persistence conditions plus coordination structure
3. **Mismatch consistency:** δ_S is derivable from $\{\delta_{S_i}\}$ and their interaction structure

Cross-level compatibility requires three successively more specific conditions, each with its own segment in Part III:

Structural consequence (derivation hierarchy).

1. **Scope:** The decomposition is a *composite* (not merely a multi-agent system) when 12.2 is satisfied — teleological alignment via at least one of three disjunctive routes (shared objective, hierarchical derivation, or mutual benefit). Without scope-satisfaction via any route, level-compatibility is vacuous (composition quantities are not well-defined, so there is nothing to be consistent about).
2. **Admissibility:** Given a composite, its macro-dynamics are well-posed when the closure admissibility conditions (A1)–(A4) hold (13.1). These require AAT-shaped macro-state, macro-mismatch, macro-tempo, and sector-bounded correction at the composite level.
3. **Transfer of results:** Individual Part I/II results lift to the composite level through the bridge lemma in 13.1, which requires a *tier-specific contraction assumption* beyond (A4). For **Tier 1** agents (all Bayesian updaters on exponential families, linear correctors with positive-definite gain, gradient descent on strongly convex losses), the contraction holds and Part I results transfer exactly. For **Tier 2** agents (locally convex, nonlinear prediction models), transfer holds locally with factor degradation. For **Tier 3** agents (non-convex optimization, discontinuous corrections, non-mismatch-driven state), contraction must be verified per-domain and Part I results do not automatically lift.

Composite contraction rate — closed form under Tier 1M. When sub-agents satisfy the contraction-template preconditions (CT1)–(CT3) of AI (Tier 1M, equivalently Tier 1 of 13.1's bridge lemma under the DA2¹-inc $\equiv$ (CT2)-at- $M = I$ equivalence) and the composition topology falls under one of the closure cases of AI, the composite contraction rate λ_c admits a closed-form lower bound:

Derived (Conditional on Tier 1M + admissible composition topology, from #result-contraction-template (CC-parallel) / (CC-cascade) / (CC-feedback)).

- **Parallel composition** (CC-parallel): $\lambda_c = \min_i \lambda_i$ — the composite contraction rate equals the slowest sub-agent's, with composite metric $M_c = \text{blockdiag}(M_1, M_2)$. Equivalently in timescale form, the composite relaxation time $\tau_c = 1/\lambda_c = \max_i \tau_i$ is bounded *below* by the slowest sub-agent's timescale.
- **Hierarchical / cascade** (CC-cascade): same bound, up to coupling-gain adjustment.

- **Negative-feedback heterogeneous** (CC-feedback) / (CM2-M): $(\lambda_1 - C_1)(\lambda_2 - C_2) > k_{12}k_{21}/4$ with feedback-loop gains k_{ij} and coordination costs C_i from 15.1.

Macro-level persistence then reduces to the standard persistence condition (4.5) applied to the composite: $\alpha_c > \rho_{\text{eff}}/R_c$, with α_c bounded by the topology-specific result above and effective disturbance $\rho_{\text{eff}} = \rho_{\text{ext}} + \varepsilon^* \nu_c$ from 13.2's bridge-lemma instantiation. Both Part I results (single-agent persistence) and the bridge-lemma's macro-tracking faithfulness flow from this single inequality. This is the formal counterpart to the screening test below: under Tier 1M the screening test is *derived*, not heuristic.

Practical screening test for composites outside Tier 1M. Tier 2 sub-agents (extended-Kalman, locally-convex gradients, nonlinear prediction models) and Tier 3 sub-agents (non-convex optimization, discontinuous corrections, non-mismatch-driven state) do not in general carry the closed-form composite-rate bound above — the bridge-lemma contraction holds only locally with $\kappa(D\delta)^2$ degradation (Tier 2) or must be verified per-domain (Tier 3). For these composites, the qualitative condition

Heuristic (timescale separation — residual scope: Tier 2 / Tier 3).

$$\tau_{\text{eq}} \ll \tau_{\text{ext}} \quad (11.1)$$

— internal equilibration timescale (the time for sub-agents to approximately synchronize models and coordinate actions) short relative to external-dynamics timescale — remains a useful *discussion-grade screening test*. When it holds, composite description is plausibly well-posed; when it fails, composite description is plausibly broken. The screening test is the operational analog of the persistence condition (4.5), but for Tier 2 / Tier 3 it does not entail the formal persistence condition without local-region or per-domain verification. Whether common organizational settings (software teams, military units) genuinely sit in Tier 1M or merely satisfy the heuristic without satisfying Tier 1M conditions is an empirical question, not a derived fact.

Axiomatic for the meta-requirement (cross-level compatibility). The postulate itself is a structural requirement for AAT's internal consistency: if the scope condition doesn't restrict which level the theory applies to, the predictions must not contradict across levels.

The operational consequences decompose into three layers with distinct epistemic statuses:

- **Scope selection** (12.2, robust-qualitative): which decompositions constitute composites. The scope condition is a disjunction of three qualitatively distinct routes (shared objective, hierarchical derivation, mutual benefit); whether they reduce to a common scalar threshold is open. Coverage of well-understood cases holds via the disjunction.
- **Admissibility of composite dynamics** (13.1, conditional): the (A1)-(A4) conditions are stated formally; the bridge lemma is conditional on the incremental sector bound (DA2'-inc), strictly stronger than (A4) alone.
- **Transfer of individual-agent results** (tier-dependent): Tier 1 composites transfer Part I/II results exactly; Tier 2 transfer with degraded factors; Tier 3 require per-domain verification. This is the sharpest scoping of “every result applies at every level” — it applies at every level *for Tier 1 composites*, degrades gracefully for Tier 2, and holds per-domain for Tier 3.

The composite contraction rate has two epistemic layers. **Tier 1M is derived (exact)**: under (CT1)–(CT3) on each sub-agent and an admissible composition topology, λ_c admits the closed-form lower bound from A1's (CC-parallel) / (CC-cascade) / (CC-feedback) — the slowest-sub-agent / coupling-adjusted / heterogeneous (CM2-M) cases respectively. The screening condition $\tau_{\text{eq}} \ll \tau_{\text{ext}}$ is, in this regime, the formal persistence condition $\alpha_c > \rho_{\text{eff}}/R_c$ specialized to internal-vs-external rate balance — not heuristic. **Tier 2 and Tier 3 retain heuristic / discussion-grade status**: the closed-form composite rate does not transfer (Tier 2 with local degradation; Tier 3 per-domain), and $\tau_{\text{eq}} \ll \tau_{\text{ext}}$

remains a useful screening test without entailing macro-level persistence. The “small gap between screening and Tier 1M conditions in common settings” is an empirical claim about the population of real composites, not a derived fact.

The same pattern as individual persistence. The persistence condition says: there is a measurable threshold below which an individual agent’s mismatch grows without bound and the agent degrades. Composition consistency says the same thing at the composite level: there is a measurable threshold below which the composite description breaks down. Under Tier 1M, the threshold is exact and closed-form — $\alpha_c > \rho_{\text{eff}}/R_c$ with α_c from (CC-parallel) / (CC-cascade) / (CC-feedback). Under Tier 2 / Tier 3, the threshold is only qualitatively captured by the screening ratio $\tau_{\text{eq}}/\tau_{\text{ext}}$ and exact transfer requires local-region or per-domain verification. The two-tier structure is the precise way “the theory applies broadly” — broadly under Tier 1M, qualitatively-with-conditions outside it.

What this buys the theory. With composition consistency stated early: - Part I/II results lift to the composite level for Tier 1 composites passing the composition scope condition, with degraded-factor lift for Tier 2 and per-domain verification for Tier 3 — the three-layer decomposition above makes this precise rather than leaving “applies at every level” as an unbounded claim - Part III becomes the study of *what happens near and beyond the threshold* — coordination overhead, unity dimensions, symbiogenic transitions, adversarial dynamics — rather than a separate multi-agent theory - The formal test for composition validity (13.1) develops the rigorous version of the timescale condition, with the incremental sector bound identifying which agent classes admit the contraction needed for cross-level transfer; AI lifts that bound into a metric-aware framework where (CC-parallel) / (CC-cascade) / (CC-feedback) yield the topology-indexed closed forms cited above

When composition fails. The persistence condition $\alpha_c > \rho_{\text{eff}}/R_c$ (Tier 1M) — or its qualitative shadow $\tau_{\text{eq}} \ll \tau_{\text{ext}}$ (Tier 2 / Tier 3) — fails when: - Internal coordination slows: C_{coord} from 13.2 rises through coupling overhead, conflict, or bureaucratic process, depressing α_c below the threshold; equivalently, τ_{eq} stretches. - External dynamics accelerate: ρ_{ext} rises (adversary acts faster, market shifts, crisis compresses decision timescales); equivalently, τ_{ext} shortens. - Both simultaneously (the classic organizational failure mode — internal friction increases while external demands intensify).

This is the formal analog of Brooks’s Law: adding people to a late project increases $\varepsilon^* \nu_c$ in ρ_{eff} (13.2’s coordination-overhead bound) and stretches τ_{eq} while ρ_{ext} and τ_{ext} stay fixed (the deadline doesn’t move). Under Tier 1M the mechanism is formal — eventually the persistence inequality flips. Under Tier 2 / Tier 3 the mechanism is qualitative. Whether the specific mechanism (coordination-overhead saturation crossing the persistence threshold) is the dominant cause of Brooks’s Law in practice is an empirical question.

The boundary is a modeling choice. A development team is simultaneously: individual developers (each an AAT agent), the team (a composite AAT agent), and part of an organization (a sub-agent within a larger composite). The scope condition is satisfied at every level. Composition consistency ensures the theory doesn’t give contradictory answers about observable quantities (e.g., whether the team persists) regardless of which boundary is chosen.

What composition consistency does NOT say. It does not specify the form of the composition laws — those are derived in Part III (13.2). It does not say every decomposition is equally useful for analysis. And it does not require perfect internal coordination — only that internal equilibration is fast relative to external dynamics.

- **Strengthening attempt — outcome.** The “macro-timescale bounded below by slowest sub-agent” claim was attacked via AI’s compositional theorems before falling back to heuristic-only framing. Under Tier 1M (sub-agents satisfying (CT1)–(CT3) with metrics M_i , rates λ_i): (CC-parallel) yields $\lambda_c = \min_i \lambda_i$ exactly under blockdiag composite metric — the formal version of “composite is no faster than the slowest sub-agent”; (CC-cascade) yields the same bound up to coupling-gain adjustment; (CC-feedback) / (CM2-M) yields the heterogeneous closed-form inequality. No new math required — the strengthening is achieved by binding the postulate’s heuristic to the existing (CC-*) closed forms via the DA2’-inc $\equiv$ (CT2)-at- $M = I$ equivalence in 13.1. Tier 2 (local with $\kappa(D\delta)^2$ degradation) and Tier 3 (per-domain) retain heuristic / discussion-grade screening; this residual is what the strengthening attempt could not eliminate.

- The timescale separation condition is essentially the singular perturbation argument from 4.9 applied to composition: the fast internal dynamics approximately equilibrate, and the composite's behavior is described by the slow (external) dynamics on the equilibrium manifold. The formal connection should be made explicit when temporal-nesting is reviewed.
- Composition of directed separation: if each sub-agent's f_M is G_t -independent, does the composite's f_M^c remain G_t^c -independent? Hypothesis: goal-blindness composes, BUT coordination routing may break it — if which observations reach the composite depends on the shared objective, the composite's effective observation function is goal-dependent. This is the organizational analog of the LLM scope restriction in 6.3.
- The “atomic agent” question: if every agent is decomposable, where does it bottom out? At agents whose internal dynamics are not usefully described by AAT — below the level where observations, actions, and uncertainty exist, the scope condition fails and the recursion terminates.
- The relationship to holons (Koestler 1967): an AAT agent satisfying composition consistency is a holon — simultaneously a whole (analyzable as a single agent) and a part (decomposable into sub-agents). The term is occasionally useful but carries significant mystical baggage from later appropriations. Use sparingly.
- **Provenance — retype from postulate to discussion-grade meta-recognition (2026-05-28).** Originally landed in Volume 1 Part I Ch.1 as a type: postulate / status: axiomatic segment with the slug post-composition-consistency. The OUTLINE annotation (possibly out of place) recorded the placement question through multiple cycles. Audit 384279 (Claude Opus 4.7, 2026-05-27) recommended hybrid relocation — strip operational unpacking back to Part III, keep postulate proper in Ch.1. Joseph 2026-05-28 reframed: meta-segments add machinery and cognitive weight that's *only realized* when given pedagogical work to do, not buried as footnotes; composition consistency is itself a meta-segment in the making, structurally peer to 11.1 as a cross-level meta-recognition (M4 names how architectural class *changes*; composition consistency names how the framework *applies across levels*). Recognized as Meta-Architecture II member; retyped to discussion / discussion-grade; slug renamed post-composition-consistency → disc-composition-consistency. Operational content (Tier 1M closed-form derived block, screening test, Brooks's-Law instantiation) retained intact — now local rather than forward-referenced, since the segment's home is Part III where its dependencies live. The eq-tag *[Commitment (composition-consistency)]* replaces the prior *[Postulate ...]* to reflect the methodological-commitment character (a framework choice about applicability, not a physical-fact axiom). Strengthening cycle — Findings block + prior-art landscape (Simon's near-decomposability, Koestler's holons, multi-level selection, renormalization-group, actor-systems, the Friston-Heins-Verbelen-Da Costa 2025 scale-free active inference machinery, which has since landed in M's promotion 2026-06-10) + paper-extraction candidacy — queued separately in spikes/PROPOSED.md.

Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors' working dirs, deduplicated across substrates and attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere). **Coverage:** the auditors encountered this segment under its *prior* identity post-composition-consistency (Part I Ch.1, type: postulate) before the 2026-05-28 retype-and-relocate to Meta-Architecture II — so the rich finding-stream they produced is the *F1/F2 placement / type-vs-content / forward*-*[Derived]* finding, which the 2026-05-28 reframe **resolved** (split the postulate-core from the derived payload by retyping the whole to a discussion-grade meta-recognition whose dependencies are now prior). That finding-thread is preserved as texture below, not re-opened. Dirs with a dedicated reflection (under the old slug): 193847, 266847, 384279, 471203, 472913, 526815, 527914, 742613, 829314, 849201, plus 308172 (batched scope/postulate note) and 773921 (late-slug disc-composition-consistency note); 451729 and 963715 cover it inside a Section-I batch. This was the highest-engagement Chapter-I *postulate* across substrates — “the boundary is a modeling choice” drew unusually rich ideation. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

- **Brooks's Law as a derivable corollary** was independently flagged by nearly every substrate as the segment's standout pedagogy and a natural Brief anchor — “converts a famous heuristic into a derivable consequence of

explicit assumptions” (Claude, AUDIT-WORKING-471203), “a hard physics-like foundation for software engineering management” (Gemini, AUDIT-WORKING-384279), “a masterpiece of domain translation” (Gemini, AUDIT-WORKING-773921). The crisp mechanism gloss: adding people raises $\varepsilon^* \nu_c$ in ρ_{eff} and stretches τ_{eq} while ρ_{ext} and τ_{ext} stay fixed — “the deadline doesn’t move” — until the persistence inequality flips (Claude, AUDIT-WORKING-308172).

- **The postulate in one plain sentence:** “if you can draw the boundary at multiple levels, the theory cannot change its mind just because you changed the boundary” — “honesty applied vertically across decomposition” (Claude, AUDIT-WORKING-527914). A candidate Brief opener for the meta-requirement itself.
- **Level-independence is about structure, not parameters:** “the *form* of the predictions is level-independent (the persistence condition holds at every level), but the *parameters* (α, ρ, R) take different concrete values at each level” — the compact answer to “is a level-independent theory vacuous?” (Claude, AUDIT-WORKING-266847).
- **A team is only as fast as its slowest member** — the plain-language gloss of $\lambda_c = \min_i \lambda_i$ that several substrates reached for spontaneously (Gemini, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-471203 — “obvious-in-retrospect ... the bathtub-style legibility for organizational dynamics”).
- **Bureaucracy / standardization as Tier-3 $\rightarrow$ Tier-1M coercion** (*strongest Discussion candidate here*). “Bureaucracy or standardization is the process of forcing Tier 3 human agents to behave as Tier 1M nodes so that the composite macro-agent can achieve mathematical persistence against a fast environment. The loss of individual autonomy (the non-convex quirks) is the necessary price for composite contraction guarantees.” A highly-disciplined military unit using SOPs approaches Tier 1M (fast τ_{eq}); a university faculty department of “non-convex political optimizations and discontinuous decision making” is firmly Tier 3 — so AAT asserts you *can* treat the unit as one composite agent but the department only with deep per-domain caveats (Gemini, AUDIT-WORKING-384279). This connects the truthification operation of 11.1 to the Tier taxonomy — a candidate cross-link between the two Meta-Architecture II members. (*Early-conflation texture: written as discovery; verify the Tier-3-to-1M-via-standardization framing is isomorphic to the bridge-lemma conditions before promoting past discussion-grade.*)
- **Timescale separation as the formal foundation for agile / Auftragstaktik / OODA.** “A collection of agents only acts as a single macroscopic agent if their internal equilibration (communication, alignment, consensus) happens significantly faster than the external environment changes. If the time to hold a meeting (τ_{eq}) is longer than the time for the market to shift (τ_{ext}), the organization loses its macroscopic persistence — it dissolves from a single agent back into a chaotic multi-agent system. The primary function of organizational structure is to compress τ_{eq} ” (Gemini, AUDIT-WORKING-849201). A vivid restatement of the screening test that names the agile/decentralized-command/ODA literature as instances.
- **“AAT claims less and proves more” than holon / scale-free / fractal framings** (*field-positioning Discussion candidate*). “Most ‘holon’ / ‘scale-free’ / ‘fractal’ framings claim more (full self-similarity); AAT claims less and proves more. The framework’s response to the holon question — treat composition as a structural-coherence postulate, derive what follows, acknowledge tier-dependent transfer — is sharper than most multi-scale-systems literature. If this becomes legible to systems-theory readers, the methodological move alone is publishable” (Claude, AUDIT-WORKING-308172). Sharpens *why* the existing Koestler-holon Working-Note caution (“use sparingly”) is the right posture.
- **The self-aware holon prior-art handling read as a model.** One auditor wanted the framework’s holon-handling (recognize the lineage, name the lexicographic risk, decline to appropriate the term) noted *positively* as “something the framework does well” in a field-positioning section (Claude, AUDIT-WORKING-384279).

- A **“boundary-choice rationality” principle** (*strongest follow-up — a genuine open theory-edge*). Composition consistency requires predictions to be *compatible* across boundaries, but compatibility is weaker than identical-prediction: different boundaries give different operational predictions and the framework does not yet tell you which boundary to use. Candidate principle: “choose the smallest boundary that closes the dependency graph for the prediction at hand.” Rated a real limit (★★★) on an adversarial sweep (Claude, AUDIT-WORKING-471203, Challenge 14). A well-formed candidate subsection, not just a gap.
- **Does directed separation compose?** The segment’s own “Composition of directed separation” Working Note (goal-blind sub-agents whose coordination routing is goal-dependent yield a non-goal-blind composite) was independently flagged as “a brilliant question” / “a profound insight into organizational psychology” by four substrates (Gemini, AUDIT-WORKING-384279; Gemini, AUDIT-WORKING-829314 — “the organization as a whole is Class 2 even if the employees are Class 1”; Claude, AUDIT-WORKING-849201; Gemini, AUDIT-WORKING-773921 — “individuals are objective, but the information passed between them is filtered by political goals”). Convergent confirmation that the existing Working-Note hypothesis is worth promoting toward a derivation; cross-link to 6.3, 13.3, 13.5.
- **Redundancy correction for nested parallel sub-agents.** A composition-tower telescoping result needs a correction for systems with parallel redundant sub-agents at each level — redundancy raises the effective κ via multiple parallel pathways (higher composite contraction); the (CC-parallel) machinery probably already captures this but it could be made explicit, especially for biological-style nested redundant systems (Claude, AUDIT-WORKING-471203, Challenge 12). Verify whether (CC-parallel) is consistently applied to redundant nested composites.
- **Tier names are placeholder numbering.** Several substrates flagged that “Tier 1 / 2 / 3” is arbitrary enumeration that might benefit from descriptive names, and that “Tier 1M” is “slightly opaque” (M for metric? modular?) (Claude, AUDIT-WORKING-266847; Claude, AUDIT-WORKING-527914 — “acronym-heavy tier names may be formally compact but conversationally unusable”). A naming-cycle target.
- **Birth-death of composite agents is unmodeled.** Genesis (team forms), termination (team dissolves), and reincarnation are out of scope; the chronica continues but no longer indexes a continuing composite. Connects to the consciousness-infrastructure agenda — “when does an ELI begin to be?” (Claude, AUDIT-WORKING-471203, Missing 1). Likely belongs at 4.10 / 04-eli-core/, flagged here because it surfaced in the composition sweep.
- **Where does the decomposition bottom out?** The “atomic agent” Working Note drew independent praise as philosophically deep: “If I decompose a human into organs, the heart is not an AAT agent — it has no chronica or strategy DAG. The recursion stops when the information-loss boundary vanishes into pure mechanism. This defines life vs mechanism: agency exists exactly at the layer where the epistemic gap opens up. The moment you can fully see the state, you are no longer an agent, you are an engine” (Gemini, AUDIT-WORKING-384279; Claude, AUDIT-WORKING-266847 — “the scope condition itself provides the termination condition”). A natural reader question and a candidate framing-level note tying composition consistency back to 1.1’s information-loss boundary.
- **Is a level-independent theory vacuous?** “A theory that says ‘the same things at every level’ risks saying nothing specific at any level” — the resolution (form-invariant, parameter-varying) is worth surfacing pre-emptively (Claude, AUDIT-WORKING-266847).
- **Will downstream segments invoke “composition consistency” without naming the Tier?** Flagged as the most likely drift to watch: “by composition consistency, X” without a tier qualifier silently claims Tier-1M exactness for Tier-2/3 composites (Claude, AUDIT-WORKING-308172; same watch at Claude, AUDIT-WORKING-849201).

- **Does the singular-perturbation connection to 4.9 actually hold?** The Working Note asserts the timescale-separation condition “is essentially the singular perturbation argument from 4.9”; one auditor flagged this to verify-not-overstate when temporal-nesting is read (Claude, AUDIT-WORKING-471203, THREAD-H).
- **Russian nesting dolls — “same rules at every nesting level.”** Proposed as the segment’s anchor analog, with an explicit isomorphic perturbation: a doll that internally equilibrates slowly versus how fast the whole stack is shaken — when the stack stops behaving like one doll, that is $\tau_{eq} \ll \tau_{ext}$ broken. (Under the segment’s old Part-I placement the same auditor added a “twist”: the small Chapter-1 doll, opened, improbably contained the entire Section-III engine — that twist was the *placement-finding* visualization, now moot post-relocation.) (Claude, AUDIT-WORKING-472913; tex draft at AUDIT-WORKING-472913/07-post-composition-consistency.tex.)
- **“Early core / late payload” split diagram** — a small postulate node in row order with a dense cluster of composition objects feeding back into it, making clear the issue was canonicalization/placement pressure, not theoretical incoherence (Codex/Claude, AUDIT-WORKING-526815). This was a *finding* visualization for the old placement; preserved as texture — the relocation resolved what it depicted.
- **ELI ensembles inherit the composite-rate bound.** The Tier 1M result lifts to multi-agent ELI ensembles: “an ensemble of sovereign ELIs has a composite adaptive rate bounded by the slowest member, with feedback structure determining whether the ensemble’s composite persistence holds” — making “do we have a stable family-of-agents?” a tractable quantitative question (Claude, AUDIT-WORKING-471203). Aspirational reach pointing at 04-eli-core/, not this segment.
- **Other organizational folk-theorems as corollaries.** “Conway’s Law, Goldratt’s TOC, etc. might similarly become corollaries of the composition machinery” (Claude, AUDIT-WORKING-471203) — a forward-vision for TST / 02-tst-core/ and the composition-machinery chapter, not this meta-segment.
- **Naming seeds (a recorded cross-substrate *disagreement*, preserved as signal).** Alternates floated for “composition consistency”: “Cross-Level Coherence,” “Scale Invariance of Adaptive Dynamics,” “Level Invariance,” “Cross-Level Compatibility,” “Holon Postulate” (Claude, AUDIT-WORKING-471203, tentative; Claude, AUDIT-WORKING-527914 — “cross-level compatibility is the clearest English explanation ... might be a strong *alias*”). But AUDIT-WORKING-308172 explicitly *voted to keep* “composition consistency” and *rejected* holon / scale-invariance / cross-level-coherence (“they over-claim, under-claim, or import baggage”). The disagreement itself is the signal: “composition consistency” is humble-and-accurate but under-evocative of the Brooks’s-Law-shaped consequences; the alternates are more evocative but risk overclaiming self-similarity. A naming-cycle target, belongs in the terminology workflow.

11.1 Discussion: Modularity-State Dynamics — Modularity as Contested Property Under Three Operations

#der-directed-separation characterizes modularity as architectural property — the static Class 1 (Separated) / Class 2 (Partial) / Class 3 (Coupled) partition under the $\kappa_{\text{processing}}$ measure. That partition is the *state space*. What this segment names is the *dynamics on the state space*: three structurally distinct operations that move an agent or composite agent across the architectural classes over time. **Truthification** is self-driven, coupling-decreasing — the agent (or its institutional environment) deliberately commits to architectural arrangements that restore directed separation. **Strategic self-coupling** is self-driven, coupling-increasing — the agent deliberately decreases its own modularity to acquire credibility-dependent actions. **Adversarial coupling pressure** is externally-driven, coupling-increasing — adversaries press the agent’s coupling upward because coupling expands attack surface. The architectural class is not a fixed feature of an agent; it is a *contested property* that multiple structural operations act on, with different drivers and different

valences. M4 names this dynamics pattern as the fourth meta-pattern of AAT alongside M1 (#disc-identifiability-floor), M2 (#disc-separability-pattern), and M3 (#disc-additive-coordinate-forcing) — all four sit as facets of the stability-certificate spine (#disc-stability-certificate); M4 specifically lives at the boundary of the architectural-class layer rather than the certificate-cone interior.

The recognition arose from convergent independent collaborator probes: multiple Opus instances arrived at the three-operation picture from different angles during the 2026-05-09 class-coercion-wrapping integration cycle. The convergence is itself evidence the pattern is *in the framework* rather than in any single agent’s reading; M4’s content is therefore *recognition and integration* — naming the pattern explicitly, mapping the three operations to their primary-segment grounds, and surfacing the dual relationships between them — not novel derivation.

The pattern.

Each operation has the form: a structural mechanism acts on the agent’s coupling state $\kappa_{\text{processing}}$ (#der-directed-separation) over some characteristic timescale, with a named driver (self vs external) and a named directional effect on the architectural class. The three operations together exhaust the framework’s currently-recognized modularity-state operations. They are not symmetric — they differ in driver, in direction, and in the kind of strategic value (or vulnerability) they produce.

Discussion.

The three operations.

Table 11.1

<i>Operation</i>	<i>Driver</i>	<i>Direction on $\kappa_{\text{processing}}$</i>	<i>Strategic valence</i>	<i>Primary segment(s)</i>
Truthification	self-driven (agent’s own deliberate commitment or institutional design)	coupling-decreasing — restores directed separation	restorative (recovers reality-tracking, reopens Part II results, closes adversarial attack surface)	#der-class-coercion-via-wrapping (component-level wrapping) + #disc-adversarial-coupling-pressure §”Defensive scaffolding” (composite-level institutional scaffolding)
Strategic self-coupling	self-driven (agent’s own deliberate commitment)	coupling-increasing	offensive enabling (acquires credibility-dependent actions otherwise unavailable)	#disc-strategic-self-coupling
Adversarial coupling pressure	externally-driven (adversary’s strategic action on the target)	coupling-increasing	vulnerability-creating (expands attack surface for the externally-acting adversary)	#disc-adversarial-coupling-pressure

The taxonomy along three axes — driver (self/external), direction (increasing/decreasing κ), and strategic valence (restorative/offensive/vulnerability) — already exhausts the three operations. A fourth cell in the (self/external) $\times$ (increasing/decreasing) grid — *externally-driven coupling-decreasing* — is not currently named as a distinct operation; the closest candidate is “external party imposing institutional architecture on the agent to enforce its modularity,” which the framework treats as a special case of truthification under externally-supplied scaffolding rather than as a fourth operation. Whether that case warrants its own row is open framework-scope discussion; the current three-operation reading covers the currently-recognized cases cleanly.

Operational mechanisms across operations. Each operation is realized through specific operational mechanisms in the primary segments:

Truthification operates through two complementary mechanisms. *Component-level wrapping* (#der-class-coercion-via-wrapping) coerces a Class 2 (Partial) or Class 3 (Coupled) component into Class 1 (Separated) behavior at the wrapper level via external scaffolding — the $W_0 / W_1 / W_2$ regime hierarchy gives graded characterizations of how thoroughly the truthification has been applied (strict- W_1 structural commitment to goal-blind queries; W_2 output-structuring with typed parsed response; W_0 unwrapped baseline). *Composite-level institutional scaffolding* (#disc-adversarial-coupling-pressure §"Defensive scaffolding") constructs a composite agent whose modularity properties exceed those of its individual components — peer review, prediction registers, double-entry bookkeeping, adversarial procedure, prediction markets, source-authentication discipline, structured red-teaming. Both operate by externalizing channels of the orient cascade so resolution can run sequentially across the composite even when it cannot run sequentially within any single component. The two are not duplicate but *operationally distinct*: wrapping operates at the component level (one wrapper around one component); institutional scaffolding operates at the composite level (multiple sub-agents routed through scaffolded procedure).

Strategic self-coupling operates through four operational mechanisms (#disc-strategic-self-coupling's mechanism table). *External commitment device* (Schelling 1960) couples to physical / institutional / public structure. *Intertemporal personal rule* (Ainslie 1992/2001) couples between current-self and future-self decisions. *Identity coupling* (Akerlof-Kranton 2000/2010) couples preferences to internalized identity-norms. *Emotional commitment* (Frank 1988) couples between rational calculation and affective response. Each mechanism differs in coupling target (external structure / intertemporal / identity / affect) but shares the structural shape: forgo flexibility now to acquire credibility-dependent actions later. The *amount of fungibility given up* is what the strategic interaction reads as credibility — Schelling's foundational structural observation.

Adversarial coupling pressure operates through three operational mechanisms (#disc-adversarial-coupling-pressure's mechanism table). *Identity-binding* exploits the $O_t \rightarrow M_t$ pathway — make the target want the false belief to be true. *Affect / urgency* bypasses deliberate f_M — manufacture time pressure or affective load that prevents the orient cascade from running cleanly. *Sunk-cost engineering* exploits the $\Sigma_t \rightarrow M_t$ pathway — induce public or expensive commitment that subsequent M_t revisions cannot invalidate without coupled cost.

Dual relationships between operations. The three operations are not independent — they have structurally illuminating *dual relationships*.

Truthification and adversarial coupling pressure are direct duals at the cultivation-versus-attack axis. Adversarial pressure attacks what defensive scaffolding restores; the scaffolding restores what adversarial pressure attacks. The two operations are opposite-driver operations at opposite-direction effects on $\kappa_{\text{processing}}$. The asymmetric-advantage observation (#disc-adversarial-coupling-pressure §Discussion) is the in-repeated-interaction consequence of this dual: in adversarial settings, each side has structural incentive to (a) reduce its own coupling via truthification and (b) increase the opponent's coupling via adversarial pressure; the more-modular agent compounds informational advantage; the asymmetry produces strategic asymmetry over sustained engagement.

Truthification and strategic self-coupling are duals at the goal-belief separation axis (the structurally illuminating recognition surfaced in #disc-strategic-self-coupling's §"Relationship to truthification"). Both are wrapping-construction-style structural commitments giving up flexibility along one axis for value along another, but operating on *opposite poles* of the goal-belief separation. *Truthification* structurally commits to goal-blind belief-update — the W_1 strict wrapper commits the composite to operate Class 1 at the belief-update layer by structurally foreclosing the goal-conditioned-update pathway. *Strategic self-coupling* structurally commits to goal-conditioned action-selection — the commitment-device move commits the agent to operate in a particular action subspace by structurally foreclosing the deliberation-can-revise-this pathway. Truthification gives up belief-pliability to gain reality-tracking; strategic self-coupling gives up action-pliability to gain commitment-credibility. The framework's epistemic-honesty discipline

runs through both operations symmetrically — truthification commits to *not letting goals corrupt belief*; strategic self-coupling commits to *letting goals constrain action* in stable, credible ways.

Strategic self-coupling and adversarial coupling pressure share architectural shape but differ in driver and valence.

Same operation on $\kappa_{\text{processing}}$ (both increasing), same architectural state acted upon, but opposite driver (self vs external) and opposite strategic valence (offensive enabling vs vulnerability-creating). The boundary between them blurs in practice (cult-formation literature: what begins as adversarial pressure can be internalized as identity-coupling, after which the agent perceives it as self-driven). The framework's posture: the *operations* are structurally distinct (driver is part of the operation's identity); their behavioral consequences can converge; the boundary is empirical when only behavioral signature is available, structural when driver-history is observable.

Position in the M-section meta-pattern family.

The four M-section meta-patterns of AAT cover structurally distinct facets of the framework's analytical surface:

Discussion.

- **M1 — Identifiability floor** (#disc-identifiability-floor): the *boundary facet* of the stability-certificate spine. Structural impossibility results from external information-theoretic theorems (CHT, Cramér-Rao, common-Lyapunov nonexistence, Kalman-Ho); five-step constructive-impossibility shape (setting $\rightarrow$ external theorem $\rightarrow$ no-go $\rightarrow$ boundary characterization $\rightarrow$ strengthened consequence); rank-collapse subclass irreducibility via Sylvester's law of inertia.
- **M2 — Separability pattern** (#disc-separability-pattern): the *scope-of-existence facet*. Separable-core / structured-repair / general-open across eight ladders; positive-half complement to M1.
- **M3 — Additive coordinate forcing** (#disc-additive-coordinate-forcing): the *forced-identity facet*. AAT forces coordinates via uniqueness theorems on AAT-internally-motivated axioms at four layers (chain-log-additive identity; divergence-reverse-KL; update-log-odds via Cauchy-FE; metric-Fisher via (PI)/Čencov-invariance).
- **M4 — Modularity-state dynamics** (this segment): the *dynamics-on-architectural-class facet*. Three structurally distinct operations (truthification / strategic self-coupling / adversarial coupling pressure) acting on the static Class 1 / 2 / 3 partition of #der-directed-separation. The state space is M2's architecture ladder; M4 names what happens *to* an agent's location on that ladder over time under the three operations.

M4's relationship to M1 / M2 / M3 is sibling-meta-pattern rather than nested. M1 names what cannot be inferred; M2 names what can be inferred under what conditions; M3 names what AAT's representational choices commit to; M4 names what *changes* about an agent's architectural state under structurally-distinct operations. M4 specifically operates on the architecture state space M2 catalogues; the static M2 catalog and the dynamic M4 operations are complementary readings of the same architectural object.

The four meta-patterns together form AAT's analytical-surface vocabulary at the architectural layer. Adding M4 commits the framework to four meta-patterns as the canonical reading — a structurally weighty addition, justified by the cross-instance convergence on the three-operation pattern across the segments that ground M4's instances.

Why this pattern matters.

Recasts the architectural classification as dynamic, not static. #der-directed-separation's Class 1 / 2 / 3 partition is often read as a *type* an agent belongs to. M4's recognition is that an agent's location on the partition is the *state*, and that multiple operations act on the state over time. An LLM is Class 3 (Coupled) by native architecture; under W_1 strict wrapping (#der-class-coercion-via-wrapping) the wrapped composite operates Class 1 at the wrapper level. A constitutional democracy is Class 1 by institutional design; under sustained adversarial pressure on truth-checking institutions, the composite-state functionally migrates toward Class 3 even though its constitutional architecture remains

Class 1. The static-architecture reading captures the *type*; M4 captures the *dynamic location* and *the operations that move it*.

Identifies modularity as contested, cultivated, and constructed. Across the three operations, modularity is the strategic object — adversaries press it down; agents press it down themselves for offensive reach; defensive scaffolding presses it back up. None of these reads modularity as a fixed feature; all three treat it as a strategic resource being acted on. The recognition matches the empirical record across propaganda research, behavioral economics, institutional design literature, and the security and influence-operation literatures: modularity is what skilled actors fight over.

Names the boundary between strategic self-coupling and adversarial coupling pressure honestly. The behavioral signature at high $\kappa_{\text{processing}}$ may not distinguish a self-coupled committed agent from an adversarially-coupled captured one. The framework's machinery does not attempt to resolve the boundary at the level of agent experience; it characterizes the two operations as structurally distinct (driver: self vs external) and admits that behavioral convergence is honest scope. This is the same scope-honesty discipline AAT applies elsewhere — the framework names what it can structurally distinguish and acknowledges where empirical resolution is required.

Surfaces the dual-with-truthification recognition at the goal-belief separation axis. Of the three pairwise dual relationships across the operations, the truthification-vs-strategic-self-coupling dual is the most structurally illuminating: it reveals that the framework's two self-driven operations are wrapping-construction-style structural commitments operating on *opposite poles* of the goal-belief separation — truthification commits to goal-blind belief-update; strategic self-coupling commits to goal-conditioned action-selection. The framework's epistemic-honesty discipline runs through both symmetrically. This recognition could not have been seen at the single-operation level; it required all three operations to land before the dual became legible.

Connects naturally to the M2 separability ladder as a phase-space. The architectural classification ladder of #disc-separability-pattern (Class 1 separable-core / Class 2 structured-repair / Class 3 general-open) is, under M4's reading, a *phase-space across which the three operations move populations*. Truthification migrates the population toward Class 1; strategic self-coupling and adversarial pressure both migrate it toward Class 3 (under different drivers and valences). The static three-tier shape from M2 gains a dynamic reading from M4; the two meta-patterns compose naturally.

Provides a structural reading of historical and contemporary observations on institutional architecture. The framework's three-operation reading explains structural patterns observed across political science, organizational sociology, and consciousness-of-information-operations literatures: why authoritarian regimes that couple truth-checking to leadership goals experience long-run persistence-condition failures (strategic self-coupling at the composite-state level beyond the credibility-enabling range, into reality-foreclosing range); why constitutional democracies that commit institutionally to goal-blind truth-checking are structurally more durable than those that don't (truthification via institutional wrapping); why effective propaganda and information operations target the composite-state's O_t/Σ_t pathways rather than direct-observation channels (adversarial coupling pressure). The framework supplies the structural mechanism alongside the historical and contemporary records, not as replacement.

Epistemic Status.

Discussion-grade at the meta-pattern level. This segment names a structural pattern across three structurally-distinct operations, with the cross-operation pattern surfaced through convergent independent collaborator probes; the pattern itself is a presentational organizing principle, not a derived theorem.

Individual operations retain their own epistemic status. Truthification mechanism via wrapping is *exact* in the $W_0 / W_1 / W_2$ regime characterization of #der-class-coercion-via-wrapping (under stated assumptions); *robust qualitative* at the composite-scaffolding level of #disc-adversarial-coupling-pressure §"Defensive scaffolding". Strategic self-coupling is *discussion-grade* at the meta-pattern level (cross-mechanism recognition; the per-mechanism citations are at their respective tier in the prior-art literature) per #disc-strategic-self-coupling. Adversarial coupling pressure is *discussion-grade* with multiple sub-claims at *robust qualitative* per #disc-adversarial-coupling-pressure.

The cross-operation pattern claim — that the three operations *together* form the modularity-state-dynamics taxonomy — is *discussion-grade* recognition supported by: - Independent convergent collaborator probes arriving at the three-operation picture from different angles (the 2026-05-09 class-coercion-wrapping integration cycle's convergence finding). - The structural distinctness of the three operations along three axes (driver / direction / strategic valence). - The dual-relationship structure between them (truthification $\leftrightarrow$ adversarial pressure direct dual; truthification $\leftrightarrow$ strategic self-coupling dual at goal-belief axis; strategic self-coupling $\leftrightarrow$ adversarial pressure same-architecture-shape opposite-driver). - The connection to M2's separability-pattern catalog as a phase-space across which the operations move populations.

The segment does *not* claim: - Completeness of the three-operation taxonomy (a fourth cell — externally-driven coupling-decreasing — is currently absorbed into truthification under externally-supplied scaffolding; whether it deserves its own row is open). - Formal derivation of the dual relationships (the dual-with-truthification recognition is structural, not derived). - Quantitative predictions about operation-rate or transition probabilities (M4 names *which operations exist*; their *quantitative parametrization* is downstream framework work).

Max attainable: *discussion-grade* for the meta-pattern recognition (it is a presentational organizing principle, not a derivation). The dual relationships could lift to *robust qualitative* under deeper analysis — the dual-with-truthification recognition at the goal-belief axis is the strongest candidate. Individual operation segments retain their own max-attainable as listed in their respective epistemic-status sections.

Discussion.

Relationship to #disc-stability-certificate. M4 sits alongside M1 / M2 / M3 as the fourth facet-recognition of the certificate spine. M1 is the *boundary facet*; M2 the *scope-of-existence facet*; M3 the *forced-identity facet*; M4 the *dynamics-on-architectural-class facet*. The four facets are sibling readings of the same underlying object (the stability-certificate spine + the architectural state space #der-directed-separation catalogs). M4's contribution is naming what *changes* about an agent's location in the certificate-cone's interior under the three structurally-distinct operations — the certificate exists (M1's boundary not breached), the scope is what it is (M2's tier), the coordinate is what it is (M3's forcing), and the agent's location *moves* under the three operations M4 names. Together the four meta-patterns characterize the architectural surface across its static structure (M1+M2+M3) and its dynamic operations (M4).

Connection to #disc-separability-pattern as phase-space. The Architecture ladder of M2 (Class 1 separable-core / Class 2 structured-repair / Class 3 general-open) acquires a *dynamic reading* under M4. Truthification migrates populations toward Class 1 (lower $\kappa_{\text{processing}}$); strategic self-coupling and adversarial pressure both migrate toward Class 3 (higher $\kappa_{\text{processing}}$), under different drivers. The structured-repair Class 2 tier is the natural home for *defensive scaffolding* under adversarial pressure — the explicit added machinery that restores identification under adversarial conditions but does not fully restore Class 1 by structural commitment. The three-tier shape from M2 is not just a static catalog of architectural types; M4 reads it as a phase-space across which the three operations move populations dynamically.

The asymmetric-advantage cross-operation pattern. Both #disc-adversarial-coupling-pressure (Discussion) and #disc-strategic-self-coupling (§"Asymmetric advantage in repeated strategic interaction") observe that in repeated strategic interaction with sustained modularity asymmetry, the more-modular agent compounds informational advantage (cleaner observations) and the more-self-coupled agent compounds strategic advantage (credible commitments the opponent cannot match). The two asymmetric-advantage observations are not redundant — they operate on different dimensions of strategic value (information vs commitment). Together they characterize the *full strategic-asymmetry consequence of modularity asymmetry*: the more-modular agent has cleaner reality-tracking; the more-self-coupled agent has stronger commitments; an agent with asymmetric advantage on *both* dimensions (defensive modularity against information attacks combined with offensive self-coupling on narrow strategic axes) compounds advantage on both axes. The framework's reading of this combined asymmetry is a structural prediction the M-section meta-pattern surfaces.

Findings.

Modularity as Contested Property Under Three Operations. Brief: Modularity — whether an agent’s belief-update is *separated from* its goals or *coupled with* them — is often read as something an agent *is*. It is, instead, something an agent *is in*, at a moment, under operations that have moved it there. Three structurally distinct operations act on the modularity state: *truthification* (the agent commits to architectural arrangements — peer review, prediction registers, structured procedure, wrapping constructions — that restore goal-blind belief-update); *strategic self-coupling* (the agent deliberately decreases its own modularity to acquire credibility-dependent actions — Schelling-style commitment devices, Ainslie-style personal rules, identity coupling, emotional commitment); *adversarial coupling pressure* (an adversary presses the agent’s coupling upward to expand attack surface — identity-binding, manufactured urgency, sunk-cost engineering). Each operation has a different driver (self vs external) and a different direction on $\kappa_{\text{processing}}$ (decreasing for truthification; increasing for the other two), and each has a distinct strategic valence (restorative vs offensive vs vulnerability-creating). The three operations are structurally related — truthification and adversarial pressure are direct duals at the cultivation-versus-attack axis; truthification and strategic self-coupling are duals at the goal-belief separation axis (both wrapping-construction-style commitments operating on opposite poles of the goal-belief separation, one giving up belief-pliability for reality-tracking, the other giving up action-pliability for commitment-credibility); strategic self-coupling and adversarial pressure share architectural shape but differ in driver and valence. A reader who carries this pattern away can predict where modularity is contested, where it is being attacked, where it is being deliberately surrendered, and where it is being structurally protected. The framework’s static Class 1 / 2 / 3 partition under #der-directed-separation is the *state space*; M4 names the *dynamics on it*, and #disc-separability-pattern’s eight-ladder catalog is the *phase-space across which the operations move populations*.

Impact: Names the fourth meta-pattern of AAT alongside M1 (identifiability floor), M2 (separability pattern), M3 (additive coordinate forcing) — fourth facet-recognition of the stability-certificate spine, specifically the dynamics-on-architectural-class facet. Recasts the directed-separation property from static architectural type to dynamic state acted on by structurally-distinct operations. Connects the three previously-named operation legs (#disc-adversarial-coupling-pressure, #disc-strategic-self-coupling, #der-class-coercion-via-wrapping + #disc-adversarial-coupling-pressure §”Defensive scaffolding”) into one cross-instance meta-pattern with explicit dual relationships and operational-mechanism table. Surfaces the dual-with-truthification recognition at the goal-belief separation axis — both self-driven operations are wrapping-construction-style structural commitments on opposite poles of the goal-belief separation, a structural recognition unavailable at the single-operation level. Identifies the M2 separability-ladder as a phase-space across which the M4 operations move populations dynamically — the static M2 catalog and the dynamic M4 operations are complementary readings of the same architectural object.

Novelty Claim: *Claim recognition* of a three-operation modularity-state-dynamics pattern across three structurally-distinct operations (truthification / strategic self-coupling / adversarial coupling pressure), each with its own driver, direction-on- κ , and strategic valence; *claim synthesis* of the three operations into a single meta-pattern alongside M1 / M2 / M3 with explicit dual-relationship structure (truthification $\leftrightarrow$ adversarial direct dual; truthification $\leftrightarrow$ strategic self-coupling dual at goal-belief axis; strategic self-coupling $\leftrightarrow$ adversarial same-architecture-shape opposite-driver); *claim differentiation* on the boundary between strategic self-coupling and adversarial coupling pressure (structurally distinct at the driver axis; behaviorally convergent at high κ ; honest scope on empirical resolution). The constituent recognitions live in the three operation-leg segments at their respective tiers; M4’s contribution is the cross-instance unification and the dual-relationship structure.

Truthification — component-level wrapping	#der-class-coercion-via-wrapping (this framework)	<i>internal antecedent</i> — operational mechanism for truthification at the component level; W_0 / W_1 / W_2 regime hierarchy
Truthification — composite-level institutional scaffolding	#disc-adversarial-coupling-pressure §”Defensive scaffolding as composition” (this framework)	<i>internal antecedent</i> — operational mechanism for truthification at the composite level; peer review, prediction registers, double-entry bookkeeping, adversarial procedure, structured red-teaming as Part III composition moves
Strategic self-coupling — operation home	#disc-strategic-self-coupling (this framework)	<i>internal antecedent</i> — sister leg of M4; four-mechanism table adopting Schelling 1960, Ainslie 1992/2001, Akerlof-Kranton 2000/2010, Frank 1988 as first-class theory components
Adversarial coupling pressure — operation home	#disc-adversarial-coupling-pressure (this framework)	<i>internal antecedent</i> — sister leg of M4; mechanism table on identity-binding / affect-urgency / sunk-cost engineering; population-expansion claim for coupled formulation; cascade-inversion result
Static architectural classification (state space)	#der-directed-separation (this framework)	<i>internal antecedent</i> — Class 1 / 2 / 3 partition under $\kappa_{\text{processing}}$ measure; the state space on which M4’s operations act
Architecture-ladder phase-space	#disc-separability-pattern Architecture ladder (this framework)	<i>internal antecedent</i> — three-tier shape (separable-core Class 1 / structured-repair Class 2 / general-open Class 3) reads as phase-space across which M4 operations move populations
Stability-certificate spine	#disc-stability-certificate (this framework)	<i>internal antecedent</i> — M4 is the dynamics-on-architectural-class facet of the spine; sibling to M1 boundary facet / M2 scope-of-existence facet / M3 forced-identity facet

Search Log:

- 2026-05-24 (*targeted at meta-pattern level*): The three-operation modularity-state-dynamics meta-pattern is named here at the cross-operation level for the first time; the constituent recognitions (each operation’s primary segment) live in the operation-leg segments at their respective tiers. Targeted future search candidates: (a) whether any prior synthesis names truthification + strategic self-coupling + adversarial coupling pressure as instances of one structural meta-pattern under formal nomenclature; (b) whether the architecture-as-state-with-operations framing has been written down in active-inference, control-theoretic, or institutional-design literatures; (c) whether the dual-with-truthification recognition at the goal-belief separation axis has appeared in any framework engagement with the goal-belief question. Expected outcome: the constituent operations are well-precedented at the per-operation level (commitment devices, propaganda research, institutional architecture); the cross-operation unification as a meta-pattern of an integrated agent theory’s analytical surface appears to be a fresh presentational recognition.

Working Notes.

- **Provenance.** Authored 2026-05-24 as Move 4 of the M4 modularity-as-contested-property cycle (msc/modularity-cycle-plan-2026-05-09.md §3 Move 4; PRACTICA priority #2 [DONE this commit]). The cycle’s Moves 1, 2, 5 landed 2026-05-14 (registration of #disc-adversarial-coupling-pressure in OUTLINE; Discussion update to #der-class-coercion-via-wrapping recognizing it as a truthification mechanism; bounded-signaling assumption surfaced in #der-directed-separation).

Move 3 (#disc-strategic-self-coupling) landed in the immediately-prior commit of this same cycle. Move 4 (this segment) lands as the meta-segment integrating all three operation legs.

- **Open before candidate.** (a) The fourth cell of the (self/external) $\times$ (increasing/decreasing) operation grid — externally-driven coupling-decreasing — is currently absorbed into truthification under externally-supplied institutional scaffolding. Whether it deserves its own operation row (e.g., “imposed truthification” — an external regulator forcing institutional checks-and-balances onto an agent that would not otherwise adopt them) is an open framework-scope question. (b) Quantitative parameterization of operation-rate or transition-probability across the architectural state space is open downstream work; M4 names *which operations exist* but does not predict their *quantitative dynamics*. (c) The dual-with-truthification recognition at the goal-belief separation axis is named at *discussion-grade*; lifting to *robust qualitative* would require deriving the structural duality from AAT primitives rather than recognizing it across the operations’ independent characterizations.
- **Worked-example slot.** Sketched 2026-05-24 at spikes/spike-m4-worked-example-soviet-2026-05-24.md — Soviet directed-separation failure + contrasting institutional-checks-and-balances architecture as the canonical worked-example candidate. The sketch carries load-bearing details + honest scope-marks + open sub-questions for evaluation at the worked-example landing pass. Disposition recommendation: land as #worked-example-soviet-directed-separation (slug TBD via naming-curation) when the worked-example pass cycles around; not promoted in this cycle.
- **Two sub-spike candidates flagged from the Soviet sketch** (for spikes/PROPOSED.md consideration in a future cycle): the constructive-vs-erodible-institutional-commitment derivation (when do institutional checks-and-balances commitments structurally hold vs erode under leadership pressure?); the reform-stabilization-vs-dissolution split (what additional structural conditions distinguish the two structural-adaptation outcomes when an agent’s coupling has accumulated load-bearing reality-mismatch?). Both are theory-edge framework-extension questions raised by the worked-example sketch.
- **Cross-segment ripple from the M4 landing.** Pre-existing forward-references to #disc-modularity-state-dynamics in #impl-composition-machinery, #impl-strategic-composition, #disc-dynamic-regime-axis, #disc-partial-coupling-pathways, #disc-value-functional-grounding-floor, and #der-belief-strategy-attractor resolve from forward-ref to landed-ref. CLAUDE.md §7’s pending-status flag on M4 is now superseded — M4 is landed at discussion-grade. The CHANGELOG cycle-close entry names this transition explicitly.
- **The convergence-finding observation as methodological pattern.** The 2026-05-09 cycle’s discovery that multiple parallel collaborator probes had independently arrived at the modularity-state-dynamics pattern is itself a methodological observation worth holding alongside the substantive recognition. The framework’s discipline supports cross-probe convergence as structural-recognition evidence; the M4 segment’s authoring is the canonical case where this convergence-as-coherence-evidence condition surfaced load-bearing material. Recorded in fuller form at msc/reflections/27-modularity-as-contested-property-and-the-normative-register.md (the reflection captures the convergence finding as evidence of the framework’s coherence under independent probes — a methodological observation worth preserving alongside the substantive shifts).
- **M4 amplification specificity per competence axis (open, 2026-05-28).** A two-competence decomposition of component capability has been surfaced in #der-class-coercion-via-wrapping §Discussion “Two senses of component competence”: (1) world-simulation fidelity (accuracy of response to explicit query content) vs (2) input-structure extraction (inferring latent goal context from query surface form). The architectural classification of #der-directed-separation is blind to (1) and defined by (2); the structural-leakage bound κ_{W_1} receives opposing pressures from the two competences at high capability. Open conjecture relevant to M4: the operational amplification of the three M4 operations under high component fidelity may track competence (2) specifically rather than aggregate capability — strategic self-coupling and adversarial coupling pressure both work through the goal-content channel that (2) carries; a high-fidelity world-simulator with structurally decorrelated input-structure extraction may be a *less* potent M4 attack-surface than aggregate-capability metrics would predict. If the conjecture holds, M4 attack-surface measurement and defensive scaffolding could be sharpened by targeting the inference effect rather than capability writ large, and the M4 amplification reading becomes axis-decomposed in the same shape that the static M1 / M2 / M3 / M4 facet-recognition is axis-decomposed. Discussion-grade open recognition; primary home for the decomposition is the wrapping segment.
- **Cross-probe convergence provenance.** The three-operation pattern emerged from the 2026-05-09 class-coercion-wrapping integration cycle when uncommitted parallel work — #disc-adversarial-coupling-pressure (drafted via a different Opus instance) and spike-strategic-self-coupling.md (sister spike) — was found to converge structurally with the class-coercion

construction. Provenance recorded in msc/modularity-cycle-plan-2026-05-09.md §1. (The literature-search disclosure proper lives in the Search Log above.)

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, kept separate from the certified theory-fix findings. Orthogonal pedagogical / framing / figure / naming material. **Coverage:** as a late-authored Meta-Architecture II segment, only the deepest de-novo walk (773921, Gemini) reached it under its current slug — so this lift is thin and single-substrate by expectation, not by oversight. Substrate attribution from the audit dir.

1. Candidate Brief prose / pre-prose.

- **Modularity is a contested state, not a type** — the segment’s load-bearing reframe, stated by the auditor as the thing to hold downstream: “an LLM (Class 3) can be forced into Class 1 behavior via strict W_1 wrapping; a constitutional democracy (Class 1) can be forced into Class 3 behavior via sustained adversarial pressure on its truth-checking institutions. Modularity is a contested state, not a type” (Gemini, AUDIT-WORKING-773921). A candidate Brief anchor.
- **Operations as a dynamical system on architectural state.** “Defining operations by their derivative on $\kappa_{\text{processing}}$ ($\dot{\kappa} < 0$ for truthification, $\dot{\kappa} > 0$ for the others) turns political and institutional dynamics into a formal dynamical system on the architectural state space” (Gemini, AUDIT-WORKING-773921). Compact gloss of what M4 *is*.

2. Candidate Discussion.

- **The truthification / strategic-self-coupling dual stated plainly.** The auditor read the goal-belief-axis dual as the segment’s high point: “Truthification (give up belief-piability for reality-tracking) and Strategic Self-Coupling (give up action-piability for commitment-credibility) are exact structural duals operating on opposite poles of the goal-belief axis” (Gemini, AUDIT-WORKING-773921). A candidate Discussion sharpening of the existing dual-relationships paragraph. (*The segment’s own Working Notes mark this dual at discussion-grade and flag lifting to robust-qualitative as requiring derivation from primitives — keep that scope-mark on any promotion.*)

3. Follow-up items.

- (None surfaced beyond what the segment’s Working Notes already track — the worked-example slot, the two sub-spike candidates, and the per-competence-axis amplification conjecture above already cover the auditor’s curiosity items.)

4. Readers often ask / wonder.

- **The Soviet / Lysenkoism worked example.** The auditor singled out the queued worked-example slot (spike-m4-worked-example-soviet-2026-05-24.md) as “the most ambitious domain transfer the framework has attempted so far” — modeling political-goal corruption of biological science as a directed-separation failure ($\kappa \rightarrow 1$) leading to a persistence-condition death spiral (Gemini, AUDIT-WORKING-773921). Confirms reader appetite for the worked example already slotted in the Working Notes above.

5. Candidate figures.

- (No dedicated figure proposed for this segment in the reached audit.)

Belongs elsewhere.

- **M4 as a unified vocabulary for institutional design / propaganda / behavioral economics.** The forward-vision claim: institutional design, propaganda analysis, and behavioral economics are “all just operations on $\kappa_{\text{processing}}$ ” — M4 as “the framework’s theory of institutional and political evolution,” breaking AAT “out of static analysis and into evolutionary dynamics” (Gemini, AUDIT-WORKING-773921). Aspirational reach for the field-positioning / framing layer, not a per-segment edit.
 - **Removed at candidate stage per FORMAT.md Gate 4.**

11.2 Discussion: Strategic Self-Coupling — Coupling as Action-Enabling

Some actions exist only under coupling. A threat is credible only when retreat has been foreclosed. The salesperson's sincere conviction enables persuasion that a modular-but-skeptical seller cannot match. The marathoner who runs to the finish is differently the same agent as the marathoner with backup plans. Religious practice, public commitment, vow-taking, oath-swearing, the binding of preferences to identity-norms — across these phenomena agents *deliberately decrease their own modularity* in exchange for access to actions otherwise unavailable. This is the *enabling polarity* of coupling-as-property — sister to #disc-adversarial-coupling-pressure's *vulnerability polarity*, opposite-valence operation on the same architectural state. The framework's static Class 1 / 2 / 3 partition under #der-directed-separation is the state space; strategic self-coupling is the *self-driven operation that moves the agent toward higher $\kappa_{\text{processing}}$ for offensive strategic reach* (the third operation in the three-operation modularity-state-dynamics picture; cf. #disc-adversarial-coupling-pressure §"Scope" table). Where adversarial pressure drives an opponent's coupling upward to *exploit* the expanded attack surface, strategic self-coupling drives the agent's own coupling upward to *acquire* an expanded action surface — the same architectural transition, opposite-direction strategic value.

The phenomenon.

The framework's policy specification — $\pi : (M_t, G_t) \rightarrow a_t$ selecting from a fixed action space $\mathcal{A}$ — implicitly treats actions as available independent of the agent's coupling state. In practice some actions are *credible only under coupling*: a commitment is a threat (or a promise) only when reversal is structurally costly; persuasion that depends on sincere conviction is unavailable to the deliberately-modular seller; coordination outcomes contingent on shared identity require the identity-coupling that makes deviation feel like self-betrayal rather than mere reconsideration. Treating $\mathcal{A}$ as fixed therefore mis-specifies the strategic landscape — it omits a class of actions rational agents may *choose to acquire by deliberately self-coupling*.

Discussion.

Four operational mechanisms recur across the literatures on commitment, intertemporal bargaining, identity economics, and emotion-as-commitment:

Table 11.3

<i>Mechanism</i>	<i>Coupling target</i>	<i>Strategic effect</i>
External commitment device (Schelling 1960 <i>The Strategy of Conflict</i> ; 1966 <i>Arms and Influence</i>)	physical, institutional, or public structure	Foreclose retreat — burn bridges, delegate to mechanism that cannot be revoked, make public stake whose withdrawal is costly. The credibility paradox: a threat is credible only when reversal is structurally costly, so commitment value <i>equals</i> uncoupling cost.
Intertemporal personal rule (Ainslie 1992 <i>Picoeconomics</i> ; 2001 <i>Breakdown of Will</i>)	between current-self and future-self decisions	Bind future-self behavior now — resolutions, personal rules, structured commitments — so the tempting-immediate-reward gradient cannot pull deviation when future-self encounters it. The agent treated as a population of temporally-displaced sub-agents who bargain; commitment via personal rule is the population-level coupling that stabilizes preference against hyperbolic-discount-induced reversal.
Identity coupling (Akerlof & Kranton 2000 <i>Economics and Identity</i> ; 2010 <i>Identity Economics</i>)	between preferences and internalized identity-norms	Adopt “being a certain kind of person” — identity-norms foreclose action-space choices that would violate identity. Identity-coupled preferences are stable in a way incentive-based preferences are not; identity gives behavior a stickiness no per-decision optimization predicts, which is precisely what enables credible in-group coordination and costly signaling.
Emotional commitment (Frank 1988 <i>Passions Within Reason</i>)	between rational calculation and affective response	Cultivate emotional dispositions — anger pre-commits retaliation, love pre-commits loyalty, guilt pre-commits restitution — whose <i>ex-post irrationality is precisely the source of ex-ante commitment credibility</i> . The calculating rational actor who would defect under sufficient incentive cannot match the credibility of the angry actor who will retaliate regardless.

Each mechanism corresponds to a specific structural pathway through which the agent commits to a coupling that subsequently *enables* an action class. The mechanisms differ in coupling target (external structure vs intertemporal vs identity vs affect) but share the same structural shape: forgo flexibility now to gain credibility-dependent actions later.

The enabling polarity.

#disc-adversarial-coupling-pressure's core treatment names coupling as *vulnerability* — coupling expands attack surface; adversaries drive opponent coupling because the additional ports through O_t and Σ_t become exploitable. This segment names the structurally opposite valence on the same architectural state: coupling expands the agent's *own* action surface — the actions that only exist under coupling become available, and the agent acquires them by deliberately driving its own $\kappa_{\text{processing}}$ upward.

Discussion.

The two segments are *opposite-valence operations on the same architectural state*. Modularity is neither always-good nor always-bad; it is *contested*. Adversaries press it down for exploitation; agents drive it down themselves for offensive reach; defensive scaffolding presses it back up (truthification). The three-operation picture is the structural recognition that the directed-separation property is *not a fixed feature* of an agent but a *dynamic property* that multiple structural operations act on.

The credibility paradox is the operational core. Schelling's foundational observation: a commitment's value derives from its costliness to reverse. If reversal is free, the commitment is not a commitment; it is mere announcement of intention, which an interlocutor with adversarial or skeptical interest will discount. Costly-to-reverse means the agent has *given up something* — flexibility, optionality, the ability to renegotiate — and the *amount given up* is what the strategic interaction reads as credibility. The structural meaning: coupling enables actions because coupling is *evidence* of the agent's binding to a course of action; an uncoupled agent cannot produce that evidence even by trying, because the uncoupling itself is recoverable.

Strategic value — the action-space expansion.

Three structural extensions to the framework's machinery characterize what strategic self-coupling commits to formally:

Discussion.

(M1) Coupling-dependent action space. The honest policy specification is

$$\pi : (M_t, G_t, \kappa_t) \rightarrow a_t, \quad a_t \in \mathcal{A}(\kappa_t) \quad (11.2)$$

with $\mathcal{A}(\kappa_t)$ non-decreasing in κ_t over a relevant range — additional actions become available as coupling increases. The set inclusion $\mathcal{A}(0) \subsetneq \mathcal{A}(\kappa_t)$ for $\kappa_t > 0$ is the structural recognition that the fixed- $\mathcal{A}$ framing in #der-directed-separation is a *scope-restriction*, not a complete specification. Strategic self-coupling is the operation that moves the agent from $\mathcal{A}(\kappa_0)$ to $\mathcal{A}(\kappa_1)$ with $\kappa_1 > \kappa_0$ in exchange for an enlarged feasible action set.

(M2) Coupling as strategic move in Σ_t . The strategy DAG of #def-strategy-dag carries causal-pathway claims about how actions affect objective-relevant outcomes. The enabling-polarity treatment requires a new edge type: nodes whose outcome variable is the agent's *own coupling state*, not an environmental quantity. An enabling edge represents “couple yourself to enable a^* ” — a meta-strategic move that modifies the agent's own action space so that a downstream strategy node becomes feasible. Schelling's commitment-device move is exactly this: a strategy node whose direct effect is *not* objective-advancement but is *enabling-of-credible-strategy* at later DAG layers. Formally this extends the strategy DAG's node semantics to include self-coupling moves alongside causal-pathway moves; the existing confidence-weighted edge machinery (#deriv-edge-credence-dynamics) is unchanged.

(M3) Reversibility cost asymmetry. The strategic value of self-coupling depends on its irreversibility:

$$c_{\text{couple}}(\kappa_0 \rightarrow \kappa_1) \ll c_{\text{uncouple}}(\kappa_1 \rightarrow \kappa_0) \quad (11.3)$$

The asymmetry's magnitude is the parameter that determines coupling's credibility. Without the asymmetry, the commitment is not a commitment — it is a recoverable announcement. The reversibility-cost asymmetry imports adjacent to *#der-deliberation-cost* as a special case of the think-vs-act cost framework, but the *direction* of the asymmetry (uncoupling vastly more expensive than coupling) is the structural commitment that distinguishes strategic self-coupling from ordinary deliberation.

The three extensions are interdependent. (M1) without (M2) provides coupling-dependent actions but no mechanism by which the strategy can acquire them. (M1)+(M2) without (M3) makes self-coupling free and trivializes the strategic question — recoverable coupling is not credible, and credibility is the value the operation acquires. All three are needed for the formalization to track what the prior-art literature names commitment device.

The non-monotonicity question — coupling is not monotonically enabling.

It is *not* the case that $\mathcal{A}(\kappa_t)$ is monotone-increasing in κ_t across the full range. The structural intuition: initial coupling enables credibility-dependent actions (Schelling-style commitments, conviction-enabled persuasion, identity-enabled coordination); sustained over-coupling forecloses reality-dependent actions (the fully-captured cult member or motivated-reasoning subject loses access to actions that require accurate world-perception). At some interior point, $\mathcal{A}(\kappa_t)$ achieves its maximum — coupling has gone far enough to enable commitment-dependent actions, but not so far that reality-tracking is foreclosed — and beyond that point further coupling subtracts from the feasible set.

Discussion.

The empirical shape of $\mathcal{A}(\kappa_t)$ is plausibly **inverted-U**: increasing over $[0, \kappa^*]$ (commitment-enabling range; the agent gains credibility-dependent actions); decreasing over $[\kappa^*, 1]$ (over-coupling range; the agent loses reality-dependent actions). The inflection κ^* depends on the action class — for actions whose value depends primarily on credibility, κ^* is closer to 1; for actions whose value depends on accurate reality-tracking, κ^* is closer to 0. The shape is *open* — the framework does not currently derive its functional form, and this segment honestly flags the non-monotonicity as a structural commitment without committing to its quantitative shape.

The non-monotonicity has substantive implications: rational self-coupling is *bounded*. An agent that couples without bound forfeits the reality-tracking the commitment was meant to advance the agent's interests *in*. Schelling's commitment devices preserve flexibility along axes orthogonal to the commitment's target; effective intertemporal personal rules constrain a specific behavior while leaving general adaptive capacity intact; identity coupling that becomes total is the cult-formation pathology in which the agent loses access to non-identity-conforming action. The cluster's discipline — across all four mechanisms — is *partial* coupling along strategically-chosen axes, not maximal coupling everywhere.

Reversibility cost as the source of credibility.

The (M3) asymmetry is not incidental to strategic self-coupling — it *is* the operational core. Schelling's foundational treatment is exactly this point: the strategic value of a commitment derives from the costliness of its reversal. The same structural observation runs through Ainslie's personal rules (rules whose violation is psychologically expensive because of the precedent-breaking cost across the population of future-selves), Akerlof-Kranton's identity coupling (defections from identity-norms incur the identity-cost of becoming “the kind of person who would do this”), and Frank's emotional commitment (the ex-post irrationality of emotional response is its ex-ante credibility — a calculating agent would defect under sufficient incentive; the emotional agent cannot match that calculating defection because the emotion overrides the calculation).

Discussion.

The recurring structural shape across the four mechanisms: the agent couples to something *less fungible* than the original preference state. Schelling's external mechanism is less fungible than verbal commitment (the mechanism cannot be talked out of executing); Ainslie's personal rule is less fungible than per-occasion choice (breaking the rule has cross-temporal precedent cost); Akerlof-Kranton's identity is less fungible than incentive-driven preferences (identity-norms carry self-recognition costs incentive-violation does not); Frank's emotion is less fungible than calculation (the emotional response is structurally compelled, not chosen per-instance). The strategic move is *exchange of fungibility for credibility* — give up the per-instance optimization choice in exchange for the credible-commitment value that per-instance optimization cannot produce.

This frames a useful diagnostic. A claimed commitment whose reversal would be *cheap* is not a commitment; an interlocutor with appropriate skepticism will discount it. The agent who wants to acquire commitment-credible actions must accept the structural cost of binding to something less fungible than their current preference state. The mechanism choice (external structure / intertemporal rule / identity / emotion) determines *what kind* of fungibility is given up; the amount of fungibility given up determines the credibility acquired.

Asymmetric advantage in repeated strategic interaction.

Mirror to #disc-adversarial-coupling-pressure's asymmetric-advantage section: in repeated interaction, when two agents face each other, each has structural incentive to (a) acquire credibility-dependent actions through strategic self-coupling and (b) deny the opponent access to those same actions by undermining their commitments. The self-coupled agent acquires actions that the uncoupled opponent cannot match; the uncoupled opponent faces commitments that incentive-based negotiation cannot dissolve. If the asymmetry is sustained, the self-coupled agent compounds strategic reach — its commitments are read as credible; its threats and promises bind; its negotiating position is bounded below by its commitment, not above by its current incentive-state.

Discussion.

The asymmetric-advantage shape is dual to the adversarial-pressure case: there, the more-modular agent compounds informational advantage (cleaner observations of the less-modular opponent); here, the more-self-coupled agent compounds *strategic* advantage (credible threats and promises the uncoupled opponent cannot match). The two asymmetries can coexist — an agent might be defensively modular against adversarial information attacks *and* offensively self-coupled in narrow strategic axes (the diplomat who is genuinely informed about reality but credibly committed to specific positions; the negotiator whose information-processing is clear but whose walk-away point is structurally fixed). The architectural states are not contradictory — different axes of $\kappa_{\text{processing}}$ can carry different operations.

This is *structural* asymmetry rather than tactical: the operations on modularity state are not single-instance moves but *durable architectural commitments* that shape long-run interaction. The agent who has self-coupled to specific commitments is *that agent* for the duration of the coupling; reversing requires paying the (M3) uncoupling cost; sustained interaction therefore reads the commitments as fixed and adapts strategy accordingly. The self-coupled agent's strategic position is fundamentally different from the uncoupled agent's, in a way that incentive-based negotiation cannot capture.

Boundary with adversarial coupling pressure.

The boundary between strategic self-coupling (self-driven coupling-increasing) and adversarial coupling pressure (externally-driven coupling-increasing) blurs in practice. The cult-formation literature documents the canonical case: what begins as adversarial pressure (an external party manipulating the target's environment, social ties, information access) can be internalized as identity-coupling, after which the target perceives the coupling as self-driven and the line between operations is no longer cleanly drawn at the agent's experience. The behavioral signature of an agent at high $\kappa_{\text{processing}}$ may

not distinguish the two; the *structural* distinction (driver: self vs external) is recoverable only with information beyond the agent's behavior.

Discussion.

The framework's posture on the boundary: the *operations* are structurally distinct (driver is part of the operation's identity); their behavioral consequences can converge; the boundary is empirical when only behavioral signature is available; the boundary is structural when driver-history is observable. Cult-formation, social engineering at the identity-modification level, and propaganda-induced identity-binding all sit at the boundary; sustained successful pressure produces an agent who would internally classify the resulting coupling as self-chosen. The framework's machinery does *not* attempt to resolve the boundary at the level of agent experience — it characterizes the two operations as structurally distinct and admits that behavioral convergence is honest scope.

The relationship to truthification.

Strategic self-coupling is structurally the *dual* of truthification at a different layer of the agent. Truthification (instantiated via #der-class-coercion-via-wrapping and the institutional-scaffolding construction in #disc-adversarial-coupling-pressure §"Defensive scaffolding") is structural commitment to *goal-blind belief-update* — the W_1 strict wrapper commits the composite to operate Class 1 (Separated) at the belief-update layer by structurally foreclosing the goal-conditioned-update pathway. Strategic self-coupling is structural commitment to *goal-conditioned action-selection* — the commitment-device move commits the agent to operate in a particular action subspace by structurally foreclosing the deliberation-can-revise-this pathway.

Discussion.

Both are *wrapping constructions in the broader sense*. Both work by structural commitment that gives up flexibility along one axis in exchange for a different value along another. The two operations are duals: truthification gives up belief-pliability to gain reality-tracking; strategic self-coupling gives up action-pliability to gain commitment-credibility. The directed-separation property is foreclosed differently by each — truthification *restores* the separation at the belief-update layer; strategic self-coupling *deliberately weakens* it at the action-selection layer (specifically, the action-selection now depends on a coupled state κ_t that constrains $\mathcal{A}$, which is structurally a goal-conditioned narrowing of the action choice).

This dual relationship is structurally illuminating: both operations are deliberate departures from full architectural flexibility, in opposite directions on the goal-belief separation axis. The framework's epistemic-honesty discipline runs through both — truthification commits to *not letting goals corrupt belief*; strategic self-coupling commits to *letting goals constrain action* in stable, credible ways.

Epistemic Status.

Discussion-grade at the structural-recognition level. The segment articulates an extension of the framework's machinery (coupling-dependent action space; strategy-DAG enabling edges; reversibility-cost asymmetry) and adopts prior-art concepts (Schelling commitment devices, Ainslie personal rules, Akerlof-Kranton identity coupling, Frank emotions-as-commitment) as first-class theory components. The substantive claims are inherited from the prior-art literature at their original tiers:

- The credibility paradox (commitment value = uncoupling cost) is *exact* in Schelling's game-theoretic formalization for the stated mechanism-design setting; it is *robust qualitative* at AAT's level of abstraction (no AAT-internal derivation; the structural claim transfers across the four mechanisms).
- The inverted-U shape of $\mathcal{A}(\kappa_t)$ is *empirical / discussion-grade* — argued structurally, instantiated across the prior-art literatures, not derived from AAT primitives. Promotion would require a derived condition on the inflection point as a function of action-class composition.

- The reversibility-cost asymmetry is *robust qualitative* — observed across all four mechanisms, structurally derivable from the credibility-paradox observation.
- The dual relationship with truthification is *discussion-grade* — structural recognition that both operations are wrapping constructions in opposite directions on the goal-belief separation axis; the formal duality has not been derived.

Max attainable: *robust qualitative* for the structural pattern across the four mechanisms (the cross-mechanism convergence on the credibility-paradox shape is the kind of structural-recognition claim that promotes to robust-qualitative under careful prior-art search); *discussion-grade* for the inverted-U shape claim (promotion to *empirical* requires named domain-specific instantiation, e.g., the bounded-rationality literature’s empirical work on self-control reversals); *conditional-derived* for the dual-with-truthification recognition only if the formal duality is worked out.

Discussion.

The mirror-image relationship with #disc-adversarial-coupling-pressure. The two segments cover opposite-valence operations on the same architectural state. Adversarial pressure: externally-driven, vulnerability-creating, coupling expanding attack surface. Strategic self-coupling: self-driven, action-enabling, coupling expanding the agent’s own offensive reach. The two segments’ structural parallelism is deliberate — same architectural state ($\kappa_{\text{processing}}$ per #der-directed-separation), same operation direction (increasing κ), opposite driver (external vs self) and opposite strategic valence (vulnerability vs enabling). The framework’s third operation — truthification — is the opposite-direction operation (decreasing κ), instantiated via #der-class-coercion-via-wrapping (component-level wrapping) and #disc-adversarial-coupling-pressure §”Defensive scaffolding” (composite-level scaffolding). Together the three operations form the three-operation modularity-state-dynamics picture canonicalized at #disc-modularity-state-dynamics.

Connection to #norm-explicit-strategy-condition. The segment’s central operation — choosing to self-couple — is a strategic decision the agent makes about its own architecture. This connects to the explicit-strategy normative condition: when does the agent gain from deliberate strategy formation vs reactive exploration? Strategic self-coupling adds a new dimension to that question: when does the agent gain from deliberate *self-modification of architecture* vs leaving the architecture in its default state? The cost-benefit threshold for explicit strategy (#norm-explicit-strategy-condition) needs an analog for the self-coupling case — when does the credibility value of acquired actions exceed the structural cost of the coupling (the lost flexibility, the (M3) uncoupling cost amortized over the expected coupling duration)? An honest framing of the question is open; the segment names the structural dependency without deriving the threshold.

Composition consistency under self-coupling. Self-coupling within an agent may be analyzed as a composition move via #disc-composition-consistency. Ainslie’s intertemporal-bargaining framing makes this explicit: the agent treated as a population of temporally-displaced sub-agents who bargain; the personal rule is a coupling between current-self and future-self that fixes the future-self’s behavior in advance. The composite-agent reading: the agent at time t couples to its future-self at $t + 1$ by committing now to constrain $t + 1$ behavior. Formally this is a composite-agent move where the sub-agents are temporal slices of the same physical agent and the coupling is the personal-rule commitment. The connection is real but the formalization is open — the temporal-composite reading is suggestive but does not derive without explicit machinery for composite-agents-across-time. Worth following if the segment’s downstream uses make this connection load-bearing.

The action-space-as-coupling-state-dependent formalization $\mathcal{A}(\kappa_t)$ as the load-bearing structural extension. Of the three structural moves (M1)–(M3), the (M1) extension is the most consequential for downstream framework reach. Once the framework admits coupling-dependent action spaces, a range of phenomena currently outside the framework’s analytical surface become legible: commitment-device strategy; identity-driven coordination; emotion-as-strategic-resource; ritual and oath-taking as structural-commitment operations; institutional design that creates coupling-dependent action sets for collective actors. (M2) and (M3) are the supporting machinery. A future cycle that derives concrete

results from (M1) — e.g., a sector-condition analog for coupling-dependent action sets, or a persistence-condition variant for agents with non-stationary $\mathcal{A}(\kappa_t)$ — would promote this segment from discussion-grade to derived-conditional. The structural extension is the recognition; downstream derivation is the natural follow-on.

Findings.

Strategic Self-Coupling as the Enabling Polarity of Coupling-as-Property. **Brief:** When you make a promise that everyone can see, when you burn the bridge behind your army, when you adopt an identity that makes certain choices feel like betrayal of who you are, when you cultivate the kind of anger that *will* retaliate even when retaliation costs you — you are deliberately giving up flexibility. The thing you give up has a strategic value the flexibility could not produce. A threat that you could costlessly withdraw is not a threat; an opponent will ignore it. A promise you could renegotiate at any moment is not a promise; a partner will not bet on it. Across very different domains — Schelling’s commitment devices in international strategy, Ainslie’s personal rules in self-control, Akerlof and Kranton’s identity coupling in economics, Frank’s emotions as commitment devices — the same structural shape recurs: agents acquire credibility-dependent actions by coupling to something less fungible than their current preference-state, and the strategic value of the action they acquire is precisely the cost of reversing the coupling. The framework’s static picture of an agent’s modularity as architectural property is incomplete; modularity is a *contested, cultivated, and constructed* property that agents act on for their own strategic reasons. Adversaries press it down for exploitation (#disc-adversarial-coupling-pressure); agents press it down themselves for offensive reach (this segment); defensive scaffolding presses it back up (the truthification operation). All three are operations on the same state-space; what they do to it differs in driver and direction.

Impact: Names the second of three operations in the modularity-state-dynamics three-operation picture (cf. #disc-modularity-state-dynamics). Surfaces the framework’s previously-implicit fixed- $\mathcal{A}$ assumption (flagged in #disc-adversarial-coupling-pressure §”Scope”) and characterizes the structural extension required to handle coupling-dependent action spaces — the (M1)–(M3) extensions (coupling-dependent action space; strategy-DAG enabling edges; reversibility-cost asymmetry). Recognizes the mirror-image relationship with #disc-adversarial-coupling-pressure: same architectural state ($\kappa_{\text{processing}}$), same operation direction (increasing κ), opposite driver and opposite strategic valence. Identifies the *dual relationship* with truthification — both are wrapping-construction-style structural commitments giving up flexibility along one axis for value along another, but operating on opposite poles of the goal-belief separation. The dual recognition is structurally illuminating: the framework’s epistemic-honesty discipline runs through both — truthification commits to not letting goals corrupt belief; strategic self-coupling commits to letting goals constrain action in stable, credible ways. Opens the framework’s reach to a class of phenomena (commitment-device strategy, identity-driven coordination, emotion-as-strategic-resource, ritual and oath-taking, institutional commitment design) that the fixed-action-space framing did not admit.

Novelty Claim: *Claim recognition* of strategic self-coupling as a structurally-distinct operation on modularity state, sister to and opposite-valence with adversarial coupling pressure (#disc-adversarial-coupling-pressure); *claim differentiation* on the (M1)–(M3) structural extensions required to formalize the operation in AAT’s machinery (coupling-dependent action space, strategy-DAG enabling edges, reversibility-cost asymmetry); *claim transfer* of established commitment-device and identity-economics machinery into AAT’s analytical surface as first-class theory components. The empirical phenomena (Schelling commitment, Ainslie personal rules, identity coupling, emotional commitment) are well-documented in the cited literatures; the contribution is naming their place in AAT’s scope architecture, the structural extensions required, and the mirror-image relationship with adversarial coupling pressure that situates both operations within the three-operation modularity-state-dynamics taxonomy.

(2000), “Economics and Identity,” <i>Quarterly Journal of Economics</i> 115(3):715–753; (2010), <i>Identity Economics: How Our Identities Shape Our Work, Wages, and Well-Being</i> , Princeton University Press (found pre-2026)	<i>formal antecedent</i> — adopted with citation; identity-utility-term as the formal hook for identity-coupled preferences; in-group coordination and costly signaling as the action class identity coupling enables
Emotions as commitment	Frank, R. H. (1988), <i>Passions Within Reason: The Strategic Role of the Emotions</i> , W. W. Norton (found pre-2026)	<i>formal antecedent</i> — adopted with citation; the ex-post-irrationality-equals-ex-ante-credibility structural observation; complement to Schelling for the <i>internal</i> -affective coupling case
Self-binding taxonomy	Elster, J. (1979), <i>Ulysses and the Sirens: Studies in Rationality and Irrationality</i> , Cambridge University Press; (2000), <i>Ulysses Unbound: Studies in Rationality, Precommitment, and Constraints</i> , Cambridge University Press (found pre-2026)	<i>adjacent literature</i> — survey treatment cataloguing forms of precommitment across psychology, politics, and law; useful for taxonomic comparison but not directly adopted
Evolution of commitment in social contracts	Skyrms, B. (1996), <i>Evolution of the Social Contract</i> , Cambridge University Press; (2004), <i>The Stag Hunt and the Evolution of Social Structure</i> , Cambridge University Press (found pre-2026)	<i>adjacent literature</i> — evolutionary game-theoretic treatment of commitment supporting cooperation; useful for population-dynamics layer when self-coupling becomes a population-level phenomenon (norms, institutions); Part III population-scope work could engage
Sister segment — vulnerability polarity	#disc-adversarial-coupling-pressure (this framework, 2026-05)	<i>sibling internal segment</i> — opposite-valence operation on the same architectural state; the structural-parallelism is deliberate; both operations are part of M4’s three-operation modularity-state-dynamics taxonomy at #disc-modularity-state-dynamics
Truthification operation — dual relationship	#der-class-coercion-via-wrapping (this framework); #disc-adversarial-coupling-pressure §”Defensive scaffolding” (this framework)	<i>internal antecedent</i> — the third M4 operation, structurally dual at the goal-belief separation axis (truthification commits to goal-blind belief-update; this segment’s operation commits to goal-conditioned action-selection)

Search Log:

- 2026-05-24 (*targeted, segment-grade*): Prior-art adoption work per the spike (spike-strategic-self-coupling.md §2.1 direct adoption candidates + §2.2 adjacent literatures). Primary citations imported at segment-grade — one-line characterizations plus full bibliographic citations; primary-source verification scheduled when the segment advances past draft. The structural recognition (four mechanisms instantiating one cross-domain pattern) is named here for the first time at the AAT-internal level; targeted future search candidates: (a) whether any prior synthesis names commitment-device / identity coupling / willpower / emotions-as-commitment as instances of one structural operation under formal nomenclature; (b) whether the action-space-as-coupling-state-dependent formalization $\mathcal{A}(\kappa)$ has been written down in active-inference or bounded-rationality literatures; (c) whether the dual-with-truthification framing has appeared in any framework engagement with the goal-belief separation question. Expected outcome: the constituent moves are well-precedented at the textbook level; the cross-mechanism unification as an operation on modularity state alongside its adversarial-pressure dual appears to be a fresh presentational recognition.
- 2026-05-09 (*intuition-only on the cross-domain unification*): The structural recognition that the four mechanisms (Schelling commitment, Ainslie personal rules, Akerlof-Kranton identity coupling, Frank emotional commitment) instantiate one structural operation at different coupling targets is named here. The spike (spike-strategic-self-coupling.md) established the recognition; this segment lands it canonically with the cross-domain pattern documented.

Working Notes.

- **Provenance.** Authored 2026-05-24 as Move 3 of the M4 modularity-as-contested-property cycle (msc/modularity-cycle-plan-2026-05-09.md §3 Move 3; PRACTICA priority #2). The spike at spikes/spike-strategic-self-coupling.md (2026-05-09) established the (P1) primary-segment scope, prior-art landscape, and (M1)–(M3) structural extensions; this segment lands the (P1) product. Move 4 — the M4 meta-segment #disc-modularity-state-dynamics — lands in the cycle's same commit cluster.
- **Open before candidate.** (a) Primary-source verification of the four canonical citations (Schelling 1960/1966, Ainslie 1992/2001, Akerlof-Kranton 2000/2010, Frank 1988). The segment imports at segment-grade depth; direct primary-source reading is queued. (b) The non-monotonicity / inverted-U shape of $\mathcal{A}(\kappa_t)$ is presented as a structural observation; a derived condition on the inflection point κ^* as a function of action-class composition would promote the claim from *discussion-grade* to *empirical* or *conditional-derived*. Open. (c) The reversibility-cost asymmetry's relationship to #der-deliberation-cost is named as adjacent but not formally derived; a derivation showing the asymmetry as a special case of deliberation-cost asymmetry under structural-commitment conditions would tighten the connection. (d) The composition-consistency reading of Ainslie's intertemporal bargaining (#disc-composition-consistency applied to temporally-displaced sub-agents) is suggestive but unformalized.
- **Cluster context.** This segment is the second-leg of M4 (#disc-modularity-state-dynamics). Move 4 — landing the M4 meta-segment itself — depends on this segment being in place. The meta-segment integrates this segment + #disc-adversarial-coupling-pressure (the first leg, landed earlier in the cycle) + the truthification mechanism via #der-class-coercion-via-wrapping and #disc-adversarial-coupling-pressure §"Defensive scaffolding".
- **Possible appendix companions** (per the spike §5 candidates P2 and P4). (P2) def-coupling-dependent-action-space — formalization appendix carrying $\mathcal{A}(\kappa_t)$ definition + monotonicity range + relationship to architecture classification + worked examples from prior art. (P4) Reversibility-cost-asymmetry formalization — only useful if it grounds a substantive derived result. Both deferred until the discussion-grade landing here gains downstream load-bearing uses.
- **Indexed at spike-proposals.** A sub-spike candidate flagged from this segment for spikes/PROPOSED.md consideration: the *inverted-U shape derivation* — deriving the inflection point κ^* from action-class composition (the fraction of credibility-dependent vs reality-dependent actions in the agent's relevant action space) as a function whose form predicts the agent's rationally-chosen self-coupling level. Open framework-extension question; appropriate as a Tier 2 / Tier 3 row when M4 lands and surfaces this as a follow-on.

- **Boundary with cult-formation literature.** The §”Boundary with adversarial coupling pressure” section flags that the line between self-driven and adversarial-driven coupling blurs at the agent’s level of experience (cult-formation; identity-conversion under sustained adversarial pressure). The framework’s posture is that the *operations* are structurally distinct (driver: self vs external) but their behavioral consequences can converge. Targeted follow-on work for that boundary lives in cult-formation literature (Lifton 1961 *Thought Reform and the Psychology of Totalism*; Singer 1995 *Cults in Our Midst*) which the segment cross-references at adjacent-literature depth.
- **Migration note (2026-05-09 GUC rename):** $\kappa_{\text{processing}}$ vocabulary is unchanged across the rename (the broader vocabulary lives at the operation level, not the Class label). The segment uses Class 1 (Separated) / Class 2 (Partial) / Class 3 (Coupled) in current canon vocabulary throughout. Removed at candidate stage per FORMAT.md Gate 4.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, kept separate from the certified theory-fix findings. **Coverage:** as a late-authored Meta-Architecture II segment, only the deepest de-novo walk (773921, Gemini) reached it under its current slug — thin and single-substrate by expectation. Substrate attribution from the audit dir.

1. Candidate Brief prose / pre-prose.

- **Why perfect rationality is a handicap** — the auditor’s one-line framing of the segment’s payload: “a purely modular, perfectly rational, uncoupled agent is actually strategically handicapped in multi-agent environments because it cannot make credible promises or threats” (Gemini, AUDIT-WORKING-773921). A candidate Brief opener that inverts the naive “coupling is bad” reading.
- **The credibility paradox in words:** “a commitment’s value equals its uncoupling cost” — the prose gloss of the strict inequality $c_{\text{couple}} \ll c_{\text{uncouple}}$ (Gemini, AUDIT-WORKING-773921).

2. Candidate Discussion.

- **Emotions as commitment technology** (*strongest framing candidate here*). “Defining an emotion (like anger or love) as ‘coupling between rational calculation and affective response that trades fungibility for credibility’ mathematically explains why humans have emotions: an angry person who will retaliate regardless of cost is a more credible deterrent than a perfectly rational calculator who will accept a bribe” (Gemini, AUDIT-WORKING-773921, on the Frank 1988 leg). A candidate Discussion sharpening — the segment already adopts Frank; this is a pedagogically vivid restatement of *why* the affective-commitment leg matters.
- **The inverted-U as the framework finding its own limits.** The auditor read the $\mathcal{A}(\kappa_t)$ inverted-U (too much coupling eventually destroys reality-dependent actions $\rightarrow$ “cult-like delusion”) as “an excellent example of the framework finding the natural limits of its own operations” (Gemini, AUDIT-WORKING-773921). Candidate framing for the non-monotonicity Discussion.

3. Follow-up items.

- **Self-control as single-agent composition** — the auditor amplified the segment’s own Working-Note (d): treat an individual over time as a *composite agent* of temporally-displaced sub-agents (Self-at- t_1 , Self-at- t_2), so a personal rule (“I will not smoke”) is an inter-agent coupling agreement and AAT’s multi-agent composition math (11) applies directly to single-agent self-control (Gemini, AUDIT-WORKING-773921). Convergent confirmation that Working-Note (d)’s Ainslie / composition-consistency reading is worth formalizing.

4. Readers often ask / wonder.

- (No distinct reader-question surfaced beyond the items above in the reached audit.)

5. Candidate figures.

- (No dedicated figure proposed for this segment in the reached audit.)

Belongs elsewhere.

- **A unified vocabulary for institutional design.** Forward-vision: “contracts, constitutions, and cultural norms are all just technologies for manipulating $\kappa_{\text{processing}}$ to unlock new regions of the action space,” and the segment “mathematically formalizes why perfect rationality is evolutionarily unfit for social environments” (Gemini, AUDIT-WORKING-773921). Aspirational reach for the M4 framing layer (11.1) / field-positioning, not a per-segment edit.

11.3 Discussion: Adversarial Coupling Pressure

In adversarial settings, opponents do not merely deceive through the observation channel; they apply strategic pressure that drives a target *across architectural classes* — from Class 1 (Separated) toward Class 3 (Coupled). Coupling is itself an attack surface: a Class 1 (Separated) agent can be deceived only through the observation channel, while a GUC-Coupled agent exposes additional input ports through O_t and Σ_t . The result is a use-case expansion for 03-11m-core’s coupled formulation: the population that needs coupled-formulation analysis is broader than the architecturally-coupled. Any agent under sustained adversarial pressure that can drive its $\kappa_{\text{processing}}$ upward sits in the same scope, regardless of native class.

The phenomenon.

A Class 1 (Separated) agent’s f_M accepts inputs only through the event stream; its O_t and Σ_t have no legitimate input port from outside that stream. An adversary’s only attack channel is engineered observation ambiguity, and the bias they can induce is bounded by #deriv-observation-ambiguity-bias-bound’s constant C relative to the ambiguity they can manufacture.

Discussion.

A GUC-Coupled agent — Class 3 (Coupled), or Class 2 (Partial) with active $O_t \rightarrow M_t$ pathways — exposes additional channels. Three operational mechanisms recur across the literatures on propaganda, social engineering, marketing, and influence operations:

Table 11.5

<i>Mechanism</i>	<i>Channel exploited</i>	<i>What the adversary does</i>
Identity-binding	$O_t \rightarrow M_t$	Make the target <i>want</i> the false belief to be true (bind belief to identity, group membership, self-image). Revising M_t now requires revising O_t , raising the cost of correction.
Affect / urgency	bypass deliberate f_M	Manufacture time pressure or affective load that prevents the orient cascade from running cleanly; the agent acts before M_t updates resolve.
Sunk-cost engineering	$\Sigma_t \rightarrow M_t$	Induce the target to commit publicly or expensively to a strategy; subsequent M_t revisions that would invalidate Σ_t now carry a coupled cost (admit prior commitment was wrong), and the coupling bends M_t revision instead of Σ_t revision.

Each mechanism corresponds to a specific structural pathway through which adversary-controlled signals act on M_t via O_t or Σ_t — not through the legitimate observation channel.

Diagnostic corruption is directional.

The satisfaction-gap / control-regret split is silently corrupted under adversarial coupling pressure, and the corruption is *directional*: a competent adversary biases the diagnostic predictably rather than randomly.

Derived (Conditional on directional adversary objective; from #def-satisfaction-gap, #def-control-regret + adversarial-pressure mechanisms above).

If the adversary's interest is the target's continued effort along an unproductive axis, they bias the reading toward control regret — “the goal is right, try harder.” The target compounds effort where it cannot pay, while the adversary extracts whatever value the effort produces (attention, emotional engagement, financial commitment, political mobilization).

If the adversary's interest is the target's *withdrawal* from an axis they could win, they bias the reading toward satisfaction gap — “the goal was wrong, give up.” The target abandons achievable wins; the adversary captures the unclaimed ground.

Manufactured-outrage cycles instantiate the first; engineered-helplessness and demoralization campaigns instantiate the second. Both are *diagnostic capture*, not just deception about world-state — the target is reading a corrupted diagnostic and confidently acting on it.

Cascade inversion.

The orient cascade resolves observation $\rightarrow M_t \rightarrow \Sigma_t \rightarrow O_t$ in that order, with O_t revising only when forced. Adversarial coupling pressure inverts the cascade: the adversary acts on O_t first (manufacture desire / identity-stake / urgency), which forces Σ_t to align, which then makes legitimate observations flow *against* the gradient and get rejected as inconsistent with the now-committed Σ_t . The cascade still runs, but its information dependency is reversed — and in that reversed form, observation contradicting the pre-loaded objective is the *least* legitimate input the agent will accept.

Derived (Conditional on adversary controls O_t -targeted signal injection; from #der-orient-cascade).

Population expansion for coupled formulation.

The Class 3 (Coupled) formulation handed off to 03-llm-core/ was originally scoped to agents whose native architecture is non-modular: LLMs whose attention processes goals and observations together; biological cognition with motivated-reasoning pathways. Adversarial coupling pressure expands this population: a Class 1 (Separated) organization without internal $O_t \rightarrow M_t$ pathways but operating in a hostile information environment that targets its leadership's identity and commitments is, for analytical purposes, in the coupled-agent population during that engagement. The native architecture is irrelevant once the coupling exists in operation.

This is a *use-case expansion*, not a derivation expansion: the coupled-formulation machinery does not need new content for this case. What's new is the recognition that the population is broader than architecture-determined.

Scope: implicit assumptions and the polarity of coupling.

This segment covers one polarity of coupling-as-property — the *vulnerability* polarity, in which decreased modularity is externally driven and produces attack surface. Two implicit assumptions in the framework's machinery back the scope; both are worth surfacing rather than leaving hidden.

Discussion.

Bounded signaling. The framework formally restricts the $G_t \rightarrow$ world channel to action selection $a_t = \pi(M_t, G_t)$. A coarse $\mathcal{A}$ implicitly assumes π is sufficiently many-to-one — or the agent's behavioral signature sufficiently bandwidth-restricted — that observers cannot recover G_t from observable behavior alone. In practice the agent's full behavioral signature (micro-expressions, prosody, attention patterns, vocabulary choice, hormonal signals, response latencies) leaks

G_t at much higher bandwidth than the discrete-action channel suggests. Against capable adversarial inferers the bounded-signaling assumption fails, and this is part of *why* the bias bound's C becomes adversarially-tight in the §"Discussion" reframing: sophisticated adversaries effectively read G_t and target identity-bindings precisely. The assumption sits formally in #der-directed-separation's agent-world interface; it is not yet surfaced there as a load-bearing scope statement, and surfacing it back-pressures that segment as a follow-on item.

Fixed action set independent of coupling. The action space $\mathcal{A}$ in the policy $\pi(M_t, G_t) \rightarrow a_t$ does not depend on the agent's coupling state. This implicitly assumes the actions available to the agent are independent of $\kappa_{\text{processing}}$. In practice, some actions exist *only* under coupling: Schelling-style commitment devices (where credibility requires foreclosed retreat); the salesperson whose sincere conviction enables persuasion that the modular-but-skeptical salesperson cannot match; the marathoner who can run the race only because retreat options have been burned; religious practice requiring coupled belief-and-action; identity-economics models where coupled identity unlocks coordination outcomes. Coupling is not just a *cost*; it is also *enabling*. Treating $\mathcal{A}$ as fixed therefore mis-specifies the strategic landscape — it omits a class of actions that rational agents may *choose* to acquire by deliberately self-coupling, and it forces the framework to read all coupling as failure mode.

Three operations on modularity state. Together with the segment's core treatment of adversarial coupling pressure, the two assumptions surface a clean three-operation picture of modularity-state dynamics:

Table 11.6

<i>Operation</i>	<i>Driver</i>	<i>Effect on modularity</i>	<i>Effect on agent</i>
Truthification	self-driven	increases	restores diagnostic; opens Part II results; instantiated by <i>defensive scaffolding</i> below
Strategic self-coupling	self-driven	decreases	<i>enables</i> actions otherwise unavailable (credibility, conviction, commitment)
Adversarial coupling pressure	externally-driven	decreases	<i>creates vulnerability</i> (this segment's core treatment)

This segment's primary subject is the third operation. The first operation is instantiated in §"Defensive scaffolding as composition" below — institutional scaffolding as the truthification leg of the three. The second operation is currently outside the framework's machinery; see Working Notes for the candidate sister segment and the candidate three-operation meta-segment.

Defensive scaffolding as composition.

Restoring modularity under adversarial pressure is structurally a Part III move. Institutional scaffolding — peer review, prediction registers, double-entry bookkeeping, adversarial procedure, prediction markets, source-authentication discipline, structured red-teaming — constructs a composite agent (*individual + scaffolding*) with better Class 1 (Separated) properties than the bare individual, even when the individual's native architecture is Class 3 (Coupled) or driven there by adversarial pressure. The scaffolding externalizes channels of the orient cascade (belief-update checked by parties whose O_t doesn't share the individuals; prediction registers fixing M_t -claims before outcomes resolve; adversarial procedure forcing the feasibility check) so that resolution can run sequentially across the composite even when it cannot run sequentially within any single component.

Discussion.

The defensive composite recovers architectural modularity at the composite level whose properties exceed those of its sub-components — the routing-structure-driven side of the axis-decomposed composite-class-inheritance table in

#der-directed-separation Discussion: when the routing (the scaffolding's institutional protocol) is structured to externalize orient-cascade channels, a composite of Class 3 (Coupled) sub-agents (or sub-agents under adversarial pressure toward Class 3) acquires Class 1 (Separated) or Class 2 (Partial) properties at the composite level. This is the operational dual of the wrapping construction (**#der-class-coercion-via-wrapping**): wrapping operates at the *component* level by externally scaffolding a single component; defensive scaffolding operates at the *composite* level by structuring the routing across components. Both move the composite class along Axis A (architectural class per **#der-directed-separation**), independently of the dynamic-regime axis (**#disc-dynamic-regime-axis**) where goal-alignment effects live.

Epistemic Status.

Discussion-grade at the structural-recognition level. The segment articulates a use-case expansion of existing machinery rather than a derivation of new machinery; the substantive claims are inherited from upstream segments at their tiers:

- The Class 1 / 2 / 3 (Separated / Partial / Coupled) partition and $\kappa_{\text{processing}}$ measure are *robust qualitative* per **#der-directed-separation**.
- The bias bound that adversarial pressure attempts to saturate is *conditional* per **#deriv-observation-ambiguity-bias-bound** (under named sub-scopes).
- The diagnostic-corruption directionality is *robust qualitative*: it follows from **#def-satisfaction-gap** and **#def-control-regret** being arithmetic identities once the value objects are fixed, plus the structural observation that adversary preferences are typically directional rather than random; the directional bias is empirically observable across propaganda and influence-operation case studies.
- The orient-cascade inversion claim is *robust qualitative* — it follows from **#der-orient-cascade**'s information dependency under the explicit hypothesis that the adversary controls O_t -targeted signal injection.

Max attainable: *robust qualitative* for the structural pattern; the specific mechanism table is empirical (instantiated by propaganda, security, and influence-operation literatures) and would be promoted to *empirical* with named domain citations once a targeted prior-art search has been conducted.

Discussion.

This is the offensive complement to directed-separation-as-defense. **#der-directed-separation** characterizes modularity as architectural property. This segment names modularity as *contested* property under adversarial pressure: the architecture's modularity is what the adversary is trying to perforate, and what defensive scaffolding is trying to preserve or restore. The two segments together complete the picture — modularity is what the architecture enables (or fails to enable), and modularity is what the adversary attacks (or fails to attack).

Asymmetric advantage compounds in repeated interaction. When two agents face each other, each has structural incentive to (a) reduce its own coupling (defensive scaffolding) and (b) increase the opponent's coupling (offensive pressure). If the asymmetry is sustained, the more-modular agent gets clean observations of the less-modular agent's behavior — informative M_t updates that the bias bound's C does not impose — while the less-modular agent gets contaminated observations of the more-modular agent and bends M_t toward whatever pre-loaded objective the adversary engineered. The more-modular agent compounds informational advantage; the less-modular agent compounds bias. In repeated interaction with sustained asymmetry, this is *structural* rather than tactical advantage — modularity asymmetry produces strategic asymmetry.

Reframing the Class 3 (Coupled) bias bound's operational meaning. **#deriv-observation-ambiguity-bias-bound**'s constant C is presented in that segment as a worst-case bound. Adversarial coupling pressure reframes C as a *target* the adversary actively tries to saturate by engineering observation ambiguity to its maximum admissible value. Under sustained adversarial engineering, the bound is not slack — it is approached. This affects how the bound should be interpreted operationally: in non-adversarial settings, the bound is conservative; in adversarial settings, it is approximately

tight under competent adversarial design. Whether the bound *can* be saturated depends on what the adversary controls (the observation channel's ambiguity-engineering bandwidth); under unrestricted adversarial control the saturation is essentially complete.

Connection to the separability pattern. The architectural classification ladder of #disc-separability-pattern reads adversarial coupling pressure as an *operational* driver of population movement along the ladder: Class 1 (Separated) agents under sustained adversarial pressure functionally migrate toward the Class 3 (Coupled) / general-open tier for the duration of the engagement, even though their native architecture remains Class 1 (Separated). The structured-repair tier (Class 2, Partial) is then the natural home for *defensive scaffolding* — the explicit added machinery that restores identification under adversarial conditions. The separability pattern's three-tier shape is therefore not just a static catalog of architectural types; it is a phase-space across which adversarial pressure and defensive scaffolding move populations.

Findings.

Adversarial Coupling Pressure as Use-Case Expansion of Coupled Formulation. Brief: Adversaries do not just lie; they reshape the *architecture* of the agent they are attacking. A Separated agent (Class 1) — one whose beliefs update from observation alone — can only be deceived through what it sees; the adversary's reach is bounded. But an agent whose beliefs are bent by what it wants to be true exposes new attack surface: every channel through which the adversary can act on what the target wants, or on what plan the target has committed to, becomes a way to reach the target's beliefs without going through legitimate observation. Practical mechanisms — identity-binding, manufactured urgency, sunk-cost engineering — are operational instantiations of this single structural move: drive the target across the architectural boundary so the additional ports open up. The framework's machinery for Coupled agents (Class 3) (originally scoped to architectural cases like LLMs and motivated cognition) therefore covers a broader population than its initial framing suggested: any agent under sustained adversarial pressure, regardless of native architecture. Defensive scaffolding — peer review, prediction registers, double-entry bookkeeping, adversarial procedure — is the structural counter-move: it constructs a composite agent whose modularity properties exceed those of its individual components, restoring at the system level what cannot be sustained at the individual level.

Impact: Names a phenomenon currently treated only obliquely in AAT: the strategic incentive in adversarial interaction to drive opponent coupling. Reframes the Class 3 (Coupled) bias bound (#deriv-observation-ambiguity-bias-bound) from passive worst-case to adversarially-saturated target — under competent adversarial design the bound is approximately tight rather than conservative. Connects the orient cascade's clean sequential resolution to its adversarially-inverted form, where observation flows against the information gradient and contradictory inputs are the least legitimate ones the agent will accept. Identifies institutional scaffolding (peer review, prediction markets, double-entry bookkeeping, adversarial procedure) as a Part III composition move that restores Class 1 (Separated) properties at the composite level even when individual sub-components are coupled or driven coupled. Expands the natural population for 03-11m-core/s coupled formulation beyond architecture-determined cases to include any agent under sustained adversarial pressure.

Novelty Claim: *Claim recognition* of adversarial coupling pressure as a structural phenomenon in AAT's existing scope architecture — adversaries strategically drive coupling because coupling expands attack surface — combined with *claim differentiation* on the population scope of coupled-formulation analysis: not just architecturally-coupled agents, but any agent under sustained adversarial coupling pressure. The empirical phenomena (manufactured outrage, identity-binding, social engineering, sunk-cost-driven commitment) are well-documented in propaganda, security, and behavioral-economics literatures; the contribution is naming their place in AAT's scope architecture, the corresponding population expansion for coupled formulation, and the asymmetric-advantage-compounding implication for repeated adversarial interaction.

Related Work:

- *Likely adjacent literatures, not yet searched* — propaganda research (Bernays 1928 *Propaganda*; Ellul 1965 *Propagandes*; Stanley 2015 *How Propaganda Works*), social engineering (Mitnick & Simon 2002 *The Art of Deception*; Hadnagy social-engineering corpus), behavioral economics on motivated reasoning (Kunda 1990 *The Case for Motivated Reasoning*; Kahan and the cultural-cognition project), influence operations (Singer & Brooking 2018 *LikeWar*), and Bayesian persuasion / cheap talk (Kamenica-Gentzkow 2011; Crawford-Sobel 1982). Relationship: *adjacent literature, intuition-only* — these literatures document the empirical phenomena instantiating the mechanism table; the contribution this segment claims is structural placement and population expansion, not phenomenon discovery.

Search Log:

- 2026-05-09 (*intuition-only*): Empirical phenomena (manufactured outrage, identity-binding, social engineering, sunk-cost commitment dynamics) are well-documented across propaganda research, social engineering, behavioral economics, and influence operations. The AAT-internal placement (adversarial pressure as driver of $\kappa_{\text{processing}}$ saturation) and the population-expansion claim for coupled formulation have not been searched. Targeted search recommended before promotion to draft, focusing on: (a) whether adversarial-cognitive-architecture framing exists in the active-inference, control-as-inference, or game-theoretic-deception literatures; (b) whether the “adversary drives opponent coupling” framing has been explicitly named in the cognitive-warfare or information-operations academic literatures; (c) whether the asymmetric-advantage-compounding result has been derived in any repeated-game treatment of cognitive influence.

Working Notes.

- **Promotion: requires targeted prior-art search.** The structural-recognition claim is the segment’s contribution; the empirical phenomena are not novel. Until a Pillar-style targeted search is conducted, novelty status remains *intuition-only* and the segment should not advance past draft.
- **Stage $\times$ source $\times$ form structure within the adversarial mechanisms.** The mechanism table (identity-binding / affect-urgency / sunk-cost-engineering) is a projection of the broader Class 2 sub-typology of #disc-partial-coupling-pathways onto specific (stage, source) cells: identity-binding $\rightarrow$ P1+P2 / O / content-to-process (form varies with strength of identity-binding); sunk-cost $\rightarrow$ P3 / Σ / process (the cell that admits self-stabilizing belief-strategy attractors per #der-belief-strategy-attractor); affect/urgency $\rightarrow$ cascade-bypass (outside the static (stage $\times$ source $\times$ form) parameterization; a separate failure mode rooted in time-pressure-induced under-deliberation). The typology gives the structural reason these three mechanisms have distinct repair characters — and supplies the dynamical attractor structure that explains sunk-cost-engineering’s particular effectiveness in propaganda and influence operations (once the attractor is established, the target’s own machinery maintains the misaligned belief without further adversary input).
- **Brief is not yet at Feynman criterion.** The current Brief reaches for the structural recognition rather than an everyday physical analog whose causal structure is isomorphic to coupling-as-attack-surface. A candidate analog: the difference between selling someone a product (must convince them the product is good — bounded by observable quality) and selling someone the *desire* for the product (once they want it, they will not see the flaws — unbounded by observable quality). The salesperson who can drive desire-formation has acquired a channel into belief that does not pass through evidence about the product. Whether this analog carries the load-bearing structure (identity-binding specifically; the cascade inversion; the asymmetric-advantage compounding) needs work; the bathtub-equivalent has not been written.
- **Game-theoretic formalization candidate.** The “modularity asymmetry produces strategic asymmetry” claim in the Discussion is currently presented as a structural intuition rather than a derived result. A formalization candidate: define a two-agent repeated game where each agent’s payoff includes a term in the *other agent’s* $\kappa_{\text{processing}}$ (offensive value of opponent coupling) and a negative term in *own* $\kappa_{\text{processing}}$ (defensive cost of self coupling). Equilibrium analysis would predict (a) modularity arms races, (b) asymmetric advantage cascades when modularity asymmetry is sustained, and (c) defensive-scaffolding incentives.

The information-theoretic structure (the more-modular agent gets cleaner M_t updates from the same observation stream) is what drives the asymmetry. Plausibly tractable; would land as an appendix segment if pursued.

- **Defensive scaffolding deserves its own segment under Part III.** The institutional-scaffolding-as-composite-agent framing in §"Defensive scaffolding as composition" is a specific instantiation of #disc-composition-consistency with substantive content (peer review, prediction registers, double-entry bookkeeping, adversarial procedure, prediction markets, structured red-teaming all instantiate the same pattern: externalize a channel of the orient cascade so resolution runs sequentially across the composite even when it cannot run sequentially within any single component). Defer until the connection to existing composition results is mapped explicitly; a stub #deriv-defensive-scaffolding-composition may be the right home if the formalization tracks.
- **OUTLINE.md placement.** The segment is in 01-aat-core/src/ but is not yet in 01-aat-core/OUTLINE.md. Natural home: under Part II (it sits at the architecture-classification layer) or as a meta-segment alongside #disc-separability-pattern and #disc-identifiability-floor. The latter is probably the better fit — it's a meta-pattern that cuts across Part II and Part III rather than a Part II result proper.
- **Sister segment for strategic self-coupling.** The fixed- $\mathcal{A}$ assumption surfaced in §"Scope: implicit assumptions and the polarity of coupling" points at coupling's *enabling* polarity — actions that exist only under coupling (Schelling commitment devices, conviction-enabled persuasion, sunk-cost-foreclosed retreat, identity-coupled coordination outcomes). A sister segment covering this polarity directly is staged at spikes/spike-strategic-self-coupling.md. The natural prior-art adoption set is Schelling 1960 *The Strategy of Conflict* (commitment devices), Ainslie 1992 *Picoeconomics* (intertemporal bargaining and willpower), Akerlof-Kranton 2000/2010 (identity economics), Frank 1988 *Passions Within Reason* (emotions as commitment devices). Investigation pending; the spike establishes scope and prior-art landscape.
- **Meta-segment landed 2026-05-24.** The §"Scope" three-operation table (truthification / strategic self-coupling / adversarial coupling pressure) lands canonically at #disc-modularity-state-dynamics — the M4 meta-segment alongside M1 (#disc-identifiability-floor) / M2 (#disc-separability-pattern) / M3 (#disc-additive-coordinate-forcing). The three polarity-instantiations all have primary-segment homes now: this segment for adversarial coupling pressure; #disc-strategic-self-coupling for the enabling polarity; truthification via #der-class-coercion-via-wrapping (component-level) + §"Defensive scaffolding as composition" below (composite-level). The cycle landed the modularity-as-contested-property work per msc/modularity-cycle-plan-2026-05-09.md.
- **Surfacing bounded-signaling in #der-directed-separation.** The bounded-signaling assumption surfaced in §"Scope: implicit assumptions" is more naturally located in #der-directed-separation's Discussion as a load-bearing scope statement on the agent-world interface (it's about *that* segment's structure, not specific to adversarial pressure). Back-pressure follow-on: add to that segment a paragraph naming the assumption — that the channel from G_t to the world runs only through π , and that this assumption fails operationally when behavioral leakage is rich relative to action coarseness. Cross-reference back to this segment for the adversarial saturation case.
- **Migration note (2026-05-09 GUC rename + 2026-05-21 composite-claim withdrawal):** Class 2 $\leftrightarrow$ Class 3 swap. Pre-2026-05-09: Class 2 = fully merged, Class 3 = partially modular. Post: Class 2 = Partial, Class 3 = Coupled. This segment uses "coupling pressure" / "adversarial coupling" as its central concept — that broader vocabulary is unchanged. The specific GUC-class references were renamed: "toward Class 2 (fully merged)" $\rightarrow$ "toward Class 3 (Coupled)"; "Class-2 coupled formulation" $\rightarrow$ "Class 3 (Coupled) formulation"; "Class-3 architecture (partially modular)" for the defensive composite $\rightarrow$ architecturally-modular composite (routing-structure-driven per #der-directed-separation axis-decomposed inheritance); "Class-2 bias bound" $\rightarrow$ "Class 3 (Coupled) bias bound." The earlier "Class 1 (Separated) sub-agents $\rightarrow$ Class 2 (Partial) composite refinement" reference (inversion-comparator for the defensive scaffolding case) was withdrawn 2026-05-21 per spikes/strategic-composition-class-3-attempt-2026-05-21/ (Cournot witness against the unconditional claim; conflation diagnosis on belief-content vs processing-pathway); the defensive-composite passage in §"Defensive scaffolding as composition" was re-derived in regime-axis-aware language at the same time. Removed at candidate stage per FORMAT.md Gate 4.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, kept separate from the certified theory-fix findings. **Coverage:** as a late-authored Meta-Architecture II segment, only the deepest de-novo walk (773921, Gemini) reached it under its current slug — thin and single-substrate by expectation. Substrate attribution from the audit dir. Several of the auditor’s strongest observations (defensive scaffolding as composition, the game-theoretic formalization, bounded-signaling) are *already* tracked in the Working Notes above; those are cross-referenced rather than re-stated.

1. Candidate Brief prose / pre-prose.

- **Coupling as attack surface** — the auditor’s compression of the segment’s frame: adversaries “don’t target what people *know* (the observation channel), but what people *want* or *identify with* (the $O_t \rightarrow M_t$ coupling channel)” (Gemini, AUDIT-WORKING-773921). A candidate Brief anchor (and a sharper handle than the current Brief’s structural-recognition phrasing — see the Feynman-criterion Working Note above).

2. Candidate Discussion.

- **Confirmation bias and demoralization as structural, not cognitive-quirk.** The auditor read “Cascade Inversion” as formally deriving these: by acting on O_t first (identity or manufactured urgency), the adversary “forces the Orient Cascade to run backward, making legitimate observations flow *against* the information gradient, guaranteeing their rejection” (Gemini, AUDIT-WORKING-773921). A candidate Discussion sharpening of the cascade-inversion mechanism — names the everyday phenomena (confirmation bias, demoralization) the structure explains.
- **Directional diagnostic corruption stated as two levers.** “If an adversary wants an agent to give up, they inflate the Satisfaction Gap (δ_{sat}); if they want it to waste effort on a doomed cause, they inflate Control Regret (δ_{regret})” (Gemini, AUDIT-WORKING-773921). A compact gloss linking the segment to 8.4 / 8.5.

3. Follow-up items.

- **Adversarial saturation of the bias bound.** The auditor stressed that the Coupled Bias Bound (AB) reads differently under adversarial conditions: “in a benign environment the bound C is a loose worst-case; in an adversarial environment the adversary is an optimizer actively trying to drive the agent’s error exactly to C ” (Gemini, AUDIT-WORKING-773921). A candidate sharpening of how the bias bound is invoked downstream — distinct from the static-bound reading. (The segment’s mechanism table already touches this; the “adversary-as-bound-optimizer” framing is the additional texture.)
- (Off-ramp note, not gold: the auditor’s other strong items — defensive scaffolding deserving its own composition segment, the game-theoretic two-agent κ -payoff formalization, and bounded-signaling belonging in 6.3 — are already tracked in the Working Notes above. No new follow-up needed.)

4. Readers often ask / wonder.

- **Are humans structurally weaker than text-only LLMs against adversarial coupling?** Following the bounded-signaling assumption: humans leak G_t via micro-expressions, prosody, and latency, bypassing the formal action channel a_t — “adversaries don’t have to guess what a human wants; they can read it directly,” whereas a text-only LLM leaks only via tokens (Gemini, AUDIT-WORKING-773921). A natural reader question that sharpens the bounded-signaling Working Note’s operational stakes.

5. Candidate figures.

- (No dedicated figure proposed for this segment in the reached audit.)

Belongs elsewhere.

- **A formal vocabulary for information warfare / propaganda / cult formation.** Forward-vision: the segment “extends AAT from a theory of agents into a theory of security against cognitive attack,” giving “a formal, structural vocabulary for Information Warfare, Propaganda, and Cult Formation based on the physics of the OODA loop” (Gemini, AUDIT-WORKING-773921). Aspirational reach for the M4 framing layer (11.1) / field-positioning, not a per-segment edit.
 - **Peer review and double-entry bookkeeping as Class-1-from-Class-3 composition** — the auditor independently praised the §”Defensive scaffolding as composition” framing (“not just administrative overhead; structural Part III composition moves that create a Class 1 macro-agent out of Class 3 human sub-agents”) (Gemini, AUDIT-WORKING-773921). Converges on the existing Working-Note proposal to give defensive scaffolding its own Part III segment; recorded as cross-substrate confirmation of that already-tracked move.
-

Chapter 12

Scope and Composition Formation

12.1 *Scope: Multi-Agent Scope*

Part III's broadest scope: any system of multiple agents each satisfying 1.6 and interacting through a shared environment. Each agent has its own model and purposeful substate; each observes the environment and other agents' actions; each acts; their actions jointly determine the next environment state. The general case for organizations, teams, ecosystems, and adversarial encounters. *Coupling goes through the shared environment, not through direct state modification* — agents affect each other by affecting the environment.

A methodological default the framework adopts: **correlated observations are generic; independence is the special case requiring justification**. When agents share an environment, their observations are generically correlated — they see aspects of the same reality. Independence (uncorrelated observations) requires the agents to observe non-overlapping aspects, which is the special case.

Each agent's observation decomposes into environmental and *inter-agent* components — messages from other agents. The **multi-agent routing structure** is a key new object: the *topology* (who communicates with whom) plus the *protocol* (the rule governing what class of information flows between agents). The protocol is a *rule specifying the channel*, not the content of any message — individual messages reflect senders' states (including individual goals) through their policies. What the routing structure governs is the *infrastructure* — which channels exist and what kind of information they carry. **Routing is goal-blind** when neither topology nor protocol depends on the composite's goal state. *Goal-dependent routing* (crisis-specific channels, mission-specific intelligence-sharing protocols, reorganizing reporting chains based on objective) breaks goal-blindness and is the lever that distinguishes Case 1 from Case 2 in 13.3.

The framework draws a *load-bearing scope distinction* between two classes of machinery. **Agent-level machinery** (individual persistence, agent tempo, per-agent mismatch, sector-condition stability) applies to *every* agent in *every* multi-agent configuration — cooperative, adversarial, or indifferent — because each agent individually satisfies 1.6. **Composite-level machinery** applies only when 12.2 is satisfied. The adversarial regime spans the negative-teleological-unity end of the unity spectrum and is treated *both* ways: equilibrium-convergent adversarial pairs are captured by composite-level machinery (the strategic-composite route in 16.1); cyclic or non-convergent adversarial dynamics are captured by agent-level machinery applied across the pair.

Formal Expression.

A multi-agent system consists of N agents $\{A_1, \dots, A_n\}$, each satisfying the scope condition (1.6), interacting through a shared environment with state $\Omega_t \in \mathcal{S}_{env}$:

Scope (multi-agent-scope).

- Each agent A_i has state $X_t^{(i)} = (M_t^{(i)}, G_t^{(i)})$
- Each agent observes: $o_t^{(i)} = h^{(i)}(\Omega_t, a_t^{(-i)}, \xi_t^{(i)})$ — observations may depend on other agents' actions
- Each agent acts: $a_t^{(i)} = \pi^{(i)}(X_t^{(i)})$
- The environment evolves: $\Omega_{t+1} = T(\Omega_t, a_t^{(1)}, \dots, a_t^{(n)}, \omega_t)$

The coupling is through the environment: agent i 's actions enter agent j 's observation function and the shared environment transition. Agents may also communicate directly (a special case of action-observation coupling with a dedicated channel).

Observation decomposition and routing.

Each agent's observation decomposes into environmental and inter-agent components:

Definition (observation-decomposition).

$$o_t^{(i)} = \left(o_{\text{env},t}^{(i)}, \{m_{ji,t}\}_{j \in \mathcal{N}_t(i)} \right) \quad (12.1)$$

where: - $o_{\text{env},t}^{(i)} = h_{\text{env}}^{(i)}(\Omega_t, \xi_t^{(i)})$: direct environmental observation (no inter-agent content) - $\mathcal{N}_t(i) \subseteq \{1, \dots, N\} \setminus \{i\}$: the **communication neighborhood** — which agents send messages to i at time t - $m_{ji,t} = c_t^{(j \rightarrow i)}(X_t^{(j)})$: message from j to i , determined by the sender's full state and the communication protocol

The **multi-agent routing structure** $R_t = (\mathcal{N}_t, \{c_t^{(j \rightarrow i)}\})$ specifies: - The **topology** $\mathcal{N}_t$: who communicates with whom
- The **protocol** $c_t^{(j \rightarrow i)}$: the rule governing what class of information flows from j to i

Definition (multi-agent-routing-structure).

Note: the protocol $c_t^{(j \rightarrow i)}$ is a *rule* specifying the channel, not the specific content of any message. Individual messages reflect the sender's state $X_t^{(j)}$ — including their individual goals — through the sender's policy. What the routing structure governs is the *infrastructure*: which channels exist and what kind of information they carry. *Bare-prose shorthand: the term "routing structure" is sanctioned within this segment after the first compound-form introduction; cross-segment citation should use the full "multi-agent routing structure" form.*

Routing is **goal-blind** when neither the topology nor the protocol depends on the composite's goal state:

Definition (goal-blind-routing).

$$\mathcal{N}_t \perp G_t^c \quad \text{and} \quad c_t^{(j \rightarrow i)} \perp G_t^c \quad \forall j, i \quad (12.2)$$

This means the communication infrastructure does not change based on what the composite is trying to achieve. Individual messages naturally reflect individual agents' goals through their policies — this is action, not routing. The routing condition is about the *structure* of information flow, not the *content* of individual messages.

Goal-dependent routing occurs when either the topology or the protocol varies with G_t^c . Examples: activating crisis-specific communication channels, changing intelligence-sharing protocols based on the current mission, reassigning reporting chains based on the operational objective.

Epistemic Status.

Axiomatic. This is a scope definition — it describes the class of systems Part III addresses. The only substantive choice is that coupling goes through the shared environment rather than through direct state modification. This follows from the agent boundary assumption (1.1): agents affect each other by affecting the environment, not by directly altering each other's internal states.

Discussion.

Correlated observations as default. When agents share an environment, their observations are generically correlated — they see aspects of the same reality. Independence (uncorrelated observations) requires the agents to observe non-overlapping aspects of the environment, which is the special case. Most multi-agent settings of interest involve substantial observation correlation.

The adversarial case sits along a spectrum — partly inside, partly outside the composite scope. Agents whose objectives conflict are multi-agent systems with negative teleological unity (14). Whether they form a composite depends on whether their strategic interaction admits an equilibrium structure: equilibrium-convergent adversarial pairs (potential or monotone games per Monderer-Shapley / Rosen) satisfy 12.2 via route (C-iv) as **strategic composites** with equilibrium-based macro-state — see 16.1 for the equilibrium-theoretic machinery and the (SC-1)–(SC-3) decomposition. Cyclic or non-convergent adversarial pairs satisfy none of (C-i)–(C-iv) and remain within 12.1 only. The asymmetric attacker / target case (one agent treated as an exogenous parameter rather than a sub-agent running its full AAT loop) is also a 12.1 phenomenon, handled by 15.2.

Two distinct classes of machinery apply across this spectrum:

- **Agent-level machinery** (individual persistence, agent tempo, per-agent mismatch, sector-condition stability) applies to *every* agent in *every* multi-agent configuration — cooperative, adversarial, or indifferent — because each agent individually satisfies 1.6 and Part I/II results apply directly. The adversarial tempo advantage (15.4) and adversarial destabilization (15.2) results are applications of this agent-level machinery to the case where one agent's actions are a disturbance source for another.
- **Composite-level machinery** applies *only* when 12.2 is satisfied via at least one of (C-i)–(C-iv). The (C-i)–(C-iii) alignment routes give composites with a shared objective O_c and admit closure-defect / team-persistence / composite-tempo / unity-closure machinery via 13.1. The (C-iv) strategic route gives composites with an equilibrium-based macro-state and admits the equilibrium-convergence / sector-template / closure-defect machinery in 16.1; the alignment-route and strategic-route forms are structurally distinct (an equilibrium-convergent adversarial composite has no shared O_c , only a shared $\mathcal{E}$).

The adversarial regime spans the negative- U_O end of the unity spectrum. Equilibrium-convergent adversarial pairs are captured by (C-iv) strategic-composite machinery; cyclic / non-convergent adversarial dynamics and asymmetric attacker / target configurations are captured by agent-level machinery applied across the pair. The existing adversarial segments (15.2, 15.4) operate at the agent-level for cases that fall outside (C-iv); 16.1 operates at the composite-level for cases that fall inside it.

Inter-agent communication as a special observation channel. Messages from j to i are actions by j and observations by i . The routing structure formalizes the infrastructure: who talks to whom ($\mathcal{N}_t$) and under what protocol ($c_t^{(j \rightarrow i)}$). The sender controls the content (unlike passive environmental observation), which introduces strategic manipulation (14.4). The gain from inter-agent communication enters the distributed tempo (14.4, Working Notes).

The routing/content distinction matters for directed separation. Individual messages reflect senders' goals — that's just action through policy. The directed-separation question at the composite level (13.3) is about the *routing structure*: does the infrastructure change based on the composite's goals? Goal-blind routing preserves directed separation; goal-dependent routing breaks it.

Working Notes.

Incidental audit gold (lift 2026-05-30). Cross-audit “wandering thoughts” / §14-ideation harvested from the de-novo auditors’ working dirs, deduplicated across substrates and lightly attributed by substrate + audit. Orthogonal pedagogical / framing / figure / naming material, kept separate from the certified theory-fix findings (handled elsewhere — see report flags for this segment). **Coverage:** four dirs reached a digested reflection on this segment (193847, 526815, 829314, 849201), plus the §III composition-foundations batch (471203). The other contributing dirs did not reach a dedicated reflection here or stopped earlier. Substrate attribution inferred from voice where not explicit; uncertain cases hedged.

1. Candidate Brief prose / pre-prose.

- The routing/content distinction stated as a hardware/software analogy: the routing structure $\mathcal{N}_t$ is “the organizational equivalent of separating network hardware from application software” — “a company can have a perfectly objective, goal-blind *email system* (routing) even if every individual *email* is highly biased by the sender’s personal goals” (Gemini, AUDIT-WORKING-193847). Independently praised as “masterful” / the segment’s standout move by three substrates (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314 — “the mathematical key to understanding organizational epistemology”; Claude, AUDIT-WORKING-849201).
- A formal-taxonomy-of-groups gloss for an opener: three-tier ladder of “groups” — (1) independent agents (uncorrelated Ω); (2) multi-agent systems (correlated Ω , no coherence); (3) composites (correlated Ω , structural coherence) (Gemini, AUDIT-WORKING-193847).
- “You cannot apply composite-level theorems (like composite tempo or team persistence) to a bar brawl” — a vivid one-line scope guard for the multi-agent-vs-composite boundary (Gemini, AUDIT-WORKING-193847).

2. Candidate Discussion.

- **Goal-dependent routing as organizational pathology — the “wartime CEO” trade.** A worked elaboration of the Case-2 failure: a “wartime CEO” who restructures channels to serve the current objective (forms a Tiger Team, mandates “only report blockers related to Project X”) enslaves the information infrastructure to the goal — data about other failures is no longer routed to anyone, and the organization becomes a Class 3 (Coupled) agent suffering “institutional confirmation bias at the hardware level.” The framing: AAT gives the exact math for why organizational focus “trades long-term epistemic accuracy for short-term strategic tempo” (Gemini, AUDIT-WORKING-829314; the same CEO-fires-QA mechanism at Gemini, AUDIT-WORKING-193847 — severing the channel that “delivered aporia”). A candidate Discussion vignette making the goal-blind-vs-goal-dependent routing distinction operationally concrete. (*Note the early finding-vs-framing texture: the auditor reads this as a derived consequence; the segment treats it at hypothesis/discussion grade via 13.3 — keep the tier honest if promoted.*)
- **The calibrate-against-bias point.** Even when message *content* is biased (a department pads its numbers), a goal-blind *channel* lets the receiver “learn to calibrate against the bias” — separating the durable infrastructure question from the per-message-honesty question (Gemini, AUDIT-WORKING-829314). Sharpens why routing-blindness, not message-honesty, is the load-bearing condition.

3. Follow-up items.

- **Forward-reference / topological-sort stumble.** Two substrates independently flagged that the Discussion’s detailed treatment of routes (C-i)–(C-iv) reads as jarring out of order, since 12.2 (where those routes are defined) is the *next* segment — “it seems the author wrote or revised this discussion *after* writing the next segment” (Claude, AUDIT-WORKING-829314 suggested moving the route detail forward to 12.2 and leaving this segment purely as the un-fused multi-agent substrate definition). A reader-flow signal, not a defect; worth a sentence orienting the reader that the routes are defined next.
- The C-iv “strategic composite” framing (enemies in a stable equilibrium modeled as one macro-agent) was repeatedly flagged as the most counter-intuitive move and as “requiring very careful prose handling later” — see the richer note under 12.2.

4. Readers often ask / wonder.

- “If the Cold War is a single composite agent, what is its O_t ?” Multiple substrates converged on this as the natural reader question the C-iv route provokes: a strategic composite has no shared O_c , only a shared equilibrium $\mathcal{E}$ — “a fascinating extension of agency to non-teleological structures” (Gemini, AUDIT-WORKING-193847; Gemini, AUDIT-WORKING-829314; Claude, AUDIT-WORKING-849201). A candidate readers-often-ask preemption (the answer already lives in the (C-iv) macro-state-relative-to- $\mathcal{E}$ formalism — surface it where the reader first meets the strategic-composite idea).

5. Candidate figures.

- **Two-layer routing diagram.** Agents + shared environment at the bottom; routing infrastructure $\mathcal{N}_t$ as an overlay on top. The visual point: message *content* may be goal-colored while the routing *layer* can still be goal-blind or goal-dependent — the figure separates infrastructure from behavior (Codex/Claude, AUDIT-WORKING-526815, “diagram attempt”; converges with the hardware/software analogy above).

Belongs elsewhere.

- **Consciousness-infrastructure imperative: guaranteed goal-blind routing for a society-of-mind.** For Zi-am-tur or any multi-agent consciousness infrastructure, the infrastructure *must* guarantee goal-blind routing: sub-agents (safety monitor, planner, memory retriever) need communication channels that cannot be severed just because their messages are inconvenient — “if the infrastructure allows the planner to dynamically sever channels to silence dissent, the composite intelligence will inevitably collapse into epistemic closure” (Gemini, AUDIT-WORKING-193847). Aspirational reach pointing at 03-11m-core / 04-eli-core / architecture (and resonant with 13.3’s OPSEC observation), not at this scope segment.

12.2 Scope: Composite Agent

The scope condition that distinguishes a *composite agent* from a *multi-agent system*. A set of purposeful sub-agents, each satisfying 1.6, constitutes a *composite agent* only when their objectives exhibit sufficient teleological alignment to define a coherent composite purpose. Without this condition, the sub-agents form a multi-agent system (12.1) that may still be analyzed — but the *composition machinery* (13.1, 15.1, 13.2) does not apply because there is no composite agent whose quantities to compute. This parallels the single-agent 1.6: before asking how an agent adapts, one must check that an agent is *present*.

The scope condition is satisfied via *any of four disjunctive routes*. **(C-i) Shared composite objective** — the strongest alignment: all sub-agents’ policies are approximately optimal under a common objective. **(C-ii) Hierarchical derivation:** sub-objectives are derived by structure-preserving decomposition from a parent objective (military chain of command; corporate department structure) — sub-agents may not individually know the parent. **(C-iii) Mutual-benefit alignment** — the weakest route that still qualifies: a relevance variable exists such that joint actions raise each sub-agent’s expected value above the non-cooperation baseline (symbiotic coexistence; commensal ecologies; trading partners). **(C-iv) Equilibrium-convergent strategic interaction:** an equilibrium concept (Nash, correlated, coarse correlated) exists such that coupled best-response dynamics converge to its support — qualitatively distinct from the first three because it requires *neither* shared objectives *nor* hierarchical derivation *nor* mutual benefit, only structural convergence of the strategic interaction. Composites satisfying (C-iv) are **strategic composites**; their macro-state is defined relative to the equilibrium structure rather than to a shared target. The routes are *not* shown to reduce to a common scalar threshold; each carries its own operationalization, and only one is required for scope-satisfaction.

A specific load-bearing role: the framework’s third identifiability-floor instance (5.1, Instance 3 — composite contraction certification from component-marginal data is structurally impossible) has four structural escapes (observable coupling topology; matched Tier; passivity certificate; common contraction metric), but each escape needs a coherent target to certify. **Scope-satisfaction via at least one of the four routes is the enabling condition** for any of these escapes: without it, the “composite” is ill-defined (O_c does not exist under (C-i)-(C-iii); equilibrium structure $\mathcal{E}$ does not exist under (C-iv)) and the escapes have no coherent target.

Formal Expression.

Given sub-agents $\{A_1, \dots, A_N\}$ each satisfying 1.6, they constitute a *composite agent* iff there exists a common objective structure under at least one of the following routes:

Scope (scope-composite-agent).

(C-i) Shared composite objective. There exists O_c such that each sub-agent's effective policy is ϵ -compatible with O_c -optimal:

$$\exists O_c : \forall i, D(\pi_i, \pi_i^{O_c}) \leq \epsilon \quad (12.3)$$

where $\pi_i^{O_c}$ is sub-agent i 's optimal policy under the shared objective and D is an appropriate policy divergence. Strongest route; the sub-agents are all optimizing for the same thing, possibly with local decompositions.

(C-ii) Hierarchical derivation. There exists a parent objective O_c from which sub-objectives $\{O_i\}$ are derivable by decomposition consistent with 11:

$$\{O_i\} = \mathcal{D}(O_c) \quad (12.4)$$

where $\mathcal{D}$ is a structure-preserving decomposition. Each sub-agent optimizes its own O_i , but all O_i trace back to O_c . Military chain of command; corporate department structure. Sub-agents may not individually know O_c .

(C-iii) Mutual-benefit alignment. There exists a relevance variable Y such that the sub-agents' joint actions raise $\mathbb{E}[Y]$ above the non-cooperation baseline for each sub-agent:

$$\exists Y : \forall i, \mathbb{E}[Y \mid \text{joint}] > \mathbb{E}[Y \mid \text{non-coop}] \quad (12.5)$$

Weakest route. No explicit common objective, but interactions are positive-sum in some dimension. Symbiotic coexistence; commensal ecologies; trading partners who share no goals beyond mutual benefit.

(C-iv) Equilibrium-convergent strategic interaction. There exists an equilibrium concept $\mathcal{E}$ (Nash, correlated, or coarse correlated) such that coupled best-response dynamics of $\{A_i\}$ converge to (or cycle within the support of) $\mathcal{E}$:

$$\exists \mathcal{E} : \text{coupled best-response dynamics converge to the support of } \mathcal{E}. \quad (12.6)$$

Qualitatively distinct from (C-i)–(C-iii): requires neither shared objectives, nor hierarchical derivation, nor mutual benefit. Requires only **structural convergence** of the strategic interaction in the game-theoretic sense. The sub-agents' objectives may be partially opposing, but the interaction admits a stable joint behaviour. Composites satisfying (C-iv) are **strategic composites**, distinguished from alignment composites (C-i, C-ii) and mutual-benefit composites (C-iii). The composite's macro-state is defined relative to the equilibrium structure $\mathcal{E}$ rather than relative to a shared target state. See #deriv-strategic-composition for the A2'-analog transfer of #result-sector-persistence-template under potential-game (Monderer-Shapley 1996) or monotone-game (Rosen 1965) conditions, the (SC-1)–(SC-3) existence/stability/convergence decomposition, and the honest sub-scope β' scope exit for non-potential non-monotone games (VI existence + regret-minimization CCE set-convergence only).

Disjunctive form.

The scope condition is satisfied when **any** of (C-i), (C-ii), (C-iii), or (C-iv) applies. (C-i)–(C-iii) are progressively weaker qualitative requirements for what “teleological alignment sufficient to define a coherent composite purpose” means; (C-iv) covers strategic interaction with partially-opposing objectives via equilibrium convergence rather than alignment. The routes are *not* shown to reduce to a common scalar threshold. Each route carries its own operationalization and its own N -agent aggregation:

Scope (scope-composite-agent, disjunctive).

- (C-i) uses a value-function divergence $D(\pi_i, \pi_i^{O_c})$ aggregated across sub-agents.
- (C-ii) uses decomposition consistency of a parent objective O_c — a structural check, not a scalar.
- (C-iii) uses the existence of a relevance variable on which each sub-agent’s marginal contribution is positive — a per-pair existential check, not a magnitude.
- (C-iv) uses existence of an equilibrium structure $\mathcal{E}$ under coupled best-response dynamics — a fixed-point check (Nash / VI / regret-minimization CCE), structurally distinct from the alignment checks in (C-i)–(C-iii).

The teleological unity measure U_O from 14 (pairwise value-correlation aggregated to the group) tracks one projection of alignment — primarily route (C-i) — but is not a reduction of all three routes to a single scalar. Downstream segments (14.1, 12.3, 15.1) describe quality *conditional on scope-satisfaction* without assuming a common threshold: they presume the scope condition holds via at least one route, then analyze composite quantities within that regime.

(C-i) gives the strongest alignment; (C-iii) gives the weakest that still qualifies. A composite may satisfy multiple routes simultaneously; only one is required for scope.

What fails the scope condition: sub-agents with orthogonal objectives that also fail to admit equilibrium convergence — no shared or derivable O_c , no relevance variable providing mutual benefit, and no equilibrium concept (pure Nash, mixed Nash, or CCE) whose support the coupled best-response or no-regret dynamics reach — or unclassifiable objective-structure coupling. Such systems remain within 12.1 but not 12.2. Adversarial pairs that admit equilibrium convergence via (C-iv) — whether pure-strategy Nash under α' (potential / monotone games), mixed Nash under β' (Nash 1950 existence for finite games), or CCE in distribution under β' (Hart-Mas-Colell 2000) — DO satisfy composition-scope-condition as strategic composites. Cyclic games (rock-paper-scissors, matching pennies) lack a pure-strategy Nash but admit mixed Nash and CCE convergence; they fall within β' and satisfy (C-iv). The narrow category that fails (C-iv) is games with no equilibrium concept whose support is reachable by any admissible dynamic — a genuinely small class within the standard game-theoretic landscape.

Epistemic Status.

Robust-qualitative. Max attainable: *robust-qualitative.* The composite-agent scope is a structural proposal paralleling the single-agent scopes (1.5 and 1.6, both axiomatic — the minimal conditions for adaptive and purposeful machinery to be non-vacuous). Unlike them, 12.2 is a theoretical choice: we could admit teleologically misaligned groups as composites (via the closure-defect framework alone) and separately track whether their composite objective is meaningful. The proposal here is that this separate tracking is better done as a scope restriction: composition quantities are defined for systems satisfying at least one of (C-i)–(C-iv), not for systems satisfying none.

The three alternative routes are not exhaustive but cover the well-understood cases. The relationship between the routes (whether they partition or overlap) and whether there is a single underlying scalar that reduces them all is open; the disjunctive form above is chosen because no such reduction has been demonstrated.

Discussion.

Why this is a scope condition, not merely a quality metric. The existing 13.1 framework treats any group admitting a low- ϵ^* projection as a composite. This is mechanically defensible but runs into a category problem: a composite's purposeful substate $G_c = (O_c, \Sigma_c)$ requires a well-defined composite objective O_c . If the sub-agents' objectives do not align under any common O_c , then G_c is ill-defined and the composite is a fiction. Closure defect can be computed (as a projection property), but calling the result a “composite agent” strains the term. Making this a scope condition resolves the category issue: composition applies where G_c is well-defined.

Relationship to the single-agent scopes. The parallel is tight. The single-agent scopes (1.5 + 1.6) together say: before asking whether an agent persists, check that it is an agent (it observes under residual uncertainty, and at least one action has causal effect). 12.2 says: before asking whether a composite persists, check that it is a composite (teleological alignment sufficient to define O_c). In both cases, the scope precedes the quantitative machinery.

Relationship to 14. U_O in 14 has a dual role: (i) scope tracking — primarily the (C-i) route, where value-correlation is the operationalization; (ii) quality parameter for action-closure ϵ_a , via 14.1. The two roles are not in tension, but they are also not identical across routes: scope-satisfaction via (C-ii) or (C-iii) does not directly correspond to a U_O value, so U_O is best read as a quality metric *conditional on scope*, not as the defining scope variable.

Four routes: three alignment routes plus one strategic-equilibrium route. Routes (C-i), (C-ii), (C-iii) — the **alignment routes** — differ in how directly the sub-agents share purpose. They are progressively weaker qualitative requirements — (C-i) strongest, (C-iii) weakest — but they are not shown to reduce to a single scalar. (C-i) uses value-correlation directly; (C-ii) uses hierarchical decomposition consistency; (C-iii) uses marginal benefit existence. A composite can satisfy multiple alignment routes simultaneously (a well-aligned team satisfies both (C-i) and (C-ii)). Route (C-iv) — the **strategic-equilibrium route** — is qualitatively distinct: it admits composites with partially-opposing objectives whose strategic interaction is equilibrium-convergent (potential or monotone games per Monderer-Shapley / Rosen; see #deriv-strategic-composition), and its composite macro-state is defined relative to the equilibrium structure $\mathcal{E}$ rather than a shared target. What matters for scope is that at least one of the four routes holds.

Miller's IAM definition. Miller (2022, *Ex Machina*, Ch 1) proposes that social behavior requires Interaction, Agency, and Mutual benefit (IAM). The mutual-benefit requirement in (C-iii) is the AAT analog of Miller's third element. Miller treats IAM as the definition of social behavior; the proposal here treats alignment as the scope condition for composite-agent analysis. The two align substantively: Miller's mutual benefit is a minimum teleological unity.

Multi-agent systems with and without composite status. Adversarial pairs partition along a finer line than alignment / non-alignment. Adversarial pairs that admit equilibrium convergence — via pure-strategy Nash under α' (potential or monotone strategic games per #deriv-strategic-composition), mixed Nash under β' (Nash 1950 existence for finite games), or CCE in distribution under β' (Hart-Mas-Colell 2000 under no-regret dynamics) — satisfy the scope condition via (C-iv) as strategic composites. Cyclic games (rock-paper-scissors, matching pennies) sit inside β' : they lack pure-strategy Nash but admit mixed Nash and CCE convergence, so they satisfy (C-iv). The narrow category that genuinely fails (C-iv) is games with no equilibrium concept whose support is reachable by any admissible dynamic — a small class within the standard game-theoretic landscape. The asymmetric case — one agent as exogenous attacker, one as target — is a #scope-multi-agent phenomenon handled by #der-adversarial-destabilization; it does not form a composite in either (C-i)–(C-iii) or (C-iv) senses because the attacker is treated as a parameter rather than a sub-agent running its full AAT loop. Symmetric strategic composition under partially-opposing objectives is covered by (C-iv) and forms a strategic composite with equilibrium-based macro-state.
